2. Trace: follow the actual values from setup to output, then carry forward the move from Project 236.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 238 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'boilerplate {boiler_count}/{total} = {ratio} -> {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `boiler = {'home', 'about', 'contact', 'menu', 'copyright', 'privacy', 'login'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute a boilerplate-to-content ratio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Counting how many page words appear in a known boilerplate set, divided by the total, estimates how much of a page is template versus unique content.

```
boiler = {'home', 'about', 'contact', 'menu', 'copyright', 'privacy', 'login'}
page_words = ['home', 'menu', 'login', 'solar', 'panels', 'convert',
'sunlight', 'electricity', 'copyright', 'privacy']
total = len(page_words)
boiler_count = sum(1 for w in page_words if w in boiler)
ratio = round(boiler_count / total, 3)
verdict = 'THIN (boilerplate-heavy)' if ratio > 0.5 else 'ok'
print(f'boilerplate {boiler_count}/{total} = {ratio} -> {verdict}')
```

```
output
boilerplate 5/10 = 0.5 -> ok
```

How it works:

1. A set holds common nav and footer terms for fast membership tests
2. A list represents the page's tokenised words mixing boilerplate and content
3. A generator counts how many words are in the boilerplate set
4. The ratio divides that count by the total word count, rounded
5. A threshold above 0.5 yields a boilerplate-heavy verdict

Try it:

1. Expand the boilerplate set with real header and footer phrases
2. Report the count of unique non-boilerplate words instead of a ratio
3. Lower the threshold and rescore the same page
4. Add `'footer'` and `'search'` to the boilerplate set and recompute.

⚠ Common Mistakes

- Using `>=` instead of `>` would flip this exact 0.5 case to THIN; pick the boundary deliberately.
- A tiny boilerplate set undercounts real template words and hides thin pages.

- Counting unique words instead of all occurrences ignores boilerplate that repeats.

Skills gained set membership generator sum ratio threshold

→ Where You'll Use This: Measuring boilerplate-to-content ratio helps separate genuinely useful pages from skeletal templates whose body is mostly menus, a frequent cause of thin-content flags at scale.

Mental Model

Like measuring how much of a newspaper page is ads versus story: when the ads take over, there's barely an article left to read.

Project 238 Find Duplicate Titles Across a Set

The Idea Behind It

Two pages sharing the same title tag compete in the search results and muddy which one the engine should rank. This project groups URLs by their exact title string using setdefault, then prints any title that maps to more than one page. The three pages titled 'Best Running Shoes' collapse into one group, instantly revealing the clash that a single-page check would never catch.

What You'll Build & Learn

Group pages by title and report any title shared across more than one URL.

- Grouping records by a shared key
- Detecting duplicate title tags
- Why duplicate titles hurt ranking

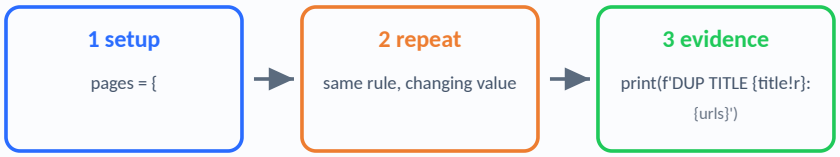
Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 237: compute a boilerplate-to-content ratio. Project 239 changes the surface problem while preserving the underlying method.

progress check

Reading target: find duplicate titles across a set is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'DUP TITLE {title!r}: {urls}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(urls) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'DUP TITLE {title!r}: {urls}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(urls) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Duplicate Titles Across a Set: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: pages, https, example, com, Best. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = { | Core: if len(urls) > 1: | Evidence: print(f'DUP TITLE {title!r}: {urls}')

🛠️ Reader to Writer Bridge

1. Read: explain find duplicate titles across a set in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 237.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 239 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'DUP TITLE {title!r}: {urls}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of find duplicate titles across a set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A dict keyed by title collects every URL sharing it; groups of size greater than one are the duplicate-title clashes to fix.

```
pages = {
    'https://example.com/a': 'Best Running Shoes',
    'https://example.com/b': 'Best Running Shoes',
    'https://example.com/c': 'Trail Running Guide',
    'https://example.com/d': 'Best Running Shoes',
}
groups = {}
for url, title in pages.items():
    groups.setdefault(title, []).append(url)
for title in sorted(groups):
    urls = sorted(groups[title])
    if len(urls) > 1:
        print(f'DUP TITLE {title!r}: {urls}')
```

```
output
DUP TITLE 'Best Running Shoes': ['https://example.com/a', 'https://example.com/b',
'https://example.com/d']
```

How it works:

1. A dictionary maps four URLs to their title strings
2. setdefault appends each URL to a list keyed by its title
3. Sorting the group keys gives deterministic output order
4. Any title with more than one URL prints a DUP TITLE line with the sorted list

Try it:

1. Normalise titles by case and whitespace before grouping
2. Also report near-identical titles differing by one word
3. Count the total number of clashing pages across all titles
4. Lowercase and strip each title before grouping to catch near-identical clashes.

⚠ Common Mistakes

- Comparing titles case-sensitively misses `'best running shoes'` versus `'Best Running Shoes'`.
- Not trimming whitespace lets a trailing space split an otherwise identical title.
- Reporting every group instead of only those with more than one URL spams the unique titles.

Skills gained `setdefault grouping` `duplicate detection` `title audit`

→ **Where You'll Use This:** Duplicate-title reports are a staple of on-page audits; identical titles across product or category pages signal templating bugs and self-competition that depress click-through.

⚡ Mental Model

Like two shops on one street with the exact same sign: shoppers and search engines can't tell which door to walk through.

Project 239 Collapse www vs Non-www Duplicates

💡 The Idea Behind It

A site answering at both www and the bare host serves every page twice under two addresses. This project treats the www prefix as cosmetic, stripping it with a single targeted replace so both variants map to the same key, then groups the original URLs under that key. Any key holding more than one variant is a www duplicate, and the fix is to pick one host and redirect the other.

What You'll Build & Learn

Detect URLs that differ only by the www prefix and group them as duplicates.

- Treating www as a cosmetic prefix
- Folding host variants to one key
- Why both hosts cause duplication

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 238: find duplicate titles across a set. Project 240 changes the surface problem while preserving the underlying method.

progress check

Reading target: collapse www vs non-www duplicates is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `urls = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.

- Evidence: `print(f'WWW DUP {canon}: {variants}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(variants) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'WWW DUP {canon}: {variants}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(variants) > 1:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Collapse www vs Non-www Duplicates: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: urls, https, www, example, com. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: urls = [| Core: if len(variants) > 1: | Evidence: print(f'WWW DUP {canon}: {variants}')

🛠️ Reader to Writer Bridge

1. Read: explain collapse www vs non-www duplicates in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 238.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 240 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'WWW DUP {canon}: {variants}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `urls = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of collapse www vs non-www duplicates and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Replacing the first `://www.` with `://` maps both host variants to one key, so grouping reveals which paths exist under both.

```
urls = [
    'https://www.example.com/blog',
    'https://example.com/blog',
    'https://www.example.com/about',
    'https://example.com/contact',
]
def strip_www(u):
    return u.replace('://www.', '://', 1)
groups = {}
for u in urls:
    groups.setdefault(strip_www(u), []).append(u)
for canon in sorted(groups):
    variants = sorted(groups[canon])
    if len(variants) > 1:
        print(f'WWW DUP {canon}: {variants}')
```

```
output
WWW DUP https://example.com/blog: ['https://example.com/blog',
'https://www.example.com/blog']
```

How it works:

1. A list holds URLs mixing www and bare-host spellings
2. strip_www replaces the www. prefix once to produce the folded key
3. setdefault collects original URLs under each stripped key
4. Keys with more than one variant print a WWW DUP report with both spellings

Try it:

1. Handle URLs that already lack a scheme gracefully
2. Choose a canonical host and emit the redirect that should exist
3. Combine this with trailing-slash folding in one pass
4. Decide `www.` is canonical and rewrite bare hosts to add it instead.

⚠ Common Mistakes

- Using `.replace('www.', '')` without the `://` anchor would also strip `www.` from a path or query.
- Passing no count argument to `replace` could rewrite a later `://www.` in a redirect target.
- Assuming the bare host is always canonical; some sites canonicalise to `www.` instead.

Skills gained str.replace | url folding | host normalization

→ Where You'll Use This: The www-versus-non-www split is one of the oldest duplicate-content traps; auditors confirm one host redirects to the other so ranking signals don't divide across two front doors.

Mental Model

www and the bare domain are two doorbells on the same house; press either and the same family answers, but visitors think there are two homes.

Project 240 Detect a Page Served Over Two Protocols

The Idea Behind It

When one page answers on both HTTPS and HTTP it is a single page living under two URLs. This project ignores the scheme as content and groups by the host-and-path, collecting the set of protocols seen for each. A host-path that appears under more than one protocol is flagged as a duplicate, with the recommended fix being to force HTTPS and redirect the insecure variant away.

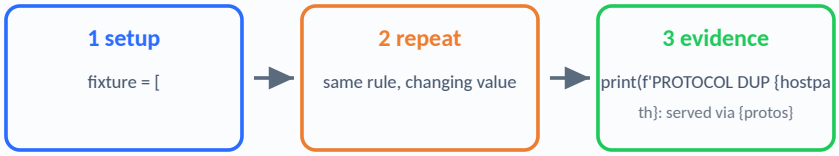
What You'll Build & Learn

Find a host-and-path served over both protocols and recommend forcing HTTPS.

- Grouping by host-and-path across schemes
- Collecting protocols in a set
- Why mixed protocols duplicate a page

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 239: collapse www vs non-www duplicates. Project 241 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a page served over two protocols is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `fixture = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'PROTOCOL DUP {hostpath}: served via {protos} (canonicalise to HTTPS)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`fixture = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(protos) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'PROTOCOL DUP {hostpath}: served via {protos} (canonicalise to HTTPS)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'PROTOCOL DUP {hostpath}: served via {protos} (canonicalise to HTTPS)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `fixture = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a page served over two protocols and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Keying a set of protocols by host-and-path reveals any path answering on more than one protocol; the fix is to redirect every request to the HTTPS variant.

```
fixture = [
    ('HTTPS', 'example.com/login'),
    ('HTTP', 'example.com/login'),
    ('HTTPS', 'example.com/home'),
```

```
]
groups = {}
for proto, hostpath in fixture:
    groups.setdefault(hostpath, set()).add(proto)
for hostpath in sorted(groups):
    protos = sorted(groups[hostpath])
    if len(protos) > 1:
        print(f'PROTOCOL DUP {hostpath}: served via {protos} (canonicalise to
HTTPS)')
```

```
output
PROTOCOL DUP example.com/login: served via ['HTTP', 'HTTPS'] (canonicalise to HTTPS)
```

How it works:

1. A fixture lists protocol and hostpath tuples for three observations
2. setdefault keyed by hostpath gathers the protocols into a set
3. Sorting the keys gives stable output
4. Any hostpath whose protocol set has more than one entry prints a PROTOCOL DUP line

Try it:

1. Add a port to the host-path and fold default ports too
2. Report which protocol is missing for single-protocol pages
3. Emit the exact redirect rule needed to force HTTPS
4. Add `('HTTP', 'example.com/home')` so the home page also flags.

⚠ Common Mistakes

- Including the protocol in the grouping key hides the duplicate by making each URL look distinct.
- Using a list instead of a set could record the same protocol twice and miscount.
- Forgetting to sort the protocols makes the printed pair order nondeterministic.

Skills gained set accumulation | tuple unpacking | protocol audit

→ Where You'll Use This: Mixed HTTP and HTTPS serving is a classic migration leftover; audits confirm the secure version is canonical and the insecure one redirects, consolidating both into one indexed URL.

Mental Model

Like a house with two address plates, one old and one new; the postman should only ever deliver to the new, secure one.

Project 241 Classify Pagination with rel next and prev

The Idea Behind It

A paginated listing links each page to its neighbours through rel-next and rel-prev pointers, and reading them reveals each page's role in the sequence. This project models three list pages as dicts with prev and next fields, then classifies each: a missing prev means first, a missing next means last, and having both means middle. The series structure falls straight out of which pointers are present.

What You'll Build & Learn

Classify each page of a paginated series as first, middle or last from its pointers.

- Reading rel-next and rel-prev pointers
- Inferring position from None pointers
- Modelling a pagination series

Skill Roadmap

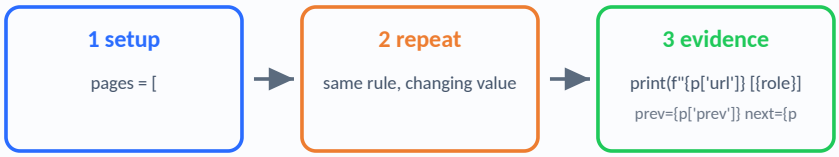
Skill step: moves you from recognition toward independent tracing. It builds on Project 240: detect a page served over two protocols. Project 242 changes the surface problem while preserving the underlying method.

progress check

Reading target: classify pagination with rel next and prev is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `pages = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f"{p['url']} [{role}] prev={p['prev']} next={p['next']}")` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`role = 'first' if p['prev'] is None else ('last' if p['next'] is None else 'middle')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"{p['url']} [{role}] prev={p['prev']} next={p['next']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `role = 'first' if p['prev'] is None else ('last' if p['next'] is None else 'middle')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. 🛠️ Reader to Writer Bridge

1. Read: explain classify pagination with rel next and prev in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 240.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 242 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{p['url']} [{role}] prev={p['prev']} next={p['next']}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `pages = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify pagination with rel next and prev and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A missing prev marks the first page and a missing next marks the last; everything with both is a middle page, which is how a series is anchored without canonicalising every page to page one.

```
pages = [
    {'url': 'https://example.com/list?page=1', 'prev': None, 'next':
'https://example.com/list?page=2'},
    {'url': 'https://example.com/list?page=2', 'prev':
'https://example.com/list?page=1', 'next': 'https://example.com/list?page=3'},
```

```
    {'url': 'https://example.com/list?page=3', 'prev':
'https://example.com/list?page=2', 'next': None},
]
for p in pages:
    role = 'first' if p['prev'] is None else ('last' if p['next'] is None else
'middle')
    print(f"{p['url']} [{role}] prev={p['prev']} next={p['next']}")
```

```
output
https://example.com/list?page=1 [first] prev=None next=https://example.com/list?
page=2
https://example.com/list?page=2 [middle] prev=https://example.com/list?page=1
next=https://example.com/list?page=3
https://example.com/list?page=3 [last] prev=https://example.com/list?page=2
next=None
```

How it works:

1. A list of dicts gives each list page a url, prev and next field
2. The loop assigns role first when prev is None, last when next is None, else middle
3. A nested ternary expresses the three-way classification
4. An f-string prints the URL, its role and both neighbour pointers

Try it:

1. Validate that each next pointer matches the following page's prev
2. Detect a broken series where a middle page has no prev
3. Build the full ordered chain from any starting page
4. Add a page 4 and confirm page 3 becomes a middle page.

⚠ Common Mistakes

- Pointing every page's canonical at page 1 instead of using rel-next/prev orphans the deeper pages.
- Treating an empty string as different from `None` breaks the first/last test.
- Assuming the list is ordered; a real crawl may see page 3 before page 1.

Skills gained None checks | nested ternary | pagination logic

→ Where You'll Use This: Understanding pagination roles matters when deciding canonical and indexing strategy for category and archive pages, where mishandling deep pages can hide content from search entirely.

⚡ Mental Model

Pagination pointers are train cars coupled front and back; the engine that has no car behind it is the locomotive, the one with none ahead is the caboose.

Project 242 Count the Faceted-Navigation URL Explosion

The Idea Behind It

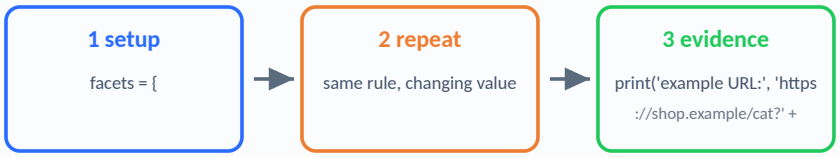
Filterable shop facets multiply combinatorially: each facet can be set to one of its values or left unset, so the number of crawlable URLs is the product of value-counts-plus-one across all facets. This project sorts the facet keys, multiplies those plus-one factors together, and prints the total alongside one example URL. Three small facets already explode into thirty-six near-identical listing pages.

What You'll Build & Learn

Count the URL variants a set of navigation facets produces and show an example.

- Why facets multiply combinatorially
- The plus-one for the unset state
- Crawl-budget impact of facets

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 241: classify pagination with rel next and prev. Project 243 changes the surface problem while preserving the underlying method. *progress check*

Reading target: count the faceted-navigation url explosion is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `facets = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('example URL:', 'https://shop.example/cat?' + example)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`facets = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`for k in keys:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('example URL:', 'https://shop.example/cat?' + example)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for k in keys:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count the Faceted-Navigation URL Explosion: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: facets, color, red, blue, size. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: facets = { | Core: for k in keys: | Evidence: print('example URL:', 'https://shop.example/cat?' + example)

🛠️ Reader to Writer Bridge

1. Read: explain count the faceted-navigation url explosion in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 241.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 243 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('example URL:', 'https://shop.example/cat?' + example)`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `facets = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count the faceted-navigation url explosion and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each facet contributes its number of values plus one (the unset state), and multiplying across facets gives the total crawlable combinations, the count to control with noindex or robots rules.

```
facets = {
    'color': ['red', 'blue'],
    'size': ['s', 'm', 'l'],
    'brand': ['acme', 'globex'],
}
```

```
keys = sorted(facets)
combos = 1
for k in keys:
    combos *= (len(facets[k]) + 1)
print('facets:', keys)
print('URL variants (incl. none-selected):', combos)
example = '&'.join(f'{k}={facets[k][0]}' for k in keys)
print('example URL:', 'https://shop.example/cat?' + example)
```

```
output
facets: ['brand', 'color', 'size']
URL variants (incl. none-selected): 36
example URL: https://shop.example/cat?brand=acme&color=red&size=s
```

How it works:

1. A dict maps each facet to its list of possible values
2. Keys are sorted for deterministic output
3. combos starts at one and is multiplied by each facet's value count plus one for unset
4. The total is printed, then an example URL is built from each facet's first value

Try it:

1. Add a fourth facet and watch the total balloon
2. Allow multi-select facets where values combine, raising the count further
3. Print every generated URL for a tiny facet set to see them all
4. Add a fourth facet and watch the count multiply again.

⚠ Common Mistakes

- Multiplying by `len(values)` without the `+1` forgets the unset state of each facet.
- Summing facet sizes instead of multiplying drastically understates the explosion.
- Ignoring parameter order: without canonicalisation each ordering is yet another URL.

Skills gained product accumulation | combinatorics | facet modelling

→ Where You'll Use This: Faceted navigation is a top cause of index bloat on e-commerce sites; estimating the explosion justifies robots rules, canonical tags or parameter handling before crawlers drown in filter combinations.

Mental Model

Each facet is a light switch; with switches that also have an off position, the number of room states multiplies fast into a wall of crawlable pages.

Project 243 Fold Parameter-Order Duplicate URLs

The Idea Behind It

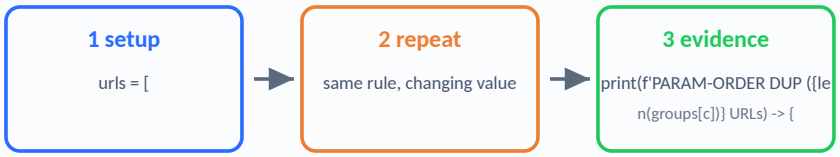
Query parameters listed in a different order point at the very same page, yet a naive crawler treats every ordering as a distinct URL. This project canonicalises each URL by splitting off the query, sorting the parameters alphabetically, and rejoining them, then groups originals under that canonical key. Three reorderings of a=1, b=2, c=3 collapse into one group, exposing them as a single page.

What You'll Build & Learn

Group URLs that differ only in parameter order under one sorted-query canonical.

- Why parameter order does not change a page
- Sorting query params for canonicalisation
- Grouping by canonical key

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 242: count the faceted-navigation url explosion. Project 244 changes the surface problem while preserving the underlying method. *progress check*

Reading target: fold parameter-order duplicate urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `urls = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'PARAM-ORDER DUP ({len(groups[c])} URLs) -> {c}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`params = '&'.join(sorted(query.split('&')) ) if query else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'PARAM-ORDER DUP ({len(groups[c])} URLs) -> {c}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `params = '&'.join(sorted(query.split('&'))) if query else ''`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Fold Parameter-Order Duplicate URLs: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: urls, https, shop, example, canon. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: urls = [| Core: params = '&'.join(sorted(query.split('&'))) if query else '' | Evidence: print(f'PARAM-ORDER DUP ({len(groups[c])} URLs) -> {c}')

🛠️ Reader to Writer Bridge

1. Read: explain fold parameter-order duplicate urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 242.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 244 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'PARAM-ORDER DUP ({len(groups[c])} URLs) -> {c}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `urls = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fold parameter-order duplicate urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Sorting the `&`-separated params produces an order-independent canonical query, so URLs differing only in parameter order collapse to one group.

```
urls = [
    'https://shop.example/p?a=1&b=2&c=3',
    'https://shop.example/p?c=3&a=1&b=2',
    'https://shop.example/p?b=2&a=1&c=3',
    'https://shop.example/q?a=1',
]
```

```
def canon(u):
    base, _, query = u.partition('?')
    params = '&'.join(sorted(query.split('&'))) if query else ''
    return base + ('?' + params if params else '')
groups = {}
for u in urls:
    groups.setdefault(canon(u), []).append(u)
for c in sorted(groups):
    if len(groups[c]) > 1:
        print(f'PARAM-ORDER DUP ({len(groups[c])} URLs) -> {c}')
```

```
output
PARAM-ORDER DUP (3 URLs) -> https://shop.example/p?a=1&b=2&c=3
```

How it works:

1. A list holds three reorderings of one query plus an unrelated URL
2. canon partitions off the query and sorts the ampersand-separated params
3. It rebuilds the URL with the sorted query, or none if empty
4. setdefault groups originals under each canonical form
5. Groups with more than one URL print a PARAM-ORDER DUP line and the count

Try it:

1. Also strip tracking parameters before sorting
2. Lowercase parameter keys before comparison
3. Report the canonical winner you would keep for each group
4. Add a fourth ordering of the same params and watch the group grow to 4.

⚠ Common Mistakes

- Sorting the whole query string as characters rather than splitting on `&` scrambles the params.
- Not handling the no-query case leaves a trailing `?` on parameterless URLs.
- Assuming param order never matters; for some apps it does and folding breaks them.

Skills gained str.partition | param sorting | url grouping

→ Where You'll Use This: Parameter-order duplication is invisible to humans but real to crawlers; canonicalising by sorted query lets a dedupe pipeline recognise these as one page and consolidate them.

Mental Model

Like three people listing the same grocery items in a different order; sort each list and you see they were buying identical baskets.

Project 244 Fold Trailing-Slash Duplicate URLs

The Idea Behind It

A URL with a trailing slash and one without usually serve the same page, so they should fold into a single canonical. This project parses the URL into host and path, ensures a leading slash, and strips a trailing slash from any path longer than the root, then groups originals under that canonical key. The blog and blog-with-slash pair collapses while the root slash is correctly left alone.

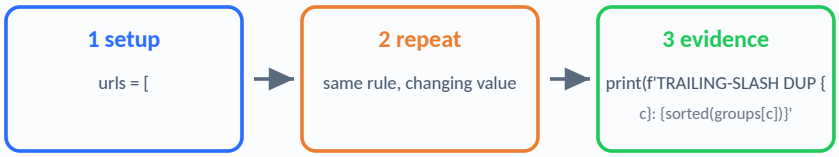
What You'll Build & Learn

Collapse URLs differing only by a trailing slash on non-root paths.

- Trailing slashes as cosmetic on non-root paths
- Preserving the root slash
- Folding to one canonical

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 243: fold parameter-order duplicate urls. Project 245 changes the surface problem while preserving the underlying method.



progress check

Reading target: fold trailing-slash duplicate urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `urls = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'TRAILING-SLASH DUP {c}: {sorted(groups[c])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(path) > 1 and path.endswith('/'):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'TRAILING-SLASH DUP {c}: {sorted(groups[c])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(path) > 1 and path.endswith('/'):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Fold Trailing-Slash Duplicate URLs: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: urls, https, example, com, blog. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: urls = [| Core: if len(path) > 1 and path.endswith('/'): | Evidence: print(f'TRAILING-SLASH DUP {c}: {sorted(groups[c])}')

🛠️ Reader to Writer Bridge

1. Read: explain fold trailing-slash duplicate urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 243.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 245 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'TRAILING-SLASH DUP {c}: {sorted(groups[c])}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `urls = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fold trailing-slash duplicate urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The `len(path) > 1` guard strips a trailing slash from real paths while leaving the root `'/'` intact, so `/blog` and `/blog/` fold but the homepage does not vanish.

```
urls = [
    'https://example.com/blog',
    'https://example.com/blog/',
    'https://example.com/about/',
    'https://example.com/',
]
```

```
def canon(u):
    scheme, rest = u.split('://', 1)
    host, slash, path = rest.partition('/')
    path = '/' + path
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]
    return scheme + '://' + host + path
groups = {}
for u in urls:
    groups.setdefault(canon(u), []).append(u)
for c in sorted(groups):
    if len(groups[c]) > 1:
        print(f'TRAILING-SLASH DUP {c}: {sorted(groups[c])}')
```

```
output
TRAILING-SLASH DUP https://example.com/blog: ['https://example.com/blog',
'https://example.com/blog/']
```

How it works:

1. A list mixes slashed and unslashed paths including the bare root
2. canon splits scheme from host, then partitions host from path
3. The path is rebuilt with a leading slash for consistency
4. A trailing slash is trimmed only when the path is longer than one character
5. setdefault groups originals, and multi-member groups print a TRAILING-SLASH DUP line

Try it:

1. Make the policy add a slash rather than remove one and rerun
2. Combine with case-folding of the host in the same function
3. Handle a path that is a single slash plus a query string
4. Add `https://example.com/about` (no slash) and watch the about pair fold.

⚠ Common Mistakes

- Stripping the slash unconditionally turns the root `'/'` into an empty path.
- Lowercasing the path here would wrongly merge case-distinct pages.
- Assuming slash and no-slash always match; some servers serve different content.

Skills gained str.partition | path normalization | slash handling

→ Where You'll Use This: Trailing-slash inconsistency splits link equity and crawl signals between two URLs; audits enforce one convention site-wide and redirect the other, which this folding logic models exactly.

Mental Model

A trailing slash is like a period at the end of a directory name; with or without it, you've arrived at the same address.

Project 245 Fingerprint a Page with MinHash-Lite

The Idea Behind It

MinHash estimates Jaccard similarity cheaply by hashing every shingle under several salts and keeping the minimum value per salt. This project builds 2-word shingles, then for each of four salts computes the smallest salted SHA-1 hash modulo a thousand to form a compact signature. Comparing two signatures slot by slot estimates the overlap without ever intersecting the full shingle sets, the trick that makes web-scale dedupe feasible.

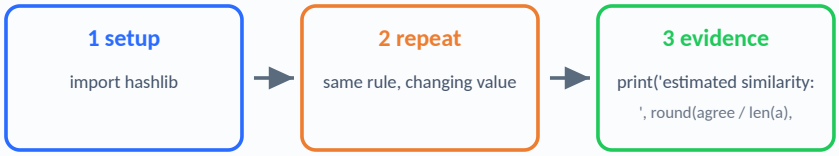
What You'll Build & Learn

Build a small MinHash signature for a page and estimate similarity from slot agreement.

- MinHash estimates Jaccard cheaply
- One minimum hash per salt
- Comparing signatures slot by slot

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 244: fold trailing-slash duplicate urls. Project 246 changes the surface problem while preserving the underlying method.



progress check

Reading target: fingerprint a page with minhash-lite is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('estimated similarity:', round(agree / len(a), 3))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`agree = sum(1 for x, y in zip(a, b) if x == y)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('estimated similarity:', round(agree / len(a), 3))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `agree = sum(1 for x, y in zip(a, b) if x == y)`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Fingerprint a Page with MinHash-Lite: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, minhash, text, salts, s1. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import hashlib | Core: agree = sum(1 for x, y in zip(a, b) if x == y) | Evidence: print('estimated similarity:', round(agree / len(a), 3))

🛠️ Reader to Writer Bridge

1. Read: explain fingerprint a page with minhash-lite in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 244.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 246 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('estimated similarity:', round(agree / len(a), 3))`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fingerprint a page with minhash-lite and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each salt acts as one hash permutation; the minimum hashed shingle under that salt is a sampled feature, and the fraction of matching signature slots estimates Jaccard similarity.

```
import hashlib

def minhash(text, salts=('s1', 's2', 's3', 's4')):
    shingles = set()
```

```
    w = text.lower().split()
    for i in range(len(w) - 1):
        shingles.add(w[i] + ' ' + w[i + 1])
    sig = []
    for salt in salts:
        mn = min(int(hashlib.sha1((salt + s).encode()).hexdigest(), 16) for s
in shingles)
        sig.append(mn % 1000)
    return sig

a = minhash('the fast red fox runs')
b = minhash('the fast red fox jumps')
agree = sum(1 for x, y in zip(a, b) if x == y)
print('sig A:', a)
print('sig B:', b)
print('estimated similarity:', round(agree / len(a), 3))
```

```
output
sig A: [999, 101, 152, 867]
sig B: [999, 589, 152, 867]
estimated similarity: 0.75
```

How it works:

1. The minhash function builds a set of space-joined word-pair shingles
2. For each salt it hashes salt-plus-shingle and keeps the minimum integer
3. Each minimum is taken modulo a thousand to keep the signature compact
4. Two near-identical phrases produce signatures of four slots each
5. Counting matching slots and dividing by the length estimates similarity

Try it:

1. Increase the number of salts and watch the estimate steady
2. Compare an unrelated phrase and confirm fewer slots match
3. Use longer signatures and measure accuracy versus speed
4. Add four more salts and watch the estimate steady.

⚠ Common Mistakes

- Reusing one salt for every slot makes all signature positions identical and uninformative.
- Hashing without `.encode()` raises a TypeError on the `str` argument.
- Too few salts make the similarity estimate coarse and jumpy.

Skills gained `hashlib.sha1` `min over hashes` `signature compare`

→ **Where You'll Use This:** MinHash signatures let search engines compare billions of documents without pairwise set math; the same trick powers practical near-duplicate clustering in large-scale SEO tooling.

Mental Model

Like polling a few random judges instead of the whole crowd: ask enough of them and the small sample's agreement closely predicts the full vote.

Project 246 Cluster Duplicate URLs to One Canonical

The Idea Behind It

A complete canonicaliser stacks every folding rule into one function: lowercase the host, drop a leading www, cut the fragment, strip utm tracking parameters, sort what remains, lowercase the path, and trim a trailing slash. This project applies all of that to a messy URL set and groups originals under the resulting key, so three differently-spelled variants of one page collapse into a single cluster while the genuinely distinct URL stands alone.

What You'll Build & Learn

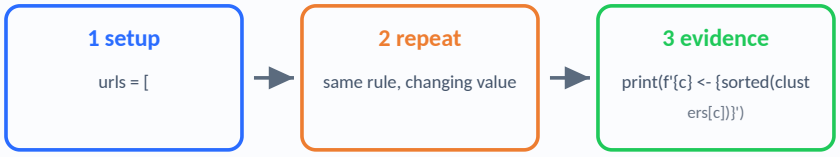
Apply every normalisation rule at once to cluster duplicate URLs to one canonical.

- Composing many normalisation rules
- Order of canonicalisation steps
- Clustering originals under one key

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 245: fingerprint a page with minhash-lite. Project 247 changes the surface problem while preserving the underlying method.

progress check



Reading target: cluster duplicate urls to one canonical is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `urls = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.

- Evidence: `print(f'{c} <- {sorted(clusters[c])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if host.startswith('www.'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c} <- {sorted(clusters[c])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if host.startswith('www.'):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Cluster Duplicate URLs to One Canonical: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: urls, https, www, Example, com. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: urls = [| Core: if host.startswith('www.'): | Evidence: print(f'{c} <- {sorted(clusters[c])}')

🛠️ Reader to Writer Bridge

1. Read: explain cluster duplicate urls to one canonical in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 245.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 247 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c} <- {sorted(clusters[c])}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `urls = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cluster duplicate urls to one canonical and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Applying host-lowercasing, www-stripping, fragment and tracking-param removal, slash-trimming, and path-lowercasing in one function makes every cosmetic variant produce the same key, so the dict groups them

automatically.

```
urls = [
    'https://www.Example.com/Page/',
    'https://example.com/page',
    'https://example.com/page?utm_source=x',
    'https://example.com/other',
]
def canon(u):
    scheme, rest = u.split('://', 1)
    rest = rest.split('#', 1)[0]
    hostpath, _, query = rest.partition('?')
    host, slash, path = hostpath.partition('/')
    host = host.lower()
    if host.startswith('www.'):
        host = host[4:]
    path = '/' + path
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]
    kept = [kv for kv in query.split('&') if kv and not kv.startswith('utm_')]
    q = '?' + '&'.join(sorted(kept)) if kept else ''
    return scheme + '://' + host + path.lower() + q
clusters = {}
for u in urls:
    clusters.setdefault(canon(u), []).append(u)
for c in sorted(clusters):
    print(f'{c} <- {sorted(clusters[c])}')
```

```
output
https://example.com/other <- ['https://example.com/other']
https://example.com/page <- ['https://example.com/page', 'https://example.com/page?
utm_source=x', 'https://www.Example.com/Page/']
```

How it works:

1. canon splits scheme, drops the fragment after a hash, and partitions host from query
2. It lowercases the host and strips a leading www prefix
3. The path gets a leading slash, loses a trailing slash, and is lowercased
4. Tracking utm params are filtered out and the rest sorted into the query
5. setdefault clusters every original URL under its full canonical form

Try it:

1. Add default-port stripping to the same function
2. Make path-lowercasing optional since real paths are case-sensitive
3. Print the chosen representative URL for each cluster
4. Add `https://EXAMPLE.com/page#top` and confirm it joins the page cluster.

⚠ Common Mistakes

- Lowercasing the path is fine only if the site treats paths case-insensitively; many do not.
- Filtering `kv` for emptiness is needed, or a query like `?` splits into a stray empty param.
- Applying the rules in the wrong order (sorting before stripping utm_) leaves the tracking param in the key.

Skills gained multi-rule canon url clustering rule composition

→ **Where You'll Use This:** Production deduplication pipelines chain exactly these rules so that all spellings of one page resolve to a single index entry, the linchpin of canonicalisation across an entire site.

⚡ Mental Model

Like running every dialect of an address through one standardiser at the post office, so a dozen scrawled envelopes all sort into the same mailbox.

Project 247 Keep a Content Fingerprint Stable

💡 The Idea Behind It

A good content fingerprint must ignore cosmetic edits like case and spacing yet still react to real changes in wording. This project normalises text by lowercasing and collapsing whitespace before hashing with SHA-1, so three differently-formatted versions of 'Hello World' produce one identical digest while adding an exclamation mark shifts it. The verdict line proves the first three fingerprints are equal, showing stability where it belongs.

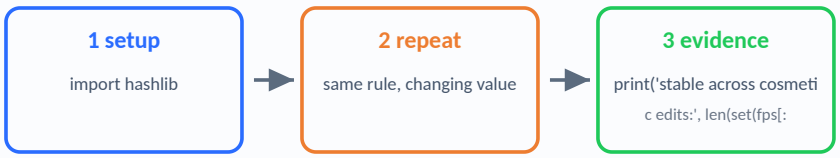
What You'll Build & Learn

Show a fingerprint stays constant across cosmetic edits but changes on real ones.

- Normalise before hashing
- Stability against case and spacing
- Sensitivity to real edits

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 246: cluster duplicate urls to one canonical. Project 248 changes the surface problem while preserving the underlying method.



progress check

Reading target: keep a content fingerprint stable is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('stable across cosmetic edits:', len(set(fps[:3])) == 1)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`fps = [fingerprint(v) for v in versions]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('stable across cosmetic edits:', len(set(fps[:3])) == 1)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `fps = [fingerprint(v) for v in versions]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Keep a Content Fingerprint Stable: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, fingerprint, text, sha1, join. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import hashlib | Core: fps = [fingerprint(v) for v in versions] | Evidence: print('stable across cosmetic edits:', len(set(fps[:3])) == 1)

🛠️ Reader to Writer Bridge

1. Read: explain keep a content fingerprint stable in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 246.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 248 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('stable across cosmetic edits:', len(set(fps[:3])) == 1)`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of keep a content fingerprint stable and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Lowercasing and collapsing whitespace before `hashlib.sha1` makes the first three variants hash identically, while real punctuation (`!`) still shifts the digest.

```
import hashlib

def fingerprint(text):
    return hashlib.sha1(' '.join(text.lower().split()).encode()).hexdigest()

versions = [
    'Hello World',
    'hello   world',
    '  HELLO WORLD  ',
    'Hello World!',
]
fps = [fingerprint(v) for v in versions]
for v, f in zip(versions, fps):
    print(f'{f[:10]} <- {v!r}')
print('stable across cosmetic edits:', len(set(fps[:3])) == 1)
```

```
output
2aae6c35c9 <- 'Hello World'
2aae6c35c9 <- 'hello   world'
2aae6c35c9 <- '  HELLO WORLD  '
430ce34d02 <- 'Hello World!'
stable across cosmetic edits: True
```

How it works:

1. fingerprint lowercases the text, collapses whitespace, encodes and hashes with SHA-1
2. Four versions vary by case, spacing and a trailing exclamation mark
3. The first three normalise identically and share one digest
4. The exclamation-mark version produces a different hash
5. A final line confirms the three cosmetic variants share one fingerprint

Try it:

1. Strip punctuation before hashing so the exclamation no longer matters
2. Add HTML stripping and confirm tags don't change the digest
3. Compare digests across two crawls to detect a real edit

4. Add `''hello world''` with a tab and confirm it still matches.

⚠ Common Mistakes

- Including punctuation in the normalised text makes trivial edits change the fingerprint.
- Stripping too aggressively (removing all punctuation) would merge genuinely different pages.
- Comparing the first 10 hex chars for the verdict risks a collision; compare full digests in production.

Skills gained `hashlib.sha1` `normalize then hash` `stability check`

→ Where You'll Use This: Stable fingerprints let you store one digest per page and detect genuine content changes between crawls without re-comparing full text, the basis of change-monitoring SEO tools.

Mental Model

Like a signature that should look the same whether you sign in pen or pencil, but visibly differs the moment you change your actual name.

Project 248 Find Duplicate Meta Descriptions

The Idea Behind It

Reused meta descriptions waste the snippet that earns clicks and hint at templated, thin pages. This project groups URLs by their exact description string with setdefault, then prints any description shared by more than one page along with every offending URL. Three pages reusing the running-gear blurb collapse into one group, exposing the copies that should each get a unique, compelling description.

What You'll Build & Learn

Group pages by meta description and list any description reused across URLs.

- Why duplicate descriptions cost clicks
- Grouping pages by description
- Listing offending URLs

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 247: keep a content fingerprint stable. Project 249 changes the surface problem while preserving the underlying method.

progress check

Reading target: find duplicate meta descriptions is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(' ', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(urls) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' ', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(urls) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Duplicate Meta Descriptions: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: pages, https, example, com, Shop. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = { | Core: if len(urls) > 1: | Evidence: print(' ', u)

🛠️ Reader to Writer Bridge

1. Read: explain find duplicate meta descriptions in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 247.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 249 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ', u)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of find duplicate meta descriptions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Grouping URLs by their meta description and reporting groups larger than one finds every set of pages sharing a snippet, the descriptions to rewrite uniquely.

```
pages = {
    'https://example.com/a': 'Shop the best deals on running gear today.',
    'https://example.com/b': 'Shop the best deals on running gear today.',
    'https://example.com/c': 'Learn to repair your own bicycle at home.',
    'https://example.com/d': 'Shop the best deals on running gear today.',
}
groups = {}
for url, meta in pages.items():
    groups.setdefault(meta, []).append(url)
for meta in sorted(groups):
    urls = sorted(groups[meta])
    if len(urls) > 1:
        print(f'DUP META ({len(urls)}x): {meta!r}')
        for u in urls:
            print('  ', u)
```

```
output
DUP META (3x): 'Shop the best deals on running gear today.'
   https://example.com/a
   https://example.com/b
   https://example.com/d
```

How it works:

1. A dictionary maps four URLs to their meta description strings
2. setdefault appends each URL to a list keyed by its description
3. Descriptions are sorted for stable output
4. Any description with more than one URL prints a DUP META line with the count
5. Each offending URL is then printed indented beneath it

Try it:

1. Normalise descriptions by case and trimming before grouping
2. Flag descriptions over the snippet length limit as well
3. Count how many pages have no description at all
4. Lowercase and strip each description before grouping.

⚠ Common Mistakes

- Not normalising case or trailing whitespace splits descriptions that are effectively identical.
- Reporting single-URL groups buries the real duplicates in noise.
- Sorting only the groups but not the URLs inside makes the inner order nondeterministic.

Skills gained setdefault grouping | duplicate detection | meta audit

→ Where You'll Use This: Duplicate meta-description reports are routine in on-page audits; identical snippets across product pages reveal CMS templating and a missed chance to differentiate results pages.

Mental Model

Like several job applicants submitting the identical cover letter; the recruiter sees the copy-paste instantly and trusts each one less.

Project 249 Catch a Canonical Pointing at a Noindex Page

The Idea Behind It

Canonicalising to a page that is itself marked noindex sends opposite orders: 'index this representative' against 'do not index it'. This project stores each page with a canonical target and a noindex flag, then for every page looks up whether its canonical destination is noindexed. When it is, the line is flagged BAD because the engine may drop the entire cluster rather than index a forbidden representative.

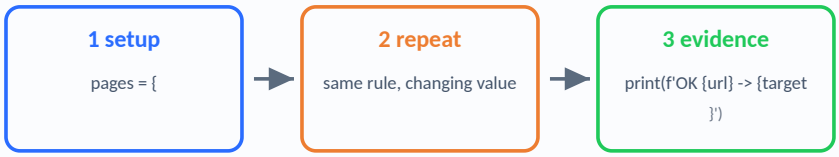
What You'll Build & Learn

Detect pages whose canonical target carries a noindex directive.

- The canonical-versus-noindex conflict
- Looking up a target's flags
- Why the cluster can vanish

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 248: find duplicate meta descriptions. Project 250 changes the surface problem while preserving the underlying method.



progress check

Reading target: catch a canonical pointing at a noindex page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'OK {url} -> {target}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if pages[target]['noindex']:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'OK {url} -> {target}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if pages[target]['noindex']:`

Construction pattern

same idea, new surface

🔍 From Concept to Code (Python)

Looking up the canonical target's own noindex flag reveals the conflict: a representative URL chosen for indexing must not itself be excluded from the index.

```
pages = {
    'https://example.com/a': {'canonical': 'https://example.com/b', 'noindex':
False},
    'https://example.com/b': {'canonical': 'https://example.com/b', 'noindex':
True},
    'https://example.com/c': {'canonical': 'https://example.com/c', 'noindex':
False},
}
for url in sorted(pages):
    target = pages[url]['canonical']
    if pages[target]['noindex']:
        print(f'BAD {url} -> canonical {target} is noindex (signal conflict)')
    else:
        print(f'OK  {url} -> {target}')
```

```
output
BAD https://example.com/a -> canonical https://example.com/b is noindex (signal
conflict)
BAD https://example.com/b -> canonical https://example.com/b is noindex (signal
conflict)
OK  https://example.com/c -> https://example.com/c
```

How it works:

1. Each page maps to a dict with a canonical URL and a noindex boolean
2. The loop reads each page's canonical target
3. It indexes back into pages to check that target's noindex flag
4. If the target is noindex it prints a BAD signal-conflict line
5. Otherwise it prints an OK line with the resolved target

Try it:

1. Also check the target returns a 200 status, not just indexable
2. Report the orphaned pages that lose their only representative
3. Suggest the nearest indexable alternative canonical
4. Clear page b's noindex flag and watch both verdicts turn OK.

⚠ Common Mistakes

- Checking the source page's noindex instead of the canonical target's misses the conflict.
- A KeyError occurs if a canonical names a target not present in the page set.
- Treating a self-noindex page as fine ignores that it still poisons pages pointing at it.

Skills gained `dict lookup` `boolean flag` `signal conflict`

→ **Where You'll Use This:** This conflict silently de-indexes pages in real audits; checking that every canonical target is itself indexable prevents accidentally pointing a whole duplicate group at a forbidden URL.

⚡ Mental Model

Like naming an heir in your will who has already renounced the inheritance; the estate has no valid recipient and the whole bequest collapses.

Project 250 Verify a Canonical Resolves to a 200

💡 The Idea Behind It

A canonical that points at a 404 or a redirect is wasted because the engine cannot index a representative that fails to return a live page. This project keeps a status-code table and a canonical map, then for each page looks up its canonical's HTTP code. Only a 200 passes; a 404 or a 301 target prints a BAD line explaining the canonical must resolve to a live, final page.

What You'll Build & Learn

Verify each canonical target returns a 200 rather than a 404 or redirect.

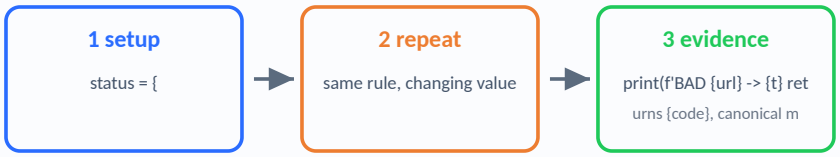
- Canonicals must resolve to 200
- Looking up a target's status code
- Why redirects and 404s fail

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 249: catch a canonical pointing at a noindex page. Project 251 changes the surface problem while preserving the underlying method.

progress check

Reading target: verify a canonical resolves to a 200 is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

🔎 Logic Lens

- Setup: `status = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'BAD {url} -> {t} returns {code}, canonical must be a 200 page')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`status = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if code == 200:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'BAD {url} -> {t} returns {code}, canonical must be a 200 page')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if code == 200:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Verify a Canonical Resolves to a 200: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: status, https, example, com, canonical. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: status = { | Core: if code == 200: | Evidence: print(f'BAD {url} -> {t} returns {code}, canonical must be a 200 page')

🛠️ Reader to Writer Bridge

1. Read: explain verify a canonical resolves to a 200 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 249.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 251 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'BAD {url} -> {t} returns {code}, canonical must be a 200 page')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `status = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of verify a canonical resolves to a 200 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Looking up the canonical target's status code and requiring exactly 200 catches canonicals aimed at missing or redirecting URLs, which silently break the indexing signal.

```
status = {
    'https://example.com/a': 200,
    'https://example.com/b': 404,
    'https://example.com/c': 301,
    'https://example.com/d': 200,
}
canonical = {
    'https://example.com/a': 'https://example.com/b',
    'https://example.com/d': 'https://example.com/c',
    'https://example.com/c': 'https://example.com/c',
}
for url in sorted(canonical):
    t = canonical[url]
    code = status.get(t, 0)
    if code == 200:
        print(f'OK  {url} -> {t} (200)')
    else:
        print(f'BAD {url} -> {t} returns {code}, canonical must be a 200 page')
```

```
output
BAD https://example.com/a -> https://example.com/b returns 404, canonical must be a
200 page
BAD https://example.com/c -> https://example.com/c returns 301, canonical must be a
200 page
BAD https://example.com/d -> https://example.com/c returns 301, canonical must be a
200 page
```

How it works:

1. A status dict maps URLs to HTTP codes including 200, 404 and 301
2. A canonical dict maps pages to their declared canonical targets
3. The loop reads each target and fetches its code from status with a default of zero
4. A target returning 200 prints OK, anything else prints BAD with the code

Try it:

1. Resolve a 301 target one hop further and re-test its final code

2. Treat any 3xx as a redirect rather than only 301
3. Tally how many canonicals are broken across the set
4. Point page c's canonical at page a and watch its verdict turn OK.

⚠ Common Mistakes

- Accepting any 3xx as fine ignores that a canonical should name the final destination, not a redirect.
- Using `status[t]` instead of `.get` raises if the target is not in the status map.
- Checking the source URL's status instead of the canonical target's misses the problem entirely.

Skills gained dict.get default | status validation | canonical audit

→ Where You'll Use This: Validating that canonical targets answer 200 is a standard crawl check; pointing at broken or redirecting URLs strands ranking signals and is a frequent post-migration defect.

Mental Model

Naming a representative who's moved away or doesn't exist: the engine knocks on the canonical's door and finds nobody home.

Project 251 Flag a Cross-Domain Canonical

The Idea Behind It

A canonical pointing to a different registrable domain hands indexing credit to another site, which is rarely intended outside syndication. This project extracts the host from each canonical URL and tests whether it equals the configured site or ends with a dot plus that site, marking same-site or CROSS-DOMAIN. A subdomain of example.com counts as same-site, while other-site.com is correctly flagged as foreign.

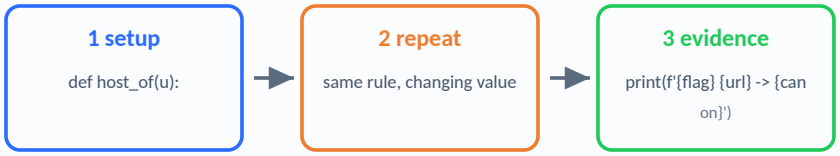
What You'll Build & Learn

Flag canonicals that point outside the configured registrable domain.

- Cross-domain canonicals leak authority
- Extracting a host from a URL
- Matching domain and its subdomains

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 250: verify a canonical resolves to a 200. Project 252 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag a cross-domain canonical is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def host_of(u):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'{flag} {url} -> {canon}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def host_of(u):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`flag = 'same-site' if same else 'CROSS-DOMAIN'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{flag} {url} -> {canon}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = 'same-site' if same else 'CROSS-DOMAIN'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Flag a Cross-Domain Canonical: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: host_of, split, lower, pages, https. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def host_of(u): | Core: flag = 'same-site' if same else 'CROSS-DOMAIN' | Evidence: print(f'{flag} {url} -> {canon}')

🛠️ Reader to Writer Bridge

1. Read: explain flag a cross-domain canonical in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 250.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 252 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{flag} {url} -> {canon}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def host_of(u):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag a cross-domain canonical and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Extracting the canonical target's host and accepting it only when it equals the site or ends with `.site` treats subdomains as same-site while flagging a foreign domain.

```
def host_of(u):
    return u.split('://', 1)[1].split('/', 1)[0].lower()

pages = {
    'https://blog.example.com/post': 'https://www.example.com/post',
    'https://shop.example.com/item': 'https://shop.example.com/item',
    'https://news.example.com/x': 'https://other-site.com/x',
}
site = 'example.com'
for url in sorted(pages):
    canon = pages[url]
    ch = host_of(canon)
    same = ch == site or ch.endswith('.' + site)
    flag = 'same-site' if same else 'CROSS-DOMAIN'
    print(f'{flag} {url} -> {canon}')
```

```
output
same-site https://blog.example.com/post -> https://www.example.com/post
CROSS-DOMAIN https://news.example.com/x -> https://other-site.com/x
same-site https://shop.example.com/item -> https://shop.example.com/item
```

How it works:

1. host_of pulls the host out of a URL by splitting on the scheme then the first slash
2. Each page maps to its canonical, and the site domain is configured as example.com
3. The check passes when the canonical host equals the site or ends with dot-site
4. Same-site canonicals are labelled, foreign ones flagged CROSS-DOMAIN

Try it:

1. Handle URLs with ports or userinfo in the host portion
2. Maintain an allowlist of approved syndication partners
3. Strip a leading www before comparing hosts
4. Add a page canonicalising to `https://evil-example.com/x` and confirm it is CROSS-DOMAIN.

⚠ Common Mistakes

- Using `in` instead of `endswith` would match `notexample.com` as same-site.

- Comparing full URLs rather than hosts misclassifies same-host pages with different paths.
- Forgetting to lowercase the host lets a capitalised domain slip through as cross-domain.

Skills gained `str.split` `domain matching` `cross-domain check`

→ Where You'll Use This: Cross-domain canonical audits catch accidental authority leaks and unauthorised syndication; deliberate cross-domain canonicals exist but should be explicit and verified, not silent surprises.

Mental Model

Like signing your house over to a stranger's name on the deed: unless you meant to gift it, the equity quietly leaves your family.

Project 252 Pick the Representative URL for a Duplicate Set

The Idea Behind It

When many URLs serve one page you must pick a single canonical, and a common deterministic policy prefers the shortest URL with alphabetical tie-breaking. This project applies min over the duplicate list with a key of length-then-string, choosing the cleanest address, then lists every other variant as a fold target. The bare product URL wins over its slashed and parameter-laden siblings.

What You'll Build & Learn

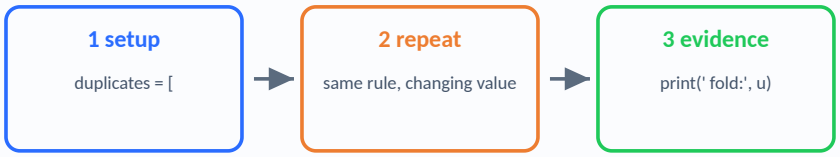
Choose one representative URL from a duplicate set by a shortest-then-alphabetical rule.

- Choosing a representative URL
- A shortest-then-alphabetical policy
- Determinism via tie-breaking

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 251: flag a cross-domain canonical. Project 253 changes the surface problem while preserving the underlying method.

progress check



Reading target: pick the representative url for a duplicate set is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `duplicates = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(' fold:', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`duplicates = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if u != chosen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' fold:', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if u != chosen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pick the Representative URL for a Duplicate Set: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: duplicates, https, example, com, product. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: duplicates = [| Core: if u != chosen: | Evidence: print(' fold:', u)

🛠️ Reader to Writer Bridge

1. Read: explain pick the representative url for a duplicate set in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 251.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 253 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' fold:', u)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `duplicates = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pick the representative url for a duplicate set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A sort key of `(len(u), u)` makes `min` prefer the shortest URL and fall back to alphabetical order, yielding a deterministic representative that the rest fold into.

```
duplicates = [
    'https://example.com/product?ref=ad&color=red',
    'https://example.com/product',
    'https://example.com/product/',
    'https://example.com/product?color=red',
]
chosen = min(duplicates, key=lambda u: (len(u), u))
print('canonical:', chosen)
for u in sorted(duplicates):
    if u != chosen:
        print('  fold:', u)
```

```
output
canonical: https://example.com/product
  fold: https://example.com/product/
  fold: https://example.com/product?color=red
  fold: https://example.com/product?ref=ad&color=red
```

How it works:

1. A list holds four spellings of one product page
2. min picks the URL minimising the tuple of length then the string itself
3. The length component favours the shortest, cleanest address
4. The string component breaks ties deterministically
5. Every other sorted URL is printed as a fold candidate

Try it:

1. Prefer URLs without query parameters over short ones
2. Add a rule favouring https over http variants
3. Let the policy prefer a manually-pinned canonical when present
4. Change the policy to prefer the URL with the fewest query params.

⚠ Common Mistakes

- Using `min` on length alone leaves ties resolved by list order, which is nondeterministic across crawls.
- Picking the longest URL canonicalises to the param-laden variant, the opposite of what you want.
- Not excluding the chosen URL from the fold list reports the canonical as folding into itself.

Skills gained min with key | tuple sort key | canonical selection

→ Where You'll Use This: Choosing the canonical representative is the decision step of any dedupe pipeline; a deterministic rule keeps the index stable across recrawls and avoids flip-flopping the chosen URL.

Mental Model

Picking the captain of identical twins by a fixed rule, like whoever's name comes first, so you always pick the same one every time.

Project 253 Measure Index Bloat from Canonicals

The Idea Behind It

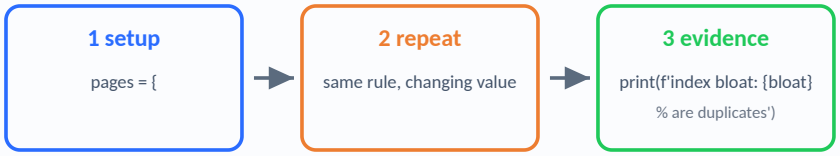
Index bloat is the gap between how many URLs are crawlable and how many distinct pages they truly represent. This project maps each crawlable URL to its canonical, counts the total URLs and the unique canonical targets via a set, and computes the duplicate share as a percentage. Five URLs resolving to two real pages reveal sixty percent bloat, quantifying the crawl budget wasted on redundant addresses.

What You'll Build & Learn

Quantify the duplicate share of a crawlable set as an index-bloat percentage.

- Defining index bloat
- Counting unique canonicals with a set
- Computing a duplicate percentage

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 252: pick the representative url for a duplicate set. Project 254 changes the surface problem while preserving the underlying method. *progress check*

Reading target: measure index bloat from canonicals is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'index bloat: {bloat}% are duplicates')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`canonicals = {p['canonical'] if isinstance(p, dict) else p for p in pages.values()}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'index bloat: {bloat}% are duplicates')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `canonicals = {p['canonical'] if isinstance(p, dict) else p for p in pages.values()}`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Index Bloat from Canonicals: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'index bloat: {bloat}% are duplicates')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure index bloat from canonicals and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

From Concept to Code (Python)

The set of distinct canonical targets is the true page count; the percentage of crawlable URLs beyond that count quantifies how much of the site is duplicate.

```
pages = {
    'https://example.com/a': 'https://example.com/a',
    'https://example.com/b': 'https://example.com/a',
    'https://example.com/c': 'https://example.com/c',
```

```
    'https://example.com/d': 'https://example.com/c',
    'https://example.com/e': 'https://example.com/c',
}
total = len(pages)
canonicals = {p['canonical'] if isinstance(p, dict) else p for p in
pages.values()}
unique = len(canonicals)
bloat = round((total - unique) / total * 100, 1)
print(f'crawlable URLs: {total}')
print(f'unique canonical pages: {unique}')
print(f'index bloat: {bloat}% are duplicates')
```

```
output
crawlable URLs: 5
unique canonical pages: 2
index bloat: 60.0% are duplicates
```

How it works:

1. A dict maps five crawlable URLs to their canonical targets
2. total is the count of all crawlable URLs
3. A set comprehension over the canonical values yields the unique page count
4. bloat is the difference over total as a rounded percentage
5. It prints crawlable count, unique pages and the bloat percentage

Try it:

1. Break the bloat figure down per directory or template
2. Handle canonical values stored as plain strings or dicts uniformly
3. Report the absolute number of wasted URLs alongside the percentage
4. Make every canonical self-referencing and watch bloat drop to 0%.

⚠ Common Mistakes

- Counting raw URLs as indexed pages massively over-reports the real index size.
- Dividing by `unique` instead of `total` measures a different and confusing ratio.
- Forgetting to dedupe canonicals into a set leaves duplicate targets in the count.

Skills gained set dedupe | percentage math | bloat metric

→ Where You'll Use This: Index-bloat metrics justify cleanup work to stakeholders; showing that most crawlable URLs are duplicates makes the case for canonical tags, redirects and parameter handling in concrete numbers.

Mental Model

Like a library catalogue listing five call numbers that all shelve to two actual books: the catalogue looks bigger than the collection really is.

Project 254 Detect Soft-404 Thin Pages

The Idea Behind It

A soft 404 returns a 200 status but carries no real content behind phrases like 'no results found' or 'page not available'. This project combines two weak signals into one strong one: it counts word tokens with a regex and scans the lowercased text for known error markers, flagging a page as SOFT-404 only when it is both thin and matches a marker. A genuine policy page with twenty-four words passes.

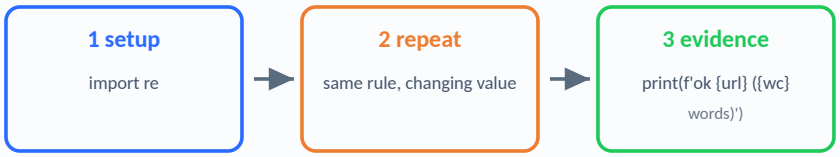
What You'll Build & Learn

Catch soft-404 pages by pairing a thin word count with error-phrase markers.

- What a soft 404 is
- Combining two weak signals
- Matching error phrasing

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 253: measure index bloat from canonicals. Project 255 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect soft-404 thin pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'ok {url} ({wc} words)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`hit = next((m for m in soft404_markers if m in text), None)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'ok {url} ({wc} words)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `hit = next((m for m in soft404_markers if m in text), None)`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Detect Soft-404 Thin Pages: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: re, pages, https, example, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: hit = next((m for m in soft404_markers if m in text), None) | Evidence: print(f'ok {url} ({wc} words)')

🛠️ Reader to Writer Bridge

1. Read: explain detect soft-404 thin pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 253.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 255 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'ok {url} ({wc} words)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect soft-404 thin pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Requiring both a low word count AND an error phrase avoids flagging a short-but-real page, catching the 200-status pages that behave like a 404.

```
import re
pages = {
    'https://example.com/real': 'Our return policy lasts thirty days from the
delivery date. Items must be unused and in original packaging to qualify for a
full refund.',
    'https://example.com/empty': 'Sorry, no results were found for your search.
```

```
Try again.',
    'https://example.com/error': 'Page not available. Please go back to the
homepage.',
}
soft404_markers = ('no results', 'not available', 'go back', 'sorry')
for url in sorted(pages):
    text = pages[url].lower()
    wc = len(re.findall(r"[a-z']+", text))
    hit = next((m for m in soft404_markers if m in text), None)
    if wc < 15 and hit:
        print(f'SOFT-404 {url} ({wc} words, matched {hit!r})')
    else:
        print(f'ok       {url} ({wc} words)')
```

```
output
SOFT-404 https://example.com/empty (10 words, matched 'no results')
SOFT-404 https://example.com/error (9 words, matched 'not available')
ok       https://example.com/real (24 words)
```

How it works:

1. A dict maps three URLs to bodies ranging from real content to error messages
2. A tuple lists soft-404 marker phrases like no results and not available
3. re.findall counts the word tokens in each lowercased body
4. next finds the first marker phrase present in the text, or None
5. A page under fifteen words and matching a marker is flagged SOFT-404

Try it:

1. Add more marker phrases such as nothing here and try later
2. Require the marker near the top of the text, not just anywhere
3. Tune the word threshold and re-evaluate borderline pages
4. Lower the word threshold to 8 and watch the error page clear.

⚠ Common Mistakes

- Flagging on the error phrase alone would catch a long article that quotes 'no results'.
- Flagging on word count alone trips on legitimately brief pages.
- Case-sensitive matching misses 'No Results' if you do not lowercase first.

Skills gained re.findall | phrase matching | combined heuristic

→ Where You'll Use This: Soft-404 detection matters because these pages waste crawl budget and pollute the index with empty search-result and error templates that return 200 instead of a proper 404.

Mental Model

Like a shop with the lights on and the open sign lit but empty shelves inside: the status says welcome, the content says there's nothing here.

Project 255 Compare Pages with Character Shingles

The Idea Behind It

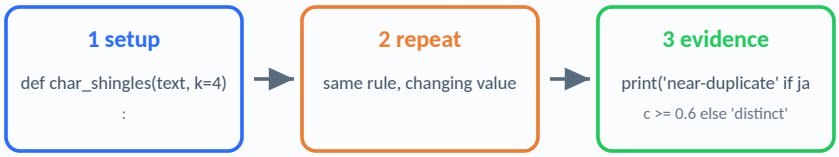
Word shingles miss tiny spelling differences such as color versus colour, so this project compares at the character level instead. It strips spaces, lowercases the text, and builds a set of 4-character grams with a sliding window, then computes Jaccard over those character n-grams. The British and American spellings share most grams but the score of 0.5 still falls under the 0.6 cutoff, marking them distinct here.

What You'll Build & Learn

Compare two texts with character 4-grams and judge them by a Jaccard cutoff.

- Character n-grams versus word shingles
- Catching small spelling differences
- Applying a similarity cutoff

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 254: detect soft-404 thin pages. Project 256 changes the surface problem while preserving the underlying method. *progress check*

Reading target: compare pages with character shingles is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def char_shingles(text, k=4):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('near-duplicate' if jac >= 0.6 else 'distinct')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def char_shingles(text, k=4):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`print('near-duplicate' if jac >= 0.6 else 'distinct')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('near-duplicate' if jac >= 0.6 else 'distinct')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('near-duplicate' if jac >= 0.6 else 'distinct')`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Compare Pages with Character Shingles: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: char_shingles, text, lower, replace, range. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def char_shingles(text, k=4): | Core: print('near-duplicate' if jac >= 0.6 else 'distinct') | Evidence: print('near-duplicate' if jac >= 0.6 else 'distinct')

🛠️ Reader to Writer Bridge

1. Read: explain compare pages with character shingles in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 254.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 256 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('near-duplicate' if jac >= 0.6 else 'distinct')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `def char_shingles(text, k=4):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare pages with character shingles and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Sliding a k-character window over the spaces-removed text builds character n-grams, and their Jaccard similarity reacts to letter-level edits that word shingles would round away.

```
def char_shingles(text, k=4):
    t = text.lower().replace(' ', '')
    return {t[i:i + k] for i in range(len(t) - k + 1)}

a = char_shingles('color of the sky')
```

```
b = char_shingles('colour of the sky')
jac = round(len(a & b) / len(a | b), 3)
print('char 4-grams A:', len(a))
print('char 4-grams B:', len(b))
print('jaccard:', jac)
print('near-duplicate' if jac >= 0.6 else 'distinct')
```

```
output
char 4-grams A: 10
char 4-grams B: 11
jaccard: 0.5
distinct
```

How it works:

1. char_shingles lowercases the text and removes spaces
2. A set comprehension forms every 4-character window across the string
3. Two near-identical spellings become gram sets a and b
4. Jaccard divides their intersection by their union, rounded
5. A score at or above 0.6 prints near-duplicate, otherwise distinct

Try it:

1. Lower k to three and see the similarity rise
2. Keep spaces in the grams and compare the effect
3. Adjust the 0.6 cutoff until these two count as duplicates
4. Lower the threshold to 0.5 and watch the verdict flip to near-duplicate.

⚠ Common Mistakes

- Leaving spaces in lets word boundaries dominate the n-grams and dilute the comparison.
- Picking k too small (1 or 2) makes almost everything similar.
- Forgetting that `set` dedupes repeated n-grams, which can deflate counts on repetitive text.

Skills gained char n-grams | set jaccard | cutoff verdict

→ Where You'll Use This: Character n-grams catch typo, localisation and inflection differences that word-level methods overlook, useful for spotting near-identical product copy that varies only in spelling across regional sites.

Mental Model

Reading by spelling out letters rather than whole words, so 'colour' and 'color' look nearly the same even though the word-level scan called them different.

Project 256 Cosine Similarity of Two Pages

The Idea Behind It

Cosine similarity treats each page as a vector of word counts and measures the angle between them, so it ignores total length and rewards shared vocabulary even when terms repeat. This project builds a Counter for each text, then computes the dot product over shared words divided by the product of the vector magnitudes. Two phrases overlapping heavily but differing in repetition score a high 0.849.

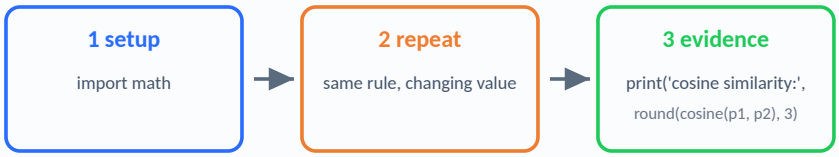
What You'll Build & Learn

Compute the cosine similarity of two pages from their word-count vectors.

- Pages as word-count vectors
- The cosine angle measure
- Why repetition is tolerated

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 255: compare pages with character shingles. Project 257 changes the surface problem while preserving the underlying method.



progress check

Reading target: cosine similarity of two pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import math` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('cosine similarity:', round(cosine(p1, p2), 3))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import math`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`dot = sum(a[t] * b[t] for t in common)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('cosine similarity:', round(cosine(p1, p2), 3))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dot = sum(a[t] * b[t] for t in common)`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Cosine Similarity of Two Pages: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: math, collections, Counter, vec, text. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import math | Core: dot = sum(a[t] * b[t] for t in common) | Evidence: print('cosine similarity:', round(cosine(p1, p2), 3))

🛠️ Reader to Writer Bridge

1. Read: explain cosine similarity of two pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 255.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 257 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('cosine similarity:', round(cosine(p1, p2), 3))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import math` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cosine similarity of two pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The dot product over shared terms divided by the product of the vector magnitudes gives the cosine of the angle between two term-frequency vectors, a length-insensitive similarity.

```
import math
from collections import Counter

def vec(text):
    return Counter(text.lower().split())
```

```
def cosine(a, b):
    common = set(a) & set(b)
    dot = sum(a[t] * b[t] for t in common)
    na = math.sqrt(sum(v * v for v in a.values()))
    nb = math.sqrt(sum(v * v for v in b.values()))
    return dot / (na * nb)

p1 = vec('buy cheap shoes cheap shoes online')
p2 = vec('buy cheap shoes online today')
print('cosine similarity:', round(cosine(p1, p2), 3))
```

```
output
cosine similarity: 0.849
```

How it works:

1. vec builds a Counter mapping each word to its frequency
2. cosine finds the words common to both vectors
3. The dot product sums the products of counts over those shared words
4. Each vector's magnitude is the square root of its summed squares
5. Dividing the dot product by the product of magnitudes gives the cosine score

Try it:

1. Remove stop words before vectorising for sharper scores
2. Use TF-IDF weights instead of raw counts
3. Guard against an empty vector that would divide by zero
4. Make the two pages identical and confirm cosine is 1.0.

⚠ Common Mistakes

- Summing over all terms instead of the shared set wastes work; absent terms contribute zero anyway.
- Dividing by zero when a page is empty crashes; guard against an empty vector.
- Confusing cosine with Jaccard: cosine weights term frequency, Jaccard only set membership.

Skills gained collections.Counter | dot product | vector cosine

→ Where You'll Use This: Cosine similarity is the workhorse of text comparison in many SEO and search systems, scoring topical overlap between pages independent of how long or repetitive each one is.

Mental Model

Two arrows shot from the same origin; cosine measures the angle between them, caring about direction of vocabulary rather than how far each arrow flies.

Project 257 Cluster Exact Duplicates with SHA-1

The Idea Behind It

To dedupe a whole site by exact content, hash each page body and group identical digests together. This project computes a SHA-1 over each raw body, buckets URLs under their digest with setdefault, then sorts the clusters by size. For any cluster larger than one it keeps the alphabetically first URL and lists the rest as drops, turning byte-identical pages into a clear keep-and-remove plan.

What You'll Build & Learn

Cluster byte-identical page bodies and choose one keeper per cluster.

- Clustering exact duplicates by hash
- Sorting clusters by size
- Choosing a keeper and drops

Skill Roadmap

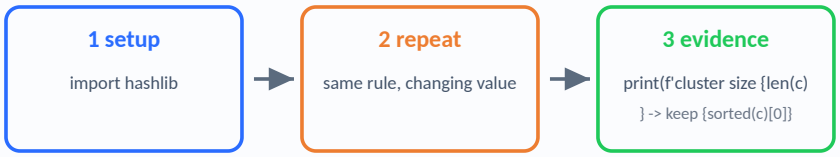
Skill step: pushes the same idea into a less automatic situation. It builds on Project 256: cosine similarity of two pages. Project 258 changes the surface problem while preserving the underlying method.

progress check

Reading target: cluster exact duplicates with sha-1 is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'cluster size {len(c)} -> keep {sorted(c)[0]}, drop {sorted(c)[1:]}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(c) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'cluster size {len(c)} -> keep {sorted(c)[0]}, drop {sorted(c)[1:]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(c) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Cluster Exact Duplicates with SHA-1: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, pages, https, example, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'cluster size {len(c)} -> keep {sorted(c)[0]}, drop {sorted(c)[1:]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cluster exact duplicates with sha-1 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Grouping URLs by `hashlib.sha1(body).hexdigest()` clusters byte-identical pages; sorting each cluster makes the keeper deterministic and lists the rest to fold away.

```
import hashlib
pages = {
    'https://example.com/a': 'identical body text here',
    'https://example.com/b': 'identical body text here',
    'https://example.com/c': 'a totally different article body',
    'https://example.com/d': 'identical body text here',
```

```
}
groups = {}
for url, body in pages.items():
    h = hashlib.sha1(body.encode()).hexdigest()
    groups.setdefault(h, []).append(url)
clusters = sorted(groups.values(), key=len, reverse=True)
for c in clusters:
    if len(c) > 1:
        print(f'cluster size {len(c)} -> keep {sorted(c)[0]}, drop {sorted(c)
[1:]}')
```

```
output
cluster size 3 -> keep https://example.com/a, drop ['https://example.com/b',
'https://example.com/d']
```

How it works:

1. A dict maps four URLs to body strings, three of them identical
2. Each body is hashed with SHA-1 and the URL appended under that digest
3. Clusters are the grouped value lists, sorted by length descending
4. For any cluster bigger than one, the sorted-first URL is the keeper
5. The remaining URLs in the cluster are listed as drops

Try it:

1. Normalise whitespace and case before hashing for looser matching
2. Pick the keeper by shortest URL instead of alphabetical
3. Emit redirect rules from each dropped URL to its keeper
4. Normalise whitespace and case before hashing to catch cosmetic copies.

⚠ Common Mistakes

- Not sorting the cluster makes which URL is kept depend on dict insertion order.
- Hashing without normalising means a single extra space splits a true duplicate.
- Reporting singleton clusters clutters the output with unique pages.

Skills gained hashlib.sha1 | setdefault grouping | cluster keeper

→ Where You'll Use This: Exact-duplicate clustering produces the actionable output of a dedupe pass: a list of which copy to keep and which URLs to redirect or canonicalise into it across the whole site.

⚡ Mental Model

Sorting a box of photocopies into stacks of identical sheets, then keeping the top sheet of each tall stack and recycling the rest.

Project 258 Fold Mixed-Case Host Duplicates

The Idea Behind It

Hostnames are case-insensitive so Example.com and example.com hit the same server, but URL paths are case-sensitive and must be left untouched. This project lowercases only the host portion while preserving the path exactly, then groups originals under that canonical host. Three case spellings of the same path collapse together, while a differently-cased path would correctly stay separate because the path is not folded.

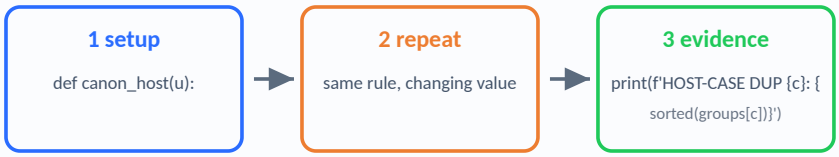
What You'll Build & Learn

Fold URLs that differ only in host letter-case while keeping paths intact.

- Hosts are case-insensitive
- Paths are case-sensitive
- Lowercasing only the host

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 257: cluster exact duplicates with sha-1. Project 259 changes the surface problem while preserving the underlying method.



progress check

Reading target: fold mixed-case host duplicates is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def canon_host(u):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'HOST-CASE DUP {c}: {sorted(groups[c])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def canon_host(u):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(groups[c]) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'HOST-CASE DUP {c}: {sorted(groups[c])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(groups[c]) > 1:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Fold Mixed-Case Host Duplicates: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: canon_host, scheme, rest, split, host. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: def canon_host(u): | Core: if len(groups[c]) > 1: | Evidence: print(f'HOST-CASE DUP {c}: {sorted(groups[c])}')

🛠️ Reader to Writer Bridge

1. Read: explain fold mixed-case host duplicates in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 257.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 259 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'HOST-CASE DUP {c}: {sorted(groups[c])}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def canon_host(u):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fold mixed-case host duplicates and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Lowercasing the host while leaving the path untouched groups the three `/Page` host variants together but keeps `/Other` distinct, respecting the path's case sensitivity.

```
def canon_host(u):
    scheme, rest = u.split('://', 1)
    host, slash, path = rest.partition('/')
    return scheme + '://' + host.lower() + '/' + path
urls = [
    'https://Example.com/Page',
    'https://EXAMPLE.com/Page',
```

```
    'https://example.com/Page',
    'https://example.com/Other',
]
groups = {}
for u in urls:
    groups.setdefault(canon_host(u), []).append(u)
for c in sorted(groups):
    if len(groups[c]) > 1:
        print(f'HOST-CASE DUP {c}: {sorted(groups[c])}')
```

```
output
HOST-CASE DUP https://example.com/Page: ['https://EXAMPLE.com/Page',
'https://Example.com/Page', 'https://example.com/Page']
```

How it works:

1. canon_host splits scheme from the rest then partitions host from path
2. Only the host is lowercased while the path is rejoined unchanged
3. A list mixes several case spellings of one host and path
4. setdefault groups originals under each canonical host string
5. Multi-member groups print a HOST-CASE DUP line with all variants

Try it:

1. Add a differently-cased path and confirm it stays separate
2. Strip a leading www in the same step
3. Lowercase the path too and observe the incorrect merge
4. Add `https://example.com/page` (lowercase path) and confirm it stays separate.

⚠ Common Mistakes

- Lowercasing the whole URL would also merge `/Page` with a hypothetical `/page`.
- Using `split('/')` instead of `partition('/')` raises if a URL has no path.
- Assuming paths are case-insensitive; many servers treat them as distinct resources.

Skills gained str.partition | selective lowercasing | host folding

→ Where You'll Use This: Mixed-case host duplicates arise from inconsistent linking and CMS output; folding only the host respects the web's case rules and avoids wrongly merging genuinely distinct paths.

⚡ Mental Model

Like a street name that doesn't care about capitals but a house number that does: SMITH STREET equals Smith Street, but 12A is not 12a.

Project 259 Fold a Default-Port Duplicate URL

The Idea Behind It

Over HTTPS the default port is 443, so example.com:443 and plain example.com are the same origin reached two ways. This project detects a host ending in colon-443 and removes those four characters, rebuilding the URL without the redundant port, then groups originals under that key. The explicit-port login URL folds together with its bare-host twin while a single-port page stays on its own.

What You'll Build & Learn

Fold a URL carrying an explicit default 443 port with its portless twin.

- The default HTTPS port is 443
- Stripping an explicit default port
- Folding origin duplicates

Skill Roadmap

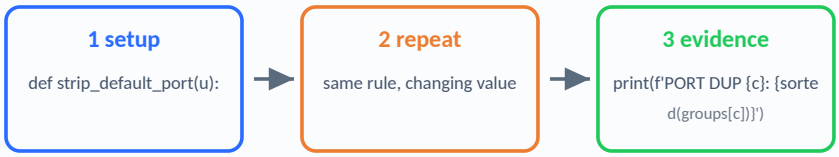
Skill step: pushes the same idea into a less automatic situation. It builds on Project 258: fold mixed-case host duplicates. Project 260 changes the surface problem while preserving the underlying method.

progress check

Reading target: fold a default-port duplicate url is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `def strip_default_port(u):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'PORT DUP {c}: {sorted(groups[c])}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def strip_default_port(u):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if host.endswith(':443'):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'PORT DUP {c}: {sorted(groups[c])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

🛠️ Reader to Writer Bridge

1. Read: explain fold a default-port duplicate url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 258.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 260 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'PORT DUP {c}: {sorted(groups[c])}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `def strip_default_port(u):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fold a default-port duplicate url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Removing a trailing `:443` from the host normalises the explicit default port to the implicit one, so the two `/login` URLs collapse into a single canonical origin.

```
def strip_default_port(u):
    scheme, rest = u.split('://', 1)
    host, slash, path = rest.partition('/')
    if host.endswith(':443'):
        host = host[:-4]
    return scheme + '://' + host + '/' + path
urls = [
```

```
    'https://example.com:443/login',
    'https://example.com/login',
    'https://example.com:443/home',
]
groups = {}
for u in urls:
    groups.setdefault(strip_default_port(u), []).append(u)
for c in sorted(groups):
    if len(groups[c]) > 1:
        print(f'PORT DUP {c}: {sorted(groups[c])}')
```

```
output
PORT DUP https://example.com/login: ['https://example.com/login',
'https://example.com:443/login']
```

How it works:

1. strip_default_port splits scheme from the rest and partitions host from path
2. If the host ends in colon-443 those four characters are sliced off
3. The URL is rebuilt with the cleaned host and original path
4. setdefault groups originals under the portless canonical
5. Groups with more than one variant print a PORT DUP line

Try it:

1. Also strip colon-80 when the scheme is http
2. Handle a host that carries a non-default port and leave it intact
3. Generalise to read the default port from the scheme
4. Add `https://example.com:8443/login` and confirm it stays separate.

⚠ Common Mistakes

- Stripping `:443` anywhere in the URL could damage a path segment that happens to contain it.
- Forgetting that a non-default port like `:8443` is a genuinely different origin and must stay.
- Slicing `host[:-4]` only works because `:443` is exactly four characters; a different port needs a split.

Skills gained str.endswith | slice trimming | port normalization

→ Where You'll Use This: Explicit default ports occasionally leak into links from proxies or misconfigurations; folding them prevents the same secure origin from being crawled twice under cosmetically different addresses.

Mental Model

Writing a phone number with the country code you didn't need to dial: 443 is the assumed extension, so adding it explicitly reaches the same line.

Project 260 Check Paginated Pages Self-Canonicalise

The Idea Behind It

Pages two and beyond of a listing series should self-canonicalise rather than fold into page one, because folding loses the deep links and content unique to later pages. This project maps each paginated URL to its declared canonical and flags any page whose canonical differs from itself. Page two pointing at page one is flagged BAD, while pages that name themselves pass the check.

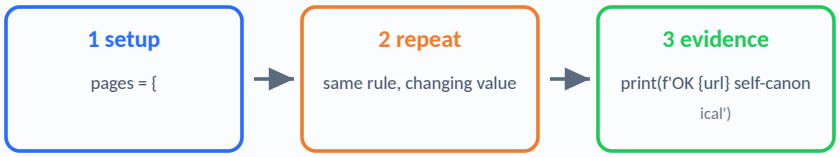
What You'll Build & Learn

Confirm later pages of a paginated series each self-canonicalise.

- Deep pages should self-canonicalise
- Why folding into page one loses content
- Flagging mis-pointed pagination

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 259: fold a default-port duplicate url. Project 261 changes the surface problem while preserving the underlying method.



progress check

Reading target: check paginated pages self-canonicalise is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'OK {url} self-canonical')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if canon != url:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'OK {url} self-canonical')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if canon != url:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Paginated Pages Self-Canonicalise: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: pages, https, example, com, page. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = { | Core: if canon != url: | Evidence: print(f'OK {url} self-canonical')

🛠️ Reader to Writer Bridge

1. Read: explain check paginated pages self-canonicalise in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 259.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 261 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'OK {url} self-canonical')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check paginated pages self-canonicalise and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A paginated page whose canonical differs from its own URL is wrongly collapsing the series; each page in the sequence should name itself so its unique listings stay indexable.

```
pages = {
    'https://example.com/list?page=1': 'https://example.com/list?page=1',
    'https://example.com/list?page=2': 'https://example.com/list?page=1',
    'https://example.com/list?page=3': 'https://example.com/list?page=3',
}
for url in sorted(pages):
    canon = pages[url]
```

```
    if canon != url:
        print(f'BAD {url} -> {canon} (page folded into page 1; lost deep
links)')
    else:
        print(f'OK  {url} self-canonical')
```

```
output
OK  https://example.com/list?page=1 self-canonical
BAD https://example.com/list?page=2 -> https://example.com/list?page=1 (page folded
into page 1; lost deep links)
OK  https://example.com/list?page=3 self-canonical
```

How it works:

1. A dict maps three list-page URLs to their canonical targets
2. Page two's canonical points at page one while the others point at themselves
3. The loop compares each page's canonical to its own URL
4. A mismatch prints a BAD line warning of lost deep links
5. A match prints OK confirming self-canonicalisation

Try it:

1. Allow a view-all page as the legitimate canonical target
2. Verify each canonical target actually exists in the set
3. Report the count of mis-canonicalised deep pages
4. Fix page 2 to self-canonicalise and watch its verdict turn OK.

⚠ Common Mistakes

- Assuming pointing every page at page 1 is correct; that is the very anti-pattern this catches.
- Confusing rel-canonical with rel-next/prev, which are the right tools for a series.
- Not sorting the pages makes the report order depend on dict insertion order.

Skills gained dict iteration | self-canonical check | pagination audit

→ Where You'll Use This: Folding deep pagination into page one is a recurring mistake that buries product and article links; auditing that each series page self-canonicalises keeps that deeper content discoverable.

Mental Model

Like stapling chapters two through ten onto chapter one's cover: the library now thinks the book is one page and shelves the rest out of sight.

Project 261 Cluster All Near-Duplicates with Union-Find

The Idea Behind It

Near-duplicate relationships are transitive, so if A resembles B and B resembles C, all three belong in one group. This project scores every page pair by Jaccard over 2-word shingles and, when a pair clears the threshold, unions them with a union-find structure. After merging, each page is mapped to its cluster root, gathering three connected coat-sale pages into one cluster while the sourdough page stands alone.

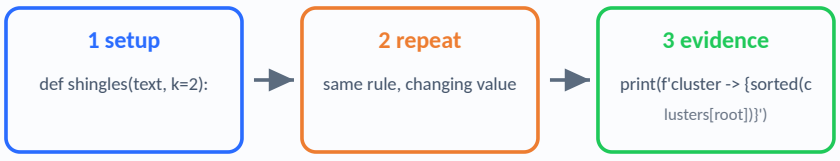
What You'll Build & Learn

Merge transitively-linked near-duplicate pages into clusters with union-find.

- Near-duplicate links are transitive
- Union-find for clustering
- Merging connected pairs

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 260: check paginated pages self-canonicalise. Project 262 changes the surface problem while preserving the underlying method.



progress check

Reading target: cluster all near-duplicates with union-find is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def shingles(text, k=2):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'cluster -> {sorted(clusters[root])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def shingles(text, k=2):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if len(a & b) / len(a | b) >= threshold:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'cluster -> {sorted(clusters[root])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(a & b) / len(a | b) >= threshold:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Cluster All Near-Duplicates with Union-Find: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 262 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'cluster -> {sorted(clusters[root])}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `def shingles(text, k=2):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cluster all near-duplicates with union-find and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each near-duplicate pair unions its two roots, so transitively similar pages end up sharing one root; grouping by that root yields complete near-duplicate clusters, even when p1 and p3 are not directly similar.

```
def shingles(text, k=2):
    w = text.lower().split()
    return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}

pages = {
    'https://example.com/p1': 'big sale on winter coats now',
    'https://example.com/p2': 'big sale on winter coats today',
    'https://example.com/p3': 'big sale on winter jackets today',
    'https://example.com/p4': 'how to bake fresh sourdough bread',
}
threshold = 0.4
urls = sorted(pages)
parent = {u: u for u in urls}
```

```
    def find(x):
        while parent[x] != x:
            x = parent[x]
        return x
    for i in range(len(urls)):
        for j in range(i + 1, len(urls)):
            a, b = shingles(pages[urls[i]]), shingles(pages[urls[j]])
            if len(a & b) / len(a | b) >= threshold:
                parent[find(urls[j])] = find(urls[i])
    clusters = {}
    for u in urls:
        clusters.setdefault(find(u), []).append(u)
    for root in sorted(clusters):
        print(f'cluster -> {sorted(clusters[root])}')
```

```
output
cluster -> ['https://example.com/p1', 'https://example.com/p2',
'https://example.com/p3']
cluster -> ['https://example.com/p4']
```

How it works:

1. A shingles helper builds word-pair sets per page
2. parent maps each URL to itself as a starting forest
3. find walks parent pointers up to a cluster root
4. Each qualifying pair unions one root under the other
5. Grouping by find root yields the final clusters, one of three pages and one alone

Try it:

1. Add union-by-rank or path compression for speed on big sets
2. Lower the threshold and watch separate clusters merge
3. Print the chosen canonical for each resulting cluster
4. Raise the threshold to 0.6 and watch p3 split into its own cluster.

⚠ Common Mistakes

- Comparing only adjacent pages misses transitive links union-find is meant to catch.
- Pointing parents the wrong way (`parent[find(i)] = find(j)`) still works but must be consistent.
- Mutating `parent` while reading `find` mid-loop is fine here but path-compression must not corrupt roots.

Skills gained union-find | transitive merge | cluster build

→ Where You'll Use This: Union-find turns pairwise similarity flags into whole clusters of duplicates, the form SEO teams actually act on when they pick one canonical for a family of barely-different pages.

Mental Model

Like merging friend circles at a party: once you learn A knows B and B knows C, you draw one circle around all three rather than three loose pairs.

Project 262 Fingerprint a Page with SimHash-Lite

The Idea Behind It

SimHash maps a whole document to a single bitstring so that similar documents produce nearby fingerprints. This project hashes each token, then for every bit position adds one when the token's bit is set and subtracts one otherwise; the sign of each accumulated total fixes the output bit. The Hamming distance between two fingerprints estimates difference, and a one-bit gap here marks the pages as near-duplicates.

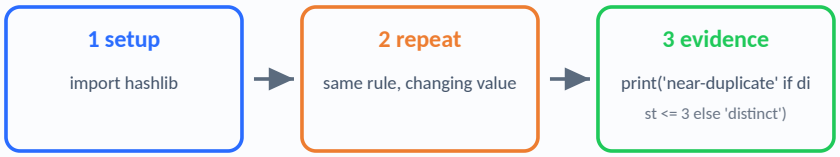
What You'll Build & Learn

Fingerprint a page with SimHash and measure difference by Hamming distance.

- SimHash yields one bitstring
- Voting bits with plus and minus one
- Hamming distance estimates difference

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 261: cluster all near-duplicates with union-find. Project 263 changes the surface problem while preserving the underlying method.



progress check

Reading target: fingerprint a page with simhash-lite is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('near-duplicate' if dist <= 3 else 'distinct')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`v[i] += 1 if (h >> i) & 1 else -1`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('near-duplicate' if dist <= 3 else 'distinct')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `v[i] += 1 if (h >> i) & 1 else -1`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Fingerprint a Page with SimHash-Lite: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, simhash, text, bits, tok. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import hashlib | Core: v[i] += 1 if (h >> i) & 1 else -1 | Evidence: print('near-duplicate' if dist <= 3 else 'distinct')

🛠️ Reader to Writer Bridge

1. Read: explain fingerprint a page with simhash-lite in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 261.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 263 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('near-duplicate' if dist <= 3 else 'distinct')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of fingerprint a page with simhash-lite and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each token votes +1 or -1 per bit position from its SHA-1; the sign of each summed column sets that fingerprint bit, so swapping one word flips only a few bits and the XOR popcount measures the difference.

```
import hashlib

def simhash(text, bits=16):
    v = [0] * bits
    for tok in text.lower().split():
```

```
            h = int(hashlib.sha1(tok.encode()).hexdigest(), 16)
            for i in range(bits):
                v[i] += 1 if (h >> i) & 1 else -1
        out = 0
        for i in range(bits):
            if v[i] > 0:
                out |= (1 << i)
        return out

a = simhash('the quick brown fox jumps over')
b = simhash('the quick brown fox leaps over')
dist = bin(a ^ b).count('1')
print('simhash A:', format(a, '016b'))
print('simhash B:', format(b, '016b'))
print('hamming distance:', dist)
print('near-duplicate' if dist <= 3 else 'distinct')
```

```
output
simhash A: 1111101000000110
simhash B: 1111001000000110
hamming distance: 1
near-duplicate
```

How it works:

1. simhash initialises a vote vector of sixteen zeros
2. Each token is hashed, and for each bit the vote rises or falls by one
3. After voting, any position with a positive total sets that output bit
4. Two phrases differing in one word produce fingerprints one bit apart
5. The Hamming distance is the popcount of the XOR, and three or fewer means near-duplicate

Try it:

1. Widen to sixty-four bits for finer discrimination
2. Weight tokens by frequency before voting
3. Compare an unrelated document and confirm a large Hamming distance
4. Change two words instead of one and watch the Hamming distance grow.

⚠ Common Mistakes

- Counting set bits with `bin(...).count('1')` on the XOR is the Hamming distance; counting on each value separately is wrong.
- Too few bits (e.g. 4) makes unrelated documents collide on the same fingerprint.
- Forgetting tokens vote -1 for zero bits collapses the fingerprint toward all-ones.

Skills gained bit voting hamming distance document fingerprint

→ Where You'll Use This: SimHash is the technique large crawlers use to bucket near-duplicate web pages at scale, letting them detect templated or scraped content without comparing full text pairwise.

Mental Model

Like a fingerprint where each ridge votes; documents about the same thing leave nearly the same print, and you count the few ridges that differ.

Project 263 Run a Full Canonical and Duplicate Audit

The Idea Behind It

This capstone fuses the chapter's three checks into one pass over a page set. For each page it counts words, hashes the normalised body, and accumulates flags: non-self-canonical when the canonical differs from the URL, duplicate-of when the hash was already seen, and thin when the word count falls under a threshold. The first seen body becomes the keeper, so later identical pages are reported as duplicates of it.

What You'll Build & Learn

Run canonical, exact-duplicate and thin-content checks together in a single pass.

- Combining three audits in one loop
- First-seen hash becomes the keeper
- Accumulating flags per page

Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 262: fingerprint a page with simhash-lite. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full canonical and duplicate audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.

- Evidence: `print(f'{url}: {flags if flags else ["clean"]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if m['canonical'] != url:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{url}: {flags if flags else ["clean"]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m['canonical'] != url:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run a Full Canonical and Duplicate Audit: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, pages, https, example, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import hashlib | Core: if m['canonical'] != url: | Evidence: print(f'{url}: {flags if flags else ["clean"]}')

🛠️ Reader to Writer Bridge

1. Read: explain run a full canonical and duplicate audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 262.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{url}: {flags if flags else ["clean"]}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full canonical and duplicate audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

One sorted pass collects every issue per page: a canonical that is not self-referencing, a content hash already seen (an exact duplicate of the first holder), and a body below the thin threshold.

```
import hashlib
pages = {
    'https://example.com/a': {'canonical': 'https://example.com/a', 'body': 'A
full article about indexing and canonical tags that runs well past the thin
threshold.'},
    'https://example.com/b': {'canonical': 'https://example.com/a', 'body': 'A
full article about indexing and canonical tags that runs well past the thin
threshold.'},
    'https://example.com/c': {'canonical': 'https://example.com/d', 'body':
'Too short.'},
}
thin = 8
seen = {}
for url in sorted(pages):
    m = pages[url]
    wc = len(m['body'].split())
    h = hashlib.sha1(' '.join(m['body'].lower().split()).encode()).hexdigest()
    flags = []
    if m['canonical'] != url:
        flags.append('non-self-canonical')
    if h in seen:
        flags.append(f'duplicate-of:{seen[h]}')
    else:
        seen[h] = url
    if wc < thin:
        flags.append(f'thin({wc}w)')
    print(f'{url}: {flags if flags else ["clean"]}')
```

```
output
https://example.com/a: ['clean']
https://example.com/b: ['non-self-canonical', 'duplicate-of:https://example.com/a']
https://example.com/c: ['non-self-canonical', 'thin(2w)']
```

How it works:

1. Each page maps to a dict with a canonical target and a body
2. The loop counts words and hashes the normalised body with SHA-1
3. A canonical not equal to the URL adds the non-self-canonical flag
4. A previously-seen hash adds a duplicate-of flag naming the keeper
5. A word count under the thin threshold adds a thin flag, and clean pages report clean

Try it:

1. Add a soft-404 marker check to the same pass
2. Lower the thin threshold and rescore the set
3. Output the flags as JSON rows for a downstream dashboard

4. Add a Jaccard near-duplicate check alongside the exact-hash check.

⚠ Common Mistakes

- Recording `seen[h]` before checking membership marks the first page as a duplicate of itself.
- Iterating the raw dict instead of `sorted(pages)` makes which URL holds a hash first nondeterministic.
- Hashing without normalising whitespace would split pages a and b into separate, non-duplicate hashes.

Skills gained `hashlib.sha1` `multi-check loop` `flag accumulation`

→ Where You'll Use This: A unified audit pass like this is the shape of a real crawl report: each row carries every problem found, so an SEO can triage canonical, duplicate and thin-content issues from one table.

⚡ Mental Model

Like an MOT inspection that checks brakes, lights and tyres in one drive-through, stamping each fault on a single sheet rather than three separate visits.

✅ Chapter Progress Checkpoint

What this chapter added: after 38 mini-projects, Canonicalization, Duplicate and Thin Content should feel like a reusable Python move: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages. *chapter checkpoint*

1 Read
Open any project from Projects 226-263 and mark `setup`, `rule`, and `evidence` without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 8 (Site Speed and Core Web Vitals) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

7 questions · 4 categories · graded

2 Recall | 4 Meaning | 1 Structure | 0 Transfer

7.1.Q1 Recall MEDIUM

Turn back to Project 226 (Check a Canonical Is Self-Referencing). Without running it, what exactly does it print?

7.1.Q2 Meaning MEDIUM Turn back to Project 237 (Compute a Boilerplate-to-Content Ratio). Without running it, what exactly does it print?

7.1.Q3 Structure MEDIUM Turn back to Project 231 (Strip Tracking Params from a URL). Without running it, what exactly does it print?

7.1.Q4 Meaning EASY What does an ordinary, healthy page's canonical tag normally point at?

- A Its parent category page
- B Itself (a self-referencing canonical)
- C The homepage
- D A noindex copy

7.1.Q5 Recall EASY Why can a SHA-1 content hash detect exact duplicates but not near-duplicates?

- A SHA-1 is too slow
- B A single changed character produces a completely different digest, so similar-but-not-identical pages never collide
- C Hashes only work on URLs
- D Near-duplicates have the same byte length

7.1.Q6 Meaning EASY During URL normalization, why do you lowercase the host but not the path?

- A The path is shorter
- B Hostnames are case-insensitive but paths are usually case-sensitive on the server
- C Search engines ignore the host
- D It is faster

7.1.Q7 Meaning MEDIUM Two pages share 3 shingles, and the union of their shingle sets is 5. What is their Jaccard similarity, and what does it measure?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 7 – Canonicalization, Duplicate and Thin Content

7.1.Q1. `self-referencing canonical: OK`

7.1.Q2. `boilerplate 5/10 = 0.5 -> ok`

7.1.Q3. `clean: https://example.com/sale?id=42&page=2` then `dropped: 2`

7.1.Q4. B a self-referencing canonical (canonical == its own URL) is the baseline; it tells the engine "this is the representative, index me."

7.1.Q5. B hashing is all-or-nothing; one different word changes the whole digest, so you need a similarity measure (shingles + Jaccard) for near-duplicates.

7.1.Q6. B `Example.com` and `example.com` are the same server, but `/Page` and `/page` can be different resources, so only the host is safe to lowercase.

7.1.Q7. 3/5 = 0.6. Jaccard similarity is the size of the shingle intersection over the union — the fraction of content the two pages share, from 0 (nothing in common) to 1 (identical).

Chapter 8 · Site Speed and Core Web Vitals

Score LCP, INP and CLS against thresholds, set performance budgets, and weigh page resources.

Chapter Skill Map

What this chapter adds: In Site Speed and Core Web Vitals, the focus is score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources. You practise it across 38 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 8 assumes the reading habits from Chapter 7: Canonicalization, Duplicate and Thin Content. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 9, Structured Data and Rich Results, reuses this chapter's discipline with a new kind of problem.

1 **Projects 264-275**	2 **Projects 276-287**	3 **Projects 288-301**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Speed is three felt moments, each graded against a threshold: LCP loads, INP responds, CLS stays still.

how fast it shows, how fast it reacts, how much it jumps

"Fast" is not one number — it is three different experiences a visitor has in the first few seconds. Largest Contentful Paint (LCP) asks *how long until the main thing I came for is on screen?* Interaction to Next Paint (INP) asks *when I tap or click, how long until something visibly happens?* And Cumulative Layout Shift (CLS) asks *did the page hold still, or did a button jump out from under my finger?* Google calls these the *Core Web Vitals*, and they are a ranking signal because they predict whether a human stays or bounces.

Each vital is a raw measurement turned into a verdict by two thresholds. Below the first you are good; between the two you need improvement; above the second you are poor. The whole of this chapter is built on mapping a measured number to one of those three bands, so the very first tool is exactly that — an LCP grader:

```
def grade_lcp(seconds):
    if seconds <= 2.5:
        return 'good'
    if seconds <= 4.0:
        return 'needs-improvement'
    return 'poor'

for s in [2.1, 3.4, 4.8]:
    print(f'LCP {s}s -> {grade_lcp(s)}')
```

```
output
LCP 2.1s -> good
LCP 3.4s -> needs-improvement
LCP 4.8s -> poor
```

The same two-threshold shape repeats for every vital — only the numbers change. INP is graded in milliseconds (≤200 good, ≤500 needs-improvement), CLS is a unitless score (≤0.1 good, ≤0.25 needs-improvement). Memorise the three pairs and you can read any vitals report at a glance.

LCP 2.5/4.0s · INP 200/500ms · CLS 0.1/0.25

Two rules tie it together. A page only `passes Core Web Vitals` when *all three* are in the good band at once — one poor metric fails the whole assessment. And the number that counts is not your laptop's reading: Google judges the `p75` — the 75th percentile of *real* visits gathered in the field (the Chrome User Experience Report, or CrUX). The rest of the chapter is the engineering behind those numbers: page weight, render-blocking resources and the performance budgets that keep them in check.

LCP (LARGEST CONTENTFUL PAINT)

How long until the largest visible element — usually the hero image or headline — finishes rendering. Bands: good ≤ `2.5s`, needs-improvement ≤ `4.0s`, poor > `4.0s`.

INP (INTERACTION TO NEXT PAINT)

Responsiveness: the time from a user interaction (tap, click, key) to the next frame the browser paints. Replaced FID in March 2024. Bands: good ≤ `200ms`, needs-improvement ≤ `500ms`, poor > `500ms`.

CLS (CUMULATIVE LAYOUT SHIFT)

Visual stability: a unitless score summing how much content jumps around unexpectedly. Each shift contributes `impact-fraction × distance-fraction`. Bands: good ≤ `0.1`, needs-improvement ≤ `0.25`, poor > `0.25`.

P75 (75TH PERCENTILE)

The field value Google grades against: 75% of real visits are at least this fast. Using p75 instead of the average means a few quick loads cannot hide many slow ones.

FIELD VS LAB DATA

Field data (CrUX) is collected from real Chrome users on their real devices and networks. Lab data is a single synthetic test (e.g. Lighthouse) on a simulated device — repeatable but optimistic.

PERFORMANCE BUDGET

A hard cap on a measurable cost — total transfer size, per-type KB, request count or a Lighthouse score — that a page is not allowed to exceed. A budget turns "keep it fast" into a pass/fail gate.

RENDER-BLOCKING RESOURCE

A CSS file or synchronous `<script>` in the document head that the browser must download and process before it can paint, directly delaying first paint and LCP.

Three vitals, three graders — same shape, different numbers

Every vital is the same algorithm: compare the measurement to two thresholds and return a band. Memorising the thresholds is most of the battle. INP — the responsiveness metric that replaced FID in 2024 — is graded in milliseconds:

```
def grade_inp(ms):
    if ms <= 200:
        return 'good'
    if ms <= 500:
        return 'needs-improvement'
    return 'poor'

for ms in [150, 480, 640]:
    print(f'INP {ms}ms -> {grade_inp(ms)}')
```

```
output
INP 150ms -> good
INP 480ms -> needs-improvement
INP 640ms -> poor
```

CLS is the odd one out: it is unitless — not seconds, not milliseconds, but a score. A layout that never moves scores 0; a page where a banner shoves the article down scores well above 0.25. Because the numbers are tiny, the thresholds feel surprisingly tight: 0.1 is good, but 0.25 is already poor.

```
def grade_cls(score):
    if score <= 0.1:
        return 'good'
```

```
    if score <= 0.25:
        return 'needs-improvement'
    return 'poor'

for c in [0.05, 0.12, 0.33]:
    print(f'CLS {c} -> {grade_cls(c)}')
```

```
output
CLS 0.05 -> good
CLS 0.12 -> needs-improvement
CLS 0.33 -> poor
```

Passing means all three good at once

A page does not pass Core Web Vitals by averaging its scores or being good "on balance". It passes only when every vital sits in the good band simultaneously — a single poor metric fails the whole assessment. Rather than write three separate cascades, drive the check from a thresholds dict so the limits live in one place:

```
metrics    = {'lcp': 2.3, 'inp': 175, 'cls': 0.07}
thresholds = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
results = {k: metrics[k] <= thresholds[k] for k in thresholds}
for k in sorted(results):
    print(f'{k}: {"good" if results[k] else "needs work"}')
print('Core Web Vitals:', 'PASS' if all(results.values()) else 'FAIL')
```

```
output
cls: good
inp: good
lcp: good
Core Web Vitals: PASS
```

When a page *fails*, the same dict tells you where to spend effort: list the metrics over their threshold and fix the first one. There is no point shaving milliseconds off INP if it is LCP that is in the red. *diagnose before you optimise*

The number Google grades is the p75 of real users

Your one fast test on a fast laptop is lab data — useful, but optimistic. Google grades the field data: real Chrome users on real phones and networks, summarised as the 75th percentile. The p75 means three-quarters of visits were at least this fast, so a handful of quick loads cannot paper over a slow majority. Here is the interpolated p75 of a list of LCP samples:

```
samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2]
ordered = sorted(samples)
rank = 0.75 * (len(ordered) - 1)
lo = int(rank)
frac = rank - lo
```

```
p75 = ordered[lo] + frac * (ordered[lo + 1] - ordered[lo]) if frac else ordered[lo]
print(f'p75 LCP = {round(p75, 3)}s')
```

```
output
p75 LCP = 3.4s
```

The average of those samples is about 2.9s — comfortably under 4.0s — yet the p75 is 3.4s, firmly in *needs-improvement*. That gap is the whole reason Google chose a percentile: the slow tail is the experience that loses you visitors. CrUX takes this one step further — a metric passes in the field when at least 75% of samples land in the good band.

Speed comes from weight — so cap it with a budget

Vitals are symptoms; page weight and render-blocking resources are the cause. The remedy is a performance budget: a hard KB cap a page may not exceed. Sum the bytes a visitor downloads and compare — if you are over, the headroom goes negative and the build fails the gate:

```
resources = {'html': 18, 'css': 42, 'js': 310, 'images': 540, 'fonts': 90}
budget_kb = 900
total = sum(resources.values())
verdict = 'within budget' if total <= budget_kb else 'OVER budget'
print(f'total = {total} KB, budget = {budget_kb} KB -> {verdict}')
print(f'headroom = {budget_kb - total} KB')
```

```
output
total = 1000 KB, budget = 900 KB -> OVER budget
headroom = -100 KB
```

A single page budget hides *which* resource type blew it, so split it per type — JS, CSS, images, fonts each get their own cap and the culprit is obvious. Separately, CSS and synchronous scripts in the head are render-blocking: the browser cannot paint until they download and run, which directly delays LCP. Counting them tells you exactly what is standing between the visitor and first paint:

```
resources = [
    {'url': 'app.js',       'blocking': True},
    {'url': 'analytics.js', 'blocking': False},
    {'url': 'main.css',     'blocking': True},
    {'url': 'font.css',     'blocking': True},
    {'url': 'lazy.js',      'blocking': False},
]
blocking = [r['url'] for r in resources if r['blocking']]
print('render-blocking:', len(blocking))
for u in sorted(blocking):
    print(' -', u)
```

```
output
```

```
render-blocking: 3
 - app.js
 - font.css
 - main.css
```

Defer the analytics, inline the critical CSS, lazy-load below-the-fold images, and the blocking count drops — which is what moves LCP from poor back into good. Budget and blocking-count are the two levers; the vitals are the readout.

cut weight and unblock paint, and the vitals follow

Example 1

A page reports field p75 values LCP 2.3s, INP 480ms, CLS 0.07. Does it pass Core Web Vitals, and if not, what do you fix first?

SOLUTION

1. Grade each against its bands. LCP 2.3s ≤ 2.5 → good.
2. INP 480ms is above 200 but ≤ 500 → needs-improvement, so it is *not* in the good band.
3. CLS 0.07 ≤ 0.1 → good. Two good, one not — and passing requires all three good.
4. The only failing metric is INP, so that is where the work goes: break up long main-thread tasks and defer non-critical JavaScript.

FAIL — INP is the single metric out of the good band, so fix responsiveness first.

one not-good metric fails the whole page

Example 2

Ten real-user LCP samples (seconds): 2.0, 2.1, 2.2, 2.3, 2.4, 2.6, 2.8, 3.0, 3.4, 5.0. The average is 2.78s. Will Google call this page good?

SOLUTION

1. Google grades the p75, not the average, so the 2.78s average is irrelevant.
2. Sort the samples (already sorted) and find the 75th-percentile position: rank = 0.75 × (10 − 1) = 6.75.
3. Interpolate between index 6 (2.8) and index 7 (3.0): 2.8 + 0.75 × (3.0 − 2.8) = 2.8 + 0.15 = 2.95s.
4. Compare 2.95s to the LCP bands: it is above 2.5 but ≤ 4.0 → needs-improvement.

No — the p75 is 2.95s (needs-improvement), even though the average of 2.78s sits in the good band. The slow tail (that 5.0s visit) drags the percentile up.

average flatters; p75 tells the truth

Example 3

A page ships js 520 KB, css 80 KB, images 600 KB, fonts 140 KB against per-type budgets of js 400, css 100, images 500, fonts 150 KB. Which types are over, and what is the total overage?

SOLUTION

1. Diff each type against its cap: js 520 − 400 = +120 over; css 80 − 100 = under (ok).
2. images 600 − 500 = +100 over; fonts 140 − 150 = under (ok).
3. Two types breach their budgets: JS (+120 KB) and images (+100 KB).
4. Total overage = 120 + 100 = 220 KB — and JS is the bigger offender, so split the bundle and defer non-critical scripts first.

JS (+120 KB) and images (+100 KB) are over, 220 KB total — a per-type budget pinpoints the category to attack, which a single page budget would have hidden. *per-type budgets name the culprit*

Mental-Math Shortcut

Loads, responds, stays still — at the 75th percentile. LCP is how fast the main content *loads* (≤2.5s good), INP is how fast the page *responds* to a tap (≤200ms good), CLS is whether it *stays still* (≤0.1 good). All three must be good to pass, and Google judges the p75 of real users — not your fast laptop, not the average. When a page is slow, look at weight and render-blocking resources; the vitals are the readout, not the root cause.

⚠ Common Mistakes

- Trusting one Lighthouse run (lab data on a fast simulated device) and ignoring the p75 field data Google actually grades — the field numbers are usually worse, especially on mobile.
- Treating Core Web Vitals as a score to average. A page passes only when LCP, INP and CLS are all in the good band; a single poor metric fails the whole assessment.
- Optimising the average load time instead of the slow tail. Google uses the 75th percentile, so the worst quarter of visits is exactly what you must fix.
- Forgetting CLS is unitless and the bands are tiny — a 0.3 score "sounds small" but is firmly poor; a single late-loading ad or un-sized image can blow it.
- Adding render-blocking CSS or synchronous scripts to the head without measuring — each one delays first paint and pushes LCP toward the poor band.

This chapter contains 38 hands-on mini-projects (Projects 264–301). Type each one out, run it, and experiment.

Project 264 Classify LCP Against Its Thresholds

The Idea Behind It

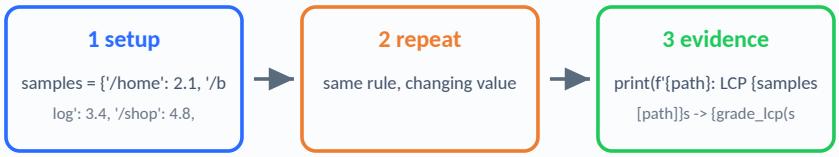
Largest Contentful Paint records the moment a page's biggest visible element finishes rendering. This project turns a raw seconds value into Google's verdict using two cutoffs: at or under 2.5 means good, at or under 4.0 means needs-improvement, and anything larger is poor. The grade_lcp function encodes those bands as ordered comparisons so every sampled path lands in exactly one bucket.

What You'll Build & Learn

Map an LCP timing to Google's good, needs-improvement, or poor band for several sampled URLs.

- The three official LCP thresholds
- Mapping a number to a labelled band
- Ordered if-checks form a cascade

Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 265 changes the surface problem while preserving the underlying method. *progress check*

Reading target: classify lcp against its thresholds is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `samples = {'/home': 2.1, '/blog': 3.4, '/shop': 4.8, '/about': 2.5}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{path}: LCP {samples[path]}s -> {grade_lcp(samples[path])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`samples = {'/home': 2.1, '/blog': 3.4, '/shop': 4.8, '/about': 2.5}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`if s <= 2.5:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{path}: LCP {samples[path]}s -> {grade_lcp(samples[path])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if s <= 2.5:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Classify LCP Against Its Thresholds: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: samples, home, blog, shop, about. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: samples = {'/home': 2.1, '/blog': 3.4, '/shop': 4.8, '/about': 2.5} | Core: if s <= 2.5: | Evidence: print(f'{path}: LCP {samples[path]}s -> {grade_lcp(samples[path])}')

🛠️ Reader to Writer Bridge

1. Read: explain classify lcp against its thresholds in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 265 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: LCP {samples[path]}s -> {grade_lcp(samples[path])}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `samples = {'/home': 2.1, '/blog': 3.4, '/shop': 4.8, '/about': 2.5}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify lcp against its thresholds and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A simple cascade of `if/elif/else` over the two thresholds buckets every LCP value into its Core Web Vitals band, exactly as PageSpeed Insights colour-codes the metric.

```
samples = {'/home': 2.1, '/blog': 3.4, '/shop': 4.8, '/about': 2.5}
def grade_lcp(s):
    if s <= 2.5:
        return 'good'
    if s <= 4.0:
```

```
        return 'needs-improvement'
    return 'poor'
for path in sorted(samples):
    print(f'{path}: LCP {samples[path]}s -> {grade_lcp(samples[path])}')
```

```
output
/about: LCP 2.5s -> good
/blog: LCP 3.4s -> needs-improvement
/home: LCP 2.1s -> good
/shop: LCP 4.8s -> poor
```

How it works:

1. A samples dict pairs four paths with their LCP seconds, from /home at 2.1 up to /shop at 4.8.
2. grade_lcp checks the boundaries top down: 2.5 returns good, then 4.0 returns needs-improvement, else poor.
3. Looping over sorted(samples) prints each path, its LCP, and the grade, so /shop at 4.8 reads as poor.

Try it:

1. Add a /pricing path at exactly 4.0 seconds and confirm it grades as needs-improvement, not poor.
2. Return a tuple of grade plus the gap to the good cutoff so callers see how far over budget a page is.
3. Replace the cascade with a list of (limit, label) pairs scanned in a loop.
4. Add a page at exactly 4.0s and confirm it grades needs-improvement, not poor.

⚠ Common Mistakes

- Using `<` instead of `<=` mis-grades a page that lands exactly on 2.5s as needs-improvement.
- Comparing the float `4.0` for equality somewhere instead of using ranges drops the boundary case.
- Forgetting to sort the dict keys before printing makes the per-page output order vary.

Skills gained LCP thresholds | cascading conditionals | dict iteration

→ Where You'll Use This: Every Lighthouse and PageSpeed report colour-codes LCP this way, so the banding logic underpins any dashboard or alert you build to flag slow-loading templates.

Mental Model

Like a swimmer's lane assignment at a meet: the clock reads a time, and that one number drops you into the fast, middle, or slow heat.

Project 265 Classify INP Against Its Thresholds

The Idea Behind It

Interaction to Next Paint took over from First Input Delay in 2024 and measures, in milliseconds, how sluggishly a page responds when someone taps or clicks. The grade_inp function applies INP's own cutoffs: 200ms or less is good, 500ms or less is needs-improvement, beyond that is poor. Each sampled interaction path gets classified independently against those latency boundaries.

What You'll Build & Learn

Convert per-page INP latencies in milliseconds into the good, needs-improvement, or poor responsiveness band.

- INP replaced FID as a responsiveness metric
- The 200 and 500 millisecond cutoffs
- Reusing the cascade pattern for a new unit

🧭 Skill Roadmap

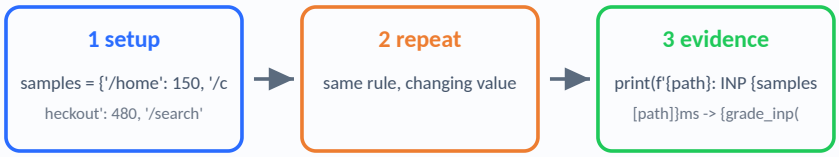
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 264: classify lcp against its thresholds. Project 266 changes the surface problem while preserving the underlying method.

progress check

Reading target: classify inp against its thresholds is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens



- Setup: `samples = {'/home': 150, '/checkout': 480, '/search': 640, '/cart': 200}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{path}: INP {samples[path]}ms -> {grade_inp(samples[path])}')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`samples = {'/home': 150, '/checkout': 480, '/search': 640, '/cart': 200}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`if ms <= 200:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{path}: INP {samples[path]}ms -> {grade_inp(samples[path])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if ms <= 200:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Classify INP Against Its Thresholds: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

🛠️ Reader to Writer Bridge

1. Read: explain classify inp against its thresholds in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 264.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 266 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: INP {samples[path]}ms -> {grade_inp(samples[path])}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `samples = {'/home': 150, '/checkout': 480, '/search': 640, '/cart': 200}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify inp against its thresholds and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

INP uses the same three-band cascade as LCP but with millisecond thresholds; the heaviest-interaction pages (search, checkout) usually fail first.

```
samples = {'/home': 150, '/checkout': 480, '/search': 640, '/cart': 200}
def grade_inp(ms):
    if ms <= 200:
        return 'good'
    if ms <= 500:
```

```
        return 'needs-improvement'
    return 'poor'
for path in sorted(samples):
    print(f'{path}: INP {samples[path]}ms -> {grade_inp(samples[path])}')
```

```
output
/cart: INP 200ms -> good
/checkout: INP 480ms -> needs-improvement
/home: INP 150ms -> good
/search: INP 640ms -> poor
```

How it works:

1. The samples dict holds four paths with INP in milliseconds, from /home at 150 to /search at 640.
2. grade_inp tests 200 first for good, then 500 for needs-improvement, otherwise poor.
3. Iterating sorted(samples) prints each path with its millisecond reading and grade; /search at 640 prints poor.

Try it:

1. Add a /menu path at 500ms and verify it grades as needs-improvement rather than poor.
2. Track which paths are poor in a list and print only those needing urgent attention.
3. Generalise grade_inp to accept the cutoffs as arguments so the same code grades any latency metric.
4. Change /search to 500ms and confirm it grades needs-improvement, not poor.

⚠ Common Mistakes

- Mixing up INP's 200/500ms bands with LCP's 2.5/4.0s bands grades everything wrong.
- Storing INP as seconds instead of milliseconds silently passes every page.
- Using `<` on the 200 boundary mis-grades /cart at exactly 200ms.

Skills gained INP thresholds | latency grading | millisecond units

→ Where You'll Use This: INP is the responsiveness pillar of Core Web Vitals, so this grading is what you reach for when triaging slow checkout or search interactions that frustrate users.

Mental Model

Think of a waiter's response time: under 200ms feels instant, half a second feels acceptable, and beyond that the table starts tapping the menu.

Project 266 Classify CLS Against Its Thresholds

The Idea Behind It

Cumulative Layout Shift is a unitless score that captures how much a page jumps around as it loads. Because its bands are tiny, 0.1 or under for good and 0.25 or under for needs-improvement, even a fraction of a point matters. The grade_cls function reads each sampled score and routes it into the matching stability band, showing how a /gallery score of 0.33 lands in poor.

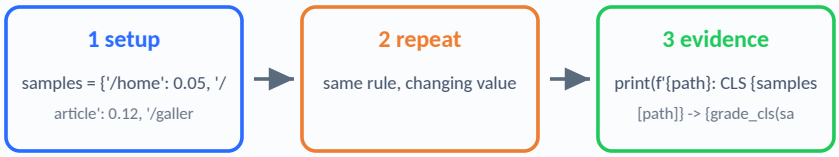
What You'll Build & Learn

Classify CLS visual-stability scores into the good, needs-improvement, or poor band for several pages.

- CLS is a unitless stability score
- The 0.1 and 0.25 boundaries are small
- Why tiny shifts still fail the band

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 265: classify inp against its thresholds. Project 267 changes the surface problem while preserving the underlying method.



progress check

Reading target: classify cls against its thresholds is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `samples = {'/home': 0.05, '/article': 0.12, '/gallery': 0.33, '/landing': 0.25}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{path}: CLS {samples[path]} -> {grade_cls(samples[path])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Code Reading Stack

Layer	What to read
Intent	Classify CLS Against Its Thresholds: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: samples, home, article, gallery, landing. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: samples = {'/home': 0.05, '/article': 0.12, '/gallery': 0.33, '/landing... | Core: if c <= 0.1: | Evidence: print(f'{path}: CLS {samples[path]} -> {grade_cls(samples[path])}')

🛠️ Reader to Writer Bridge

1. Read: explain classify cls against its thresholds in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 265.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 267 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: CLS {samples[path]} -> {grade_cls(samples[path])}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `samples = {'/home': 0.05, '/article': 0.12, '/gallery': 0.33, '/landing': 0.25}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify cls against its thresholds and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

CLS is a ratio, not a time, so the thresholds are tiny decimals; the same cascade pattern applies, and a gallery of late-loading images is a classic poor performer.

```
samples = {'/home': 0.05, '/article': 0.12, '/gallery': 0.33, '/landing': 0.25}
def grade_cls(c):
    if c <= 0.1:
        return 'good'
    if c <= 0.25:
```

```
        return 'needs-improvement'
    return 'poor'
for path in sorted(samples):
    print(f'{path}: CLS {samples[path]} -> {grade_cls(samples[path])}')
```

```
output
/article: CLS 0.12 -> needs-improvement
/gallery: CLS 0.33 -> poor
/home: CLS 0.05 -> good
/landing: CLS 0.25 -> needs-improvement
```

How it works:

1. A samples dict maps four paths to CLS scores ranging from /home at 0.05 to /gallery at 0.33.
2. grade_cls compares against 0.1 then 0.25, falling through to poor for anything higher.
3. The sorted loop prints path, score, and grade, so /landing at 0.25 reads as needs-improvement at the boundary.

Try it:

1. Add a /press path at 0.1 and confirm the boundary value still grades as good.
2. Print a star next to any path scoring poor so the worst offenders stand out.
3. Round each score to two decimals before grading to mirror how reporting tools display CLS.
4. Set /landing to 0.26 and watch it tip from needs-improvement into poor.

⚠ Common Mistakes

- Reading 0.25 as a percentage and dividing by 100 mis-grades every page.
- Treating the 0.1 boundary with `<` mis-grades /home if it sat exactly on 0.1.
- Printing the raw float chain without sorting keys gives nondeterministic order.

Skills gained CLS thresholds | fractional comparisons | stability scoring

→ Where You'll Use This: Layout-shift complaints, ad slots or images loading without reserved space, are diagnosed by exactly this banding when you audit a template's visual stability.

Mental Model

Like rating how much a table wobbles: a hair of movement is fine, a noticeable rock is annoying, and a real lurch spills your coffee.

Project 267 Decide the Overall Core Web Vitals Pass

The Idea Behind It

Core Web Vitals is an all-or-nothing assessment: a page passes only when LCP, INP, and CLS are each inside their good band simultaneously. This project hardcodes one metric snapshot and joins three comparisons with logical and, so a single boolean decides the verdict. Because every term must be true, one weak metric drags the whole page to FAIL.

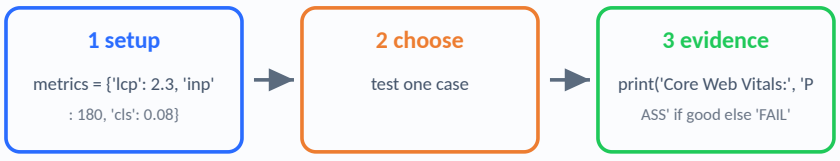
What You'll Build & Learn

Combine three metric checks with logical and to produce a single overall PASS or FAIL verdict.

- All three vitals must pass together
- Logical and chains the conditions
- One failure fails the whole assessment

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 266: classify cls against its thresholds. Project 268 changes the surface problem while preserving the underlying method.



progress check

Reading target: decide the overall core web vitals pass is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `metrics = {'lcp': 2.3, 'inp': 180, 'cls': 0.08}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('Core Web Vitals:', 'PASS' if good else 'FAIL')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`metrics = {'lcp': 2.3, 'inp': 180, 'cls': 0.08}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`print('Core Web Vitals:', 'PASS' if good else 'FAIL')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('Core Web Vitals:', 'PASS' if good else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('Core Web Vitals:', 'PASS' if good else 'FAIL')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Decide the Overall Core Web Vitals Pass: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: metrics, lcp, inp, cls, good. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: metrics = {'lcp': 2.3, 'inp': 180, 'cls': 0.08} | Core: print('Core Web Vitals:', 'PASS' if good else 'FAIL') | Evidence: print('Core Web Vitals:', 'PASS' if good else 'FAIL')

🛠️ Reader to Writer Bridge

1. Read: explain decide the overall core web vitals pass in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 266.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 268 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('Core Web Vitals:', 'PASS' if good else 'FAIL')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `metrics = {'lcp': 2.3, 'inp': 180, 'cls': 0.08}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of decide the overall core web vitals pass and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Combining the three good-band checks with `and` enforces the all-three rule Google applies; a single laggard metric flips the verdict to FAIL.

```
metrics = {'lcp': 2.3, 'inp': 180, 'cls': 0.08}
good = metrics['lcp'] <= 2.5 and metrics['inp'] <= 200 and metrics['cls'] <=
0.1
print('Core Web Vitals:', 'PASS' if good else 'FAIL')
```

```
output
Core Web Vitals: PASS
```

How it works:

1. A metrics dict carries lcp 2.3, inp 180, and cls 0.08, all comfortably inside their good bands.
2. The good variable is the and of three threshold comparisons against 2.5, 200, and 0.1.

3. A conditional expression prints PASS because every comparison is true; flipping any value to a worse number would print FAIL.

Try it:

1. Bump inp to 250 and watch the combined verdict flip to FAIL even though LCP and CLS still pass.
2. Print which specific metric broke the pass rather than just PASS or FAIL.
3. Wrap the check in a function that takes a metrics dict and returns the boolean.
4. Bump `lcp` to 2.6 and watch the whole verdict flip to FAIL.

⚠ Common Mistakes

- Using `or` instead of `and` passes a page that is good on only one metric.
- Comparing INP in seconds against the 200ms threshold gives a false pass.
- Hard-coding the thresholds in three places makes them drift out of sync over time.

Skills gained boolean and | pass/fail logic | combined thresholds

→ Where You'll Use This: This single-page gate is the smallest unit of a Core Web Vitals report and the building block for site-wide pass-rate dashboards used in SEO health checks.

⚡ Mental Model

Like a three-key safe: every key must turn at once. One stuck key and the door stays shut no matter how good the other two are.

Project 268 Score All Three Vitals From a Threshold Table

💡 The Idea Behind It

Instead of three hardcoded comparisons, this version stores the limits in a thresholds dict and builds a results dict with a comprehension that compares each metric to its matching cap. all() then collapses the per-metric booleans into one verdict. Keeping the limits in a single table means adding a new metric is a one-line edit rather than another if-branch.

What You'll Build & Learn

Drive the per-metric pass check from a thresholds table and reduce the results with all().

- Data-driven thresholds beat hardcoded branches
- Dict comprehension pairs metric to verdict
- all() reduces booleans to one result

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 267: decide the overall core web vitals pass. Project 269 changes the surface problem while preserving the underlying method.

progress check

Reading target: score all three vitals from a threshold table is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `metrics = {'lcp': 2.3, 'inp': 175, 'cls': 0.07}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('Core Web Vitals:', 'PASS' if passed else 'FAIL')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output.

visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`metrics = {'lcp': 2.3, 'inp': 175, 'cls': 0.07}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`print(f'{k}: {"good" if results[k] else "needs work"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('Core Web Vitals:', 'PASS' if passed else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{k}: {"good" if results[k] else "needs work"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 267.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 269 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('Core Web Vitals:', 'PASS' if passed else 'FAIL')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `metrics = {'lcp': 2.3, 'inp': 175, 'cls': 0.07}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score all three vitals from a threshold table and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A dict comprehension compares each metric to its threshold in lockstep, and `all()` over the booleans yields the overall pass, so adding a metric is a one-line change.

```
metrics = {'lcp': 2.3, 'inp': 175, 'cls': 0.07}
thresholds = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
results = {k: metrics[k] <= thresholds[k] for k in thresholds}
passed = all(results.values())
for k in sorted(results):
    print(f'{k}: {"good" if results[k] else "needs work"}')
print('Core Web Vitals:', 'PASS' if passed else 'FAIL')
```

```
output
cls: good
inp: good
lcp: good
Core Web Vitals: PASS
```

How it works:

1. metrics and a parallel thresholds dict share the keys lcp, inp, and cls.
2. A dict comprehension builds results, mapping each key to whether its metric is at or under its threshold.
3. all(results.values()) decides PASS, and a sorted loop prints good or needs work per metric before the verdict line.

Try it:

1. Add a ttfb key to both dicts and confirm the comprehension and all() pick it up automatically.
2. Print the count of passing metrics alongside the overall verdict.
3. Switch all() to any() and describe how the meaning of the verdict changes.
4. Add an 'fcp' metric and threshold and watch the table grow automatically.

⚠ Common Mistakes

- Iterating over `metrics` instead of `thresholds` breaks if the metrics dict has extra keys.
- Assuming every threshold is an upper bound; a 'higher is better' metric would need inverting.
- Printing the booleans dict unsorted yields nondeterministic key order.

Skills gained `dict comprehension` `all() reduction` `table-driven logic`

→ Where You'll Use This: Configuration-as-data is how real monitoring tools store metric limits, so this pattern scales when teams add new web-performance signals without rewriting the checker.

Mental Model

Like a checklist clipped to a clipboard: every item has its own tick box, and the form is approved only when every box is ticked.

Project 269 Check Total Transfer Against a Budget

The Idea Behind It

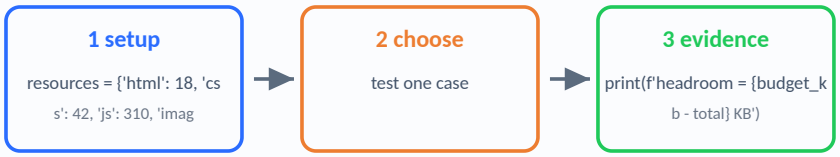
A performance budget caps the total kilobytes a page is allowed to ship. This project sums the per-type transfer sizes from a resources dict, compares the total against a fixed budget, and reports whether the page is within or over. It also prints headroom as budget minus total, which goes negative when the page busts the cap, here landing at -100 KB.

What You'll Build & Learn

Sum per-type transfer sizes, compare to a kilobyte budget, and report verdict plus headroom.

- A performance budget caps page weight
- sum() totals dict values quickly
- Negative headroom signals a busted budget

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 268: score all three vitals from a threshold table. Project 270 changes the surface problem while preserving the underlying method. *progress check*

Reading target: check total transfer against a budget is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `resources = {'html': 18, 'css': 42, 'js': 310, 'images': 540, 'fonts': 90}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'headroom = {budget_kb - total} KB')` exposes the result; match it against the output before changing the program. *output proves the trace*

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Check Total Transfer Against a Budget: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, html, css, js, images. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: resources = {'html': 18, 'css': 42, 'js': 310, 'images': 540, 'fonts':... | Core: verdict = 'within budget' if total <= budget_kb else 'OVER budget' | Evidence: print(f'headroom = {budget_kb - total} KB')

🛠️ Reader to Writer Bridge

1. Read: explain check total transfer against a budget in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 268.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 270 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'headroom = {budget_kb - total} KB')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `resources = {'html': 18, 'css': 42, 'js': 310, 'images': 540, 'fonts': 90}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check total transfer against a budget and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Summing the resource dict's values gives the page weight, and subtracting from the budget surfaces the headroom (or, when negative, the overage).

```
resources = {'html': 18, 'css': 42, 'js': 310, 'images': 540, 'fonts': 90}
budget_kb = 900
total = sum(resources.values())
verdict = 'within budget' if total <= budget_kb else 'OVER budget'
print(f'total transfer = {total} KB, budget = {budget_kb} KB -> {verdict}')
print(f'headroom = {budget_kb - total} KB')
```

```
output
total transfer = 1000 KB, budget = 900 KB -> OVER budget
headroom = -100 KB
```

How it works:

1. The resources dict lists html, css, js, images, and fonts sizes that sum to 1000 KB.
2. sum(resources.values()) gives the total, compared against budget_kb of 900.
3. A conditional sets the verdict to OVER budget, and headroom prints as budget minus total, showing -100 KB.

Try it:

1. Lower the budget to 800 KB and confirm the headroom and verdict both reflect the tighter cap.
2. Print the percentage of the budget consumed in addition to the verdict.
3. Raise an exception instead of printing when the total exceeds the budget, mimicking a CI failure.
4. Raise the budget to 1100 KB and watch the verdict flip to within budget.

⚠ Common Mistakes

- Summing the dict keys instead of `.values()` adds strings and raises a TypeError.
- Mixing KB and bytes between the budget and the sizes makes the comparison meaningless.
- Reporting only pass/fail and hiding the headroom number that tells you how close you are.

Skills gained performance budgets summing values budget gating

→ Where You'll Use This: Performance budgets are enforced in CI to block bloated builds, so this gate is the seed of a check that fails a deploy when a page outgrows its weight allowance.

Mental Model

Like a suitcase with an airline weight limit: you weigh everything packed, and if the scale tips past the allowance you are repacking or paying extra.

Project 270 Sum Resource Weights From a Manifest

The Idea Behind It

Before any budget can be checked you need the raw page weight, and that means totalling every asset a visitor downloads. This project models the manifest as a list of (url, type, size) tuples and uses a generator inside sum() to add up only the size field via tuple unpacking. The result is both the resource count and the combined transfer in kilobytes.

What You'll Build & Learn

Total the size field across a list of resource tuples to find the full page transfer weight.

- A manifest as a list of tuples
- Tuple unpacking ignores fields with underscore
- Generator expression feeds sum()

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 269: check total transfer against a budget. Project 271 changes the surface problem while preserving the underlying method.

progress check

Reading target: sum resource weights from a manifest is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

- Evidence: `print(f'{len(resources)} resources, {total} KB total')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`total = sum(size for _, _, size in resources)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{len(resources)} resources, {total} KB total')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `total = sum(size for _, _, size in resources)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Sum Resource Weights From a Manifest: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, app, js, vendor, style. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: resources = [| Core: total = sum(size for _, _, size in resources) | Evidence: print(f'{len(resources)} resources, {total} KB total')

🛠️ Reader to Writer Bridge

1. Read: explain sum resource weights from a manifest in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 269.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 271 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{len(resources)} resources, {total} KB total')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of sum resource weights from a manifest and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Unpacking each tuple and summing the size field gives total weight; counting the list length gives the request count, the two headline numbers of any waterfall.

```
resources = [
    ('app.js', 'js', 280),
    ('vendor.js', 'js', 150),
```

```
    ('style.css', 'css', 60),
    ('hero.jpg', 'image', 420),
    ('logo.png', 'image', 30),
]
total = sum(size for _, _, size in resources)
print(f'{len(resources)} resources, {total} KB total')
```

```
output
5 resources, 940 KB total
```

How it works:

1. resources is a list of five tuples, each holding a filename, a type, and a size in kilobytes.
2. sum(size for _, _, size in resources) unpacks each tuple, discarding url and type, and totals only the sizes.
3. The print reports len(resources) as the count and the total, giving 5 resources and 940 KB.

Try it:

1. Sum only the JavaScript entries by adding a type filter to the generator expression.
2. Find the single heaviest resource using max with a key on the size field.
3. Convert the total to megabytes and print it rounded to two decimal places.
4. Print the average resource size (`total / len(resources)`).

⚠ Common Mistakes

- Unpacking the tuple in the wrong order sums the type strings instead of sizes.
- Counting `len(resources)` as bytes instead of as the number of requests.
- Forgetting that a real manifest may list the same URL twice and double-count it.

Skills gained tuple unpacking | generator in sum | page weight

→ Where You'll Use This: Network panels and HAR exports hand you exactly this kind of resource list, so summing sizes is the first step in any byte-level performance audit.

Mental Model

Like adding up grocery receipt line items: you only care about the price column, scanning past the names and aisles to reach the total at the bottom.

Project 271 Count Render-Blocking Resources

The Idea Behind It

CSS and synchronous JavaScript placed in the document head stall first paint until they download and run. This project models each resource as a dict with a blocking flag, filters the list to the blocking URLs with a

comprehension, and reports how many delay rendering. Printing the sorted offenders names exactly which files sit on the critical path.

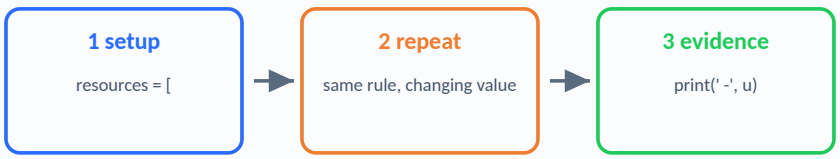
What You'll Build & Learn

Filter a resource list to the render-blocking entries and count and name what delays first paint.

- Render-blocking assets stall first paint
- Filter a list by a boolean flag
- List comprehension extracts matching URLs

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 270: sum resource weights from a manifest. Project 272 changes the surface problem while preserving the underlying method.



progress check

Reading target: count render-blocking resources is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(' -', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`blocking = [r['url'] for r in resources if r['blocking']]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' –', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `blocking = [r['url'] for r in resources if r['blocking']]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Render-Blocking Resources: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, url, app, js, blocking. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: resources = [| Core: blocking = [r['url'] for r in resources if r['blocking']] | Evidence: print(' -', u)

🛠️ Reader to Writer Bridge

1. Read: explain count render-blocking resources in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 270.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 272 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -', u)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count render-blocking resources and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Filtering the resource list on the `blocking` flag isolates the critical resources, and sorting the URLs makes the report deterministic.

```
resources = [
    {'url': 'app.js', 'blocking': True},
    {'url': 'analytics.js', 'blocking': False},
    {'url': 'main.css', 'blocking': True},
    {'url': 'font.css', 'blocking': True},
    {'url': 'lazy.js', 'blocking': False},
]
blocking = [r['url'] for r in resources if r['blocking']]
print('render-blocking:', len(blocking))
for u in sorted(blocking):
    print(' -', u)
```

```
output
render-blocking: 3
 - app.js
 - font.css
 - main.css
```

How it works:

1. resources is a list of dicts, each with a url and a blocking boolean.

2. A comprehension keeps the url where blocking is True, collecting app.js, main.css, and font.css.
3. The code prints the count of three, then loops over the sorted blocking list to name each render-blocking file.

Try it:

1. Add an async script with blocking False and confirm it is excluded from the count.
2. Group the blocking resources by file extension to see whether CSS or JS dominates.
3. Invert the filter to list the non-blocking resources that are safe to leave alone.
4. Mark `font.css` as non-blocking and watch the count drop to 2.

⚠ Common Mistakes

- Treating `async`/`defer` scripts as blocking inflates the count.
- Counting non-blocking analytics as blocking because it is also JavaScript.
- Printing the filtered set unsorted so the URL order changes run to run.

Skills gained render blocking | boolean filtering | list comprehension

→ Where You'll Use This: Eliminating render-blocking resources, by deferring scripts or inlining critical CSS, is a top Lighthouse recommendation, and this count is how you measure the problem.

Mental Model

Like a single-file doorway where a few people insist on entering first: until they squeeze through, everyone behind them waits and the room stays empty.

Project 272 Total Image Weight and Find the Heaviest

The Idea Behind It

Images are typically the heaviest slice of a page and the most common LCP element, so they deserve first attention. This project sums the values of an images dict to get total image weight and uses max with a key over the sorted keys to name the single biggest file. Identifying hero.jpg at 480 KB points straight at the asset worth optimising.

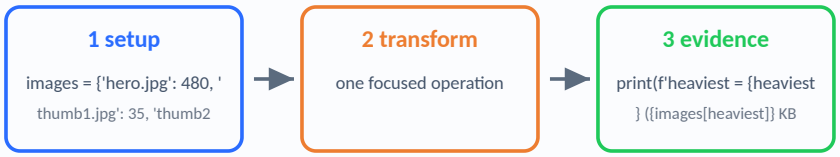
What You'll Build & Learn

Total all image sizes and name the single heaviest image to prioritise optimisation effort.

- Images often dominate page weight
- max with a key finds the heaviest
- Sorting keys makes ties deterministic

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 271: count render-blocking resources. Project 273 changes the surface problem while preserving the underlying method.



progress check

Reading target: total image weight and find the heaviest is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `images = {'hero.jpg': 480, 'thumb1.jpg': 35, 'thumb2.jpg': 40, 'banner.png': 220}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'heaviest = {heaviest} ({images[heaviest]} KB)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`images = {'hero.jpg': 480, 'thumb1.jpg': 35, 'thumb2.jpg': 40, 'banner.png': 220}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`total = sum(images.values())`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(f'heaviest = {heaviest} ({images[heaviest]} KB)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `total = sum(images.values())`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Total Image Weight and Find the Heaviest: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: images, hero, jpg, thumb1, thumb2. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: images = {'hero.jpg': 480, 'thumb1.jpg': 35, 'thumb2.jpg': 40, 'banner.... | Core: total = sum(images.values()) | Evidence: print(f'heaviest = {heaviest} ({images[heaviest]} KB)')

Reader to Writer Bridge

1. Read: explain total image weight and find the heaviest in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 271.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 273 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'heaviest = {heaviest} ({images[heaviest]} KB)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `images = {'hero.jpg': 480, 'thumb1.jpg': 35, 'thumb2.jpg': 40, 'banner.png': 220}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of total image weight and find the heaviest and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Summing the image dict's values gives total image payload, and `max` over the sorted keys with a size key picks the heaviest file deterministically.

```
images = {'hero.jpg': 480, 'thumb1.jpg': 35, 'thumb2.jpg': 40, 'banner.png':
220}
total = sum(images.values())
heaviest = max(sorted(images), key=lambda k: images[k])
print(f'total image weight = {total} KB')
print(f'heaviest = {heaviest} ({images[heaviest]} KB)')
```

```
output
total image weight = 775 KB
heaviest = hero.jpg (480 KB)
```

How it works:

1. An images dict pairs four filenames with their kilobyte sizes.
2. sum(images.values()) totals the weight to 775 KB.
3. max(sorted(images), key=lambda k: images[k]) returns hero.jpg, and the print reports it at 480 KB as the heaviest.

Try it:

1. Print the top two heaviest images instead of just one by sorting and slicing.
2. Report what percentage of total image weight the heaviest file represents.
3. Add a tiny icon at 2 KB and confirm it never wins the max comparison.
4. Add a 600 KB photo and watch the heaviest file change.

⚠ Common Mistakes

- Calling `max(images)` returns the alphabetically last key, not the heaviest file.

- Passing `images.values()` to `max` loses which filename owns the size.
- Not sorting before `max` lets a tie resolve unpredictably.

Skills gained `max with key` `image weight` `lambda keys`

→ **Where You'll Use This:** Image-heavy LCP elements are the usual culprit behind slow loads, so spotlighting the biggest file is the practical start of a compress-and-resize plan.

Mental Model

Like packing for a trip and spotting the one bulky coat that eats half the bag: shrink that and everything else fits more easily.

Project 273 Split Page Bytes Between JS and CSS

The Idea Behind It

Knowing the JavaScript-to-CSS ratio tells you whether a page is script-heavy, which often explains slow interactivity. This project sums the resource sizes separately by type using two filtered generators, then turns each subtotal into a percentage of the combined total with rounded integer arithmetic. The 83 percent JS share frames the page as decidedly script-dominant.

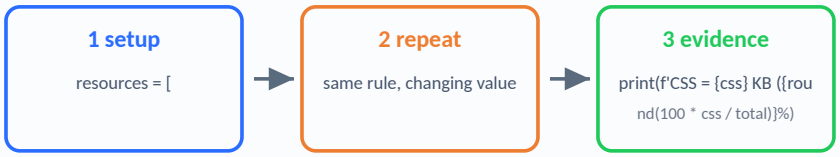
What You'll Build & Learn

Sum bytes by type and express the JS and CSS shares as rounded percentages of the total.

- JS-to-CSS ratio signals script weight
- Filtered generators sum by type
- Percentage as rounded integer division

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 272: total image weight and find the heaviest. Project 274 changes the surface problem while preserving the underlying method. *progress check*



Reading target: split page bytes between js and css is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'CSS = {css} KB ({round(100 * css / total)}%)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`js = sum(s for _, t, s in resources if t == 'js')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'CSS = {css} KB ({round(100 * css / total)}%)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `js = sum(s for _, t, s in resources if t == 'js')`

Construction pattern

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Split Page Bytes Between JS and CSS: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, app, js, vendor, style. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: resources = [| Core: js = sum(s for _, t, s in resources if t == 'js') | Evidence: print(f'CSS = {css} KB ({round(100 * css / total)}%)')

🛠️ Reader to Writer Bridge

1. Read: explain split page bytes between js and css in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 272.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 274 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'CSS = {css} KB ({round(100 * css / total)}%)')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split page bytes between js and css and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Two filtered sums split the payload by type, and rounding `100 * part / total` gives whole-number percentages that always add to roughly 100.

```
resources = [
    ('app.js', 'js', 300),
    ('vendor.js', 'js', 180),
    ('style.css', 'css', 90),
    ('reset.css', 'css', 10),
]
js = sum(s for _, t, s in resources if t == 'js')
css = sum(s for _, t, s in resources if t == 'css')
total = js + css
print(f'JS = {js} KB ({round(100 * js / total)}%)')
print(f'CSS = {css} KB ({round(100 * css / total)}%)')
```

```
output
JS = 480 KB (83%)
CSS = 100 KB (17%)
```

How it works:

1. resources is a list of tuples tagged js or css.
2. Two generators sum sizes where the type matches js then css, giving 480 and 100 KB.
3. Each is divided by the combined total, multiplied by 100, and rounded, printing 83% JS and 17% CSS.

Try it:

1. Add an image category and compute its share alongside JS and CSS.
2. Guard against a zero total so the percentage math does not divide by zero on an empty manifest.
3. Print a simple text bar whose length reflects each type's percentage.
4. Add a third type (fonts) and divide the budget three ways.

⚠ Common Mistakes

- Dividing by `js` or `css` alone instead of their combined total skews the percentages.
- Integer-dividing before multiplying by 100 collapses the ratio to 0.
- Rounding both shares independently can make them sum to 99 or 101.

Skills gained `type filtering` `percentage math` `round()`

→ **Where You'll Use This:** Script-heavy pages tend to suffer the worst INP and TBT, so this ratio guides whether your performance work should target JavaScript or styling first.

⚡ Mental Model

Like splitting a restaurant bill by category: once you see drinks were eighty percent of it, you know where the night's cost really went.

Project 274 Grade Time To First Byte

💡 The Idea Behind It

Time To First Byte measures how long the server takes to send the first byte of a response, and it feeds directly into LCP. This project applies a common rule of thumb, fast at 200ms or under, moderate at 600ms or under, slow beyond that, via an if/elif/else cascade. A reading of 640ms therefore lands in slow, pointing at server or network latency.

What You'll Build & Learn

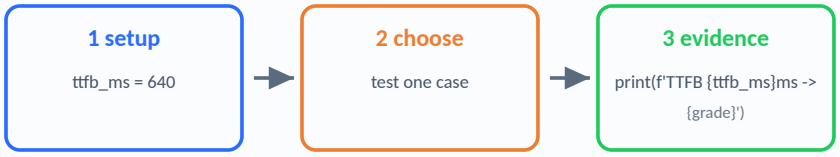
Grade a server's TTFB in milliseconds as fast, moderate, or slow using a three-way cascade.

- TTFB is server response latency
- TTFB feeds into the LCP timing
- if/elif/else builds a three-way grade

🧭 Skill Roadmap

`Skill step:` adds one small variation while the chapter pattern is still new. It builds on Project 273: split page bytes between js and css. Project 275 changes the surface problem while preserving the underlying method.

progress check



`Reading target:` grade time to first byte is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `ttfb_ms = 640` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- `Writing move:` this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

- Evidence: `print(f'TTFB {ttfb_ms}ms -> {grade}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`ttfb_ms = 640`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`if ttfb_ms <= 200:`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f'TTFB {ttfb_ms}ms -> {grade}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if ttfb_ms <= 200:`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Grade Time To First Byte: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: ttfb_ms, grade, fast, moderate, slow. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: ttfb_ms = 640 | Core: if ttfb_ms <= 200: | Evidence: print(f'TTFB {ttfb_ms}ms -> {grade}')

🛠️ Reader to Writer Bridge

1. Read: explain grade time to first byte in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 273.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 275 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'TTFB {ttfb_ms}ms -> {grade}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `ttfb_ms = 640` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of grade time to first byte and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

TTFB uses the same banded cascade as the vitals; a slow TTFB caps how good LCP can ever be because rendering cannot start until bytes arrive.

```
ttfb_ms = 640
if ttfb_ms <= 200:
    grade = 'fast'
elif ttfb_ms <= 600:
    grade = 'moderate'
else:
    grade = 'slow'
print(f'TTFB {ttfb_ms}ms -> {grade}')
```

```
output
TTFB 640ms -> slow
```

How it works:

1. ttfb_ms is set to 640 milliseconds.
2. The cascade checks 200 for fast, then 600 for moderate, otherwise slow.
3. Because 640 exceeds 600, grade becomes slow and the formatted print reports it.

Try it:

1. Wrap the logic in a grade_ttfb function so multiple readings can be graded in a loop.
2. Add an excellent band under 100ms to reward very fast servers.
3. Feed it a list of TTFB samples and print the worst reading and its grade.
4. Lower the value to 180 and confirm it grades fast.

⚠ Common Mistakes

- Treating TTFB as a Core Web Vital; it is a diagnostic input to LCP, not a graded vital.
- Using `<` on the 600ms boundary mis-grades a page sitting exactly at the limit.
- Confusing TTFB (server) with FCP (first paint) and grading the wrong number.

Skills gained TTFB grading | if/elif/else | server latency

→ Where You'll Use This: A slow TTFB usually points at backend or hosting issues, so this grading is the first triage when LCP is poor and you need to know whether the server is to blame.

Mental Model

Like timing how long a kitchen takes to acknowledge your order: quick is reassuring, a pause is tolerable, and a long silence means the meal is already running late.

Project 275 Detect Missing Cache Headers

The Idea Behind It

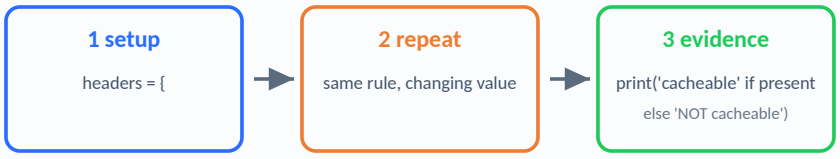
Static assets should carry caching headers so repeat visits skip the download entirely. This project inspects a response header dict for any of Cache-Control, Expires, or ETag, building present and missing lists with two comprehensions. With none of the three found, the asset is flagged NOT cacheable, exposing a missed caching opportunity.

What You'll Build & Learn

Check a response's headers for caching directives and report which are present, missing, and cacheable.

- Static assets need caching headers
- Membership test against a header dict
- Two comprehensions split present and missing

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 274: grade time to first byte. Project 276 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect missing cache headers is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `headers = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('cacheable' if present else 'NOT cacheable')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`headers = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`present = [h for h in cache_keys if h in headers]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('cacheable' if present else 'NOT cacheable')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `present = [h for h in cache_keys if h in headers]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Missing Cache Headers: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: headers, content, type, text, css. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: headers = { | Core: present = [h for h in cache_keys if h in headers] | Evidence: print('cacheable' if present else 'NOT cacheable')

🛠️ Reader to Writer Bridge

1. Read: explain detect missing cache headers in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 274.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 276 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('cacheable' if present else 'NOT cacheable')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `headers = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect missing cache headers and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Membership tests over a small set of caching headers partition them into present and missing; an asset with none of them forces a fresh download every visit.

```
headers = {
    'content-type': 'text/css',
    'content-length': '4200',
    'server': 'nginx',
}
cache_keys = ('cache-control', 'expires', 'etag')
present = [h for h in cache_keys if h in headers]
missing = [h for h in cache_keys if h not in headers]
print('caching headers present:', present)
print('missing:', missing)
print('cacheable' if present else 'NOT cacheable')
```

```
output
caching headers present: []
missing: ['cache-control', 'expires', 'etag']
NOT cacheable
```

How it works:

1. A headers dict holds content-type, content-length, and server but no caching keys.

2. cache_keys lists the three directives, and comprehensions partition them into present and missing by dict membership.
3. present is empty, so the final print reports NOT cacheable after listing the missing headers.

Try it:

1. Add a Cache-Control header and confirm the asset flips to cacheable.
2. Treat a Cache-Control of no-store as effectively not cacheable even though the header exists.
3. Run the check across a list of responses and tally how many lack caching headers.
4. Add `'cache-control': 'max-age=31536000'` and watch the verdict flip.

⚠ Common Mistakes

- Matching header names case-sensitively misses 'Cache-Control' if the dict uses 'cache-control'.
- Treating the presence of any header (like content-type) as proof of caching.
- Reporting 'cacheable' when only ETag is present but Cache-Control says no-store.

Skills gained cache headers | membership testing | list partition

→ Where You'll Use This: Missing Cache-Control is a frequent audit finding that slows repeat visits, so this check feeds directly into caching-policy recommendations for static files.

Mental Model

Like checking whether a library book has a due-date stamp: without one, every visitor has to re-borrow it from scratch each time.

Project 276 Detect Responses Missing Compression

The Idea Behind It

Text assets should travel gzip- or Brotli-compressed; an empty Content-Encoding means raw bytes are crossing the wire. This project walks a list of response dicts and uses a comprehension with a truthiness test on the encoding field to collect the uncompressed URLs. The two flagged responses are quick wins where enabling compression cuts transfer size.

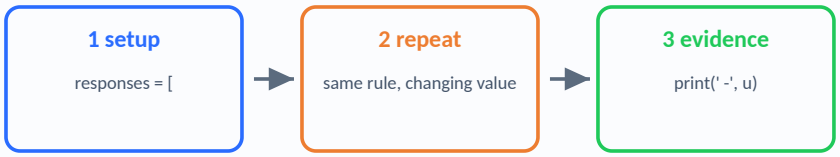
What You'll Build & Learn

Scan responses for an empty Content-Encoding and list the uncompressed URLs as compression wins.

- Text assets should be compressed
- None encoding means raw bytes
- Truthiness filters out empty values

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 275: detect missing cache headers. Project 277 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect responses missing compression is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `responses = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(' -', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`uncompressed = [r['url'] for r in responses if not r['encoding']]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' -', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `uncompressed = [r['url'] for r in responses if not r['encoding']]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Responses Missing Compression: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: responses, url, app, js, encoding. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = [| Core: uncompressed = [r['url'] for r in responses if not r['encoding']] | Evidence: print('-', u)

Reader to Writer Bridge

1. Read: explain detect responses missing compression in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 275.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 277 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -', u)`. Then compare punctuation, spacing, and order.
2. Explain: point to `responses = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect responses missing compression and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Filtering responses whose `encoding` is falsy isolates the uncompressed assets, and sorting the URLs keeps the remediation list deterministic.

```
responses = [
    {'url': 'app.js', 'encoding': 'br'},
    {'url': 'style.css', 'encoding': 'gzip'},
    {'url': 'data.json', 'encoding': None},
    {'url': 'main.js', 'encoding': None},
]
uncompressed = [r['url'] for r in responses if not r['encoding']]
print('uncompressed responses:', len(uncompressed))
for u in sorted(uncompressed):
    print(' -', u)
```

```
output
uncompressed responses: 2
 - data.json
 - main.js
```

How it works:

1. responses is a list of dicts, two with br or gzip encoding and two with None.
2. The comprehension keeps the url where not r['encoding'] is true, catching the None entries.
3. It prints the count of two, then names data.json and main.js in sorted order.

Try it:

1. Treat an encoding of identity as uncompressed too, since it means no real compression.
2. Only flag uncompressed responses that are also text-based by adding a type field.
3. Count compressed versus uncompressed and print the ratio.
4. Set `data.json` to `'gzip'` and watch the uncompressed count fall to 1.

⚠ Common Mistakes

- Treating an empty string encoding as compressed because it is not None.
- Flagging already-compressed images (jpg/png) that gain nothing from gzip.
- Printing the set unsorted so the URL order changes between runs.

Skills gained compression detection | truthiness filter | Content-Encoding

→ Where You'll Use This: Enabling gzip or Brotli is among the easiest performance wins, so detecting uncompressed text responses turns directly into a server-config to-do list.

Mental Model

Like shipping clothes loose versus vacuum-sealed: the same garments take far less space compressed, and the uncompressed boxes are the obvious ones to redo.

Project 277 Count Un-Lazyloaded Images

The Idea Behind It

Below-the-fold images should carry loading="lazy" so they do not fight for bandwidth during the initial load. This project iterates a list of image dicts and uses a comprehension with an inequality test to collect any image whose loading attribute is not exactly lazy, including those set to eager or None. The three flagged images are eager downloads worth deferring.

What You'll Build & Learn

Find images lacking loading="lazy" and count and list the eager downloads worth deferring.

- Lazy loading defers offscreen images
- Inequality filter catches non-lazy values
- None and eager both count as not lazy

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 276: detect responses missing compression. Project 278 changes the surface problem while preserving the underlying method.

progress check

Reading target: count un-lazyloaded images is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `images = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(sorted(not_lazy))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`images = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`not_lazy = [i['src'] for i in images if i['loading'] != 'lazy']`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(sorted(not_lazy))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `not_lazy = [i['src'] for i in images if i['loading'] != 'lazy']`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Un-Lazyloaded Images: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: images, src, hero, jpg, loading. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: images = [| Core: not_lazy = [i['src'] for i in images if i['loading'] != 'lazy'] | Evidence: print(sorted(not_lazy))

🛠️ Reader to Writer Bridge

1. Read: explain count un-lazyloaded images in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 276.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 278 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(sorted(not_lazy))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `images = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of count un-lazyloaded images and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering images whose `loading` value is not 'lazy' catches both eager and missing attributes; the hero image is intentionally eager, the rest are candidates to lazy-load.

```
images = [
    {'src': 'hero.jpg', 'loading': 'eager'},
    {'src': 'photo1.jpg', 'loading': 'lazy'},
    {'src': 'photo2.jpg', 'loading': None},
    {'src': 'photo3.jpg', 'loading': None},
]
not_lazy = [i['src'] for i in images if i['loading'] != 'lazy']
print('images not lazy-loaded:', len(not_lazy))
print(sorted(not_lazy))
```

```
output
images not lazy-loaded: 3
['hero.jpg', 'photo2.jpg', 'photo3.jpg']
```

How it works:

1. images is a list of dicts with a loading value of eager, lazy, or None.
2. The comprehension keeps src where loading is not equal to lazy, catching hero.jpg, photo2.jpg, and photo3.jpg.
3. It prints the count of three and the sorted list of non-lazy sources.

Try it:

1. Keep the hero image eager on purpose by excluding it from the not-lazy list.
2. Also flag images using a deprecated lazyload class instead of the native attribute.
3. Report what fraction of all images are still loading eagerly.
4. Set photo2 and photo3 to 'lazy' and watch the count drop to 1.

⚠ Common Mistakes

- Treating a missing `loading` key as already lazy and skipping a real offender.
- Lazy-loading the LCP hero image, which actually delays the largest paint.
- Comparing against 'eager' only and missing images with no attribute at all.

Skills gained lazy loading inequality filter attribute audit

→ Where You'll Use This: Deferring offscreen images frees bandwidth for the LCP element, so this audit feeds the common recommendation to add lazy loading to long image-rich pages.

Mental Model

Like a buffet that only refills trays as guests reach them: filling every tray up front wastes food and crowds the line before anyone is there to eat.

Project 278 Inventory Preload and Preconnect Hints

The Idea Behind It

Resource hints such as preconnect, preload, and dns-prefetch let the browser warm up connections and fetch critical files early. This project uses a regular expression to pull the rel value out of each link tag in a markup string, then a Counter tallies how many of each hint type appear. The result is a quick inventory showing which hints a page actually declares.

What You'll Build & Learn

Parse link tags with a regex and tally each resource-hint type to inventory a page's connection warm-ups.

- Resource hints speed critical fetches
- Regex extracts the rel attribute value
- Counter tallies occurrences by kind

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 277: count un-lazyloaded images. Project 279 changes the surface problem while preserving the underlying method.

progress check

Reading target: inventory preload and preconnect hints is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `html = '''<link rel="preconnect" href="https://fonts.gstatic.com">` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

- Evidence: `print(f'{hint}: {counts[hint]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`html = '''<link rel="preconnect" href="https://fonts.gstatic.com">`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`for hint in sorted(counts):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{hint}: {counts[hint]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for hint in sorted(counts):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Inventory Preload and Preconnect Hints: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: html, link, rel, preconnect, href. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: html = '''<link rel="preconnect" href="https://fonts.gstatic.com"> | Core: for hint in sorted(counts): | Evidence: print(f'{hint}: {counts[hint]}')

🛠️ Reader to Writer Bridge

1. Read: explain inventory preload and preconnect hints in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 277.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 279 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{hint}: {counts[hint]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `html = '''<link rel="preconnect" href="https://fonts.gstatic.com">` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of inventory preload and preconnect hints and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A regex over the `rel` attribute extracts every hint type, and a Counter tallies them so you can spot a page with zero hints or too many preloads.

```
html = '''<link rel="preconnect" href="https://fonts.gstatic.com">
<link rel="preload" href="/hero.jpg" as="image">
<link rel="stylesheet" href="/style.css">
<link rel="dns-prefetch" href="https://cdn.example.com">'''
import re
hints = re.findall(r'rel="(preconnect|preload|dns-prefetch|prefetch)"', html)
from collections import Counter
counts = Counter(hints)
for hint in sorted(counts):
    print(f'{hint}: {counts[hint]}')
```

```
output
dns-prefetch: 1
preconnect: 1
preload: 1
```

How it works:

1. An html string holds four link tags with rel values of preconnect, preload, stylesheet, and dns-prefetch.
2. re.findall with a capture group restricted to the hint names returns only the hint rels, skipping stylesheet.
3. A Counter over those matches is iterated in sorted order, printing dns-prefetch, preconnect, and preload each at one.

Try it:

1. Extend the regex to also capture the href so you can report which origin each hint targets.
2. Warn when a preload tag lacks a matching as attribute, which the browser ignores.
3. Count stylesheet links separately to see how many blocking CSS files load.
4. Add a second preload link and watch its count rise to 2.

⚠ Common Mistakes

- A greedy or loose regex would also match `rel="stylesheet"` and miscount.
- Matching `rel='preload'` with single quotes when the markup uses double quotes.
- Printing the Counter unsorted gives nondeterministic hint order.

Skills gained regex findall | Counter | resource hints

→ Where You'll Use This: Auditing resource hints reveals whether a page warms up connections to font and CDN origins, a common optimisation for cutting connection-setup latency.

Mental Model

Like a chef prepping ingredients before guests arrive: preconnect and preload are the mise en place that means the kitchen is ready the moment an order lands.

Project 279 Compare Field Data to Lab Data

The Idea Behind It

Lab tests run on a fast simulated device while field data from CrUX reflects real users on slow networks and phones, so the two rarely agree. This project pairs a lab and a field dict on the same metric keys, computes the field-minus-lab delta per metric, and prints a signed difference. The positive deltas reveal how optimistic the lab numbers were.

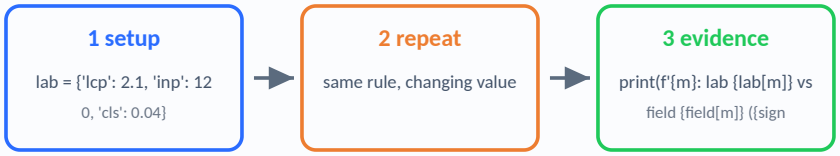
What You'll Build & Learn

Compute the per-metric gap between lab and field readings and print each as a signed delta.

- Lab data is optimistic synthetic testing
- Field data reflects real user conditions
- Signed deltas expose the gap

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 278: inventory preload and preconnect hints. Project 280 changes the surface problem while preserving the underlying method.



progress check

Reading target: compare field data to lab data is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `lab = {'lcp': 2.1, 'inp': 120, 'cls': 0.04}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{m}: lab {lab[m]} vs field {field[m]} ({sign}{delta})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`lab = {'lcp': 2.1, 'inp': 120, 'cls': 0.04}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`sign = '+' if delta >= 0 else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{m}: lab {lab[m]} vs field {field[m]} ({sign}{delta})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `sign = '+' if delta >= 0 else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compare Field Data to Lab Data: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: lab, lcp, inp, cls, field. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: lab = {'lcp': 2.1, 'inp': 120, 'cls': 0.04} | Core: sign = '+' if delta >= 0 else '' | Evidence: print(f'{m}: lab {lab[m]} vs field {field[m]} ({sign}{delta})')

🛠️ Reader to Writer Bridge

1. Read: explain compare field data to lab data in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 278.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 280 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{m}: lab {lab[m]} vs field {field[m]} ({sign}{delta})')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `lab = {'lcp': 2.1, 'inp': 120, 'cls': 0.04}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare field data to lab data and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Subtracting lab from field per metric and signing the delta exposes how much worse real users have it; a large positive gap means lab tests are flattering.

```
lab = {'lcp': 2.1, 'inp': 120, 'cls': 0.04}
field = {'lcp': 3.3, 'inp': 240, 'cls': 0.12}
for m in sorted(lab):
    delta = round(field[m] - lab[m], 3)
```

```
    sign = '+' if delta >= 0 else ''
    print(f'{m}: lab {lab[m]} vs field {field[m]} ({sign}{delta})')
```

```
output
cls: lab 0.04 vs field 0.12 (+0.08)
inp: lab 120 vs field 240 (+120)
lcp: lab 2.1 vs field 3.3 (+1.2)
```

How it works:

1. Two dicts, lab and field, share the keys lcp, inp, and cls.
2. For each sorted metric the code rounds field minus lab to three places and prepends a plus sign when non-negative.
3. It prints lab versus field with the signed delta, so lcp shows +1.2 and inp shows +120.

Try it:

1. Flag any metric where the field reading crosses into a worse band than the lab reading.
2. Express each delta as a percentage of the lab value instead of an absolute difference.
3. Add a verdict line summarising whether field data agrees with the lab overall.
4. Make field LCP better than lab and watch the sign go negative.

⚠ Common Mistakes

- Subtracting in the wrong order makes a real-world slowdown look like an improvement.
- Comparing metrics in different units (seconds vs milliseconds) across the two dicts.
- Printing raw float deltas without rounding produces noisy, unstable output.

Skills gained lab vs field | signed deltas | CrUX data

→ Where You'll Use This: Reconciling lab and field numbers is essential because Google ranks on field data, so this comparison stops you from celebrating a green lab score that real users never see.

Mental Model

Like comparing a car's advertised mileage to what you actually get in city traffic: the brochure number is best-case, and the real-world gap is what you plan around.

Project 280 Weight a Lighthouse-Style Performance Score

The Idea Behind It

Lighthouse blends several sub-metrics into one 0-100 performance score using fixed weights, with TBT and LCP carrying the most influence. This project multiplies each subscore by its weight, sums the products, and rounds

to a headline figure, then grades it green, orange, or red. Reproducing the weighted sum shows why a single slow metric like LCP at 60 can pull the score down to 67.

What You'll Build & Learn

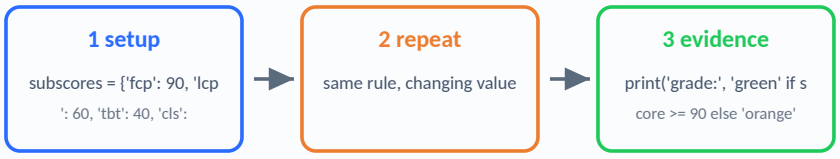
Reproduce Lighthouse's weighted performance score from sub-metric scores and grade it by colour.

- Lighthouse weights sub-metrics differently
- Weighted sum produces one headline score
- TBT and LCP carry the most weight

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 279: compare field data to lab data. Project 281 changes the surface problem while preserving the underlying method.

progress check



Reading target: weight a lighthouse-style performance score is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `subscores = {'fcp': 90, 'lcp': 60, 'tbt': 40, 'cls': 95, 'si': 70}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 else 'red')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`subscores = {'fcp': 90, 'lcp': 60, 'tbt': 40, 'cls': 95, 'si': 70}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 else 'red')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 else 'red')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Weight a Lighthouse-Style Performance Score: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: subscores, fcp, lcp, tbt, cls. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: subscores = {'fcp': 90, 'lcp': 60, 'tbt': 40, 'cls': 95, 'si': 70} | Core: print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 els... | Evidence: print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 els...

🛠️ Reader to Writer Bridge

1. Read: explain weight a lighthouse-style performance score in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 279.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 281 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 else 'red')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `subscores = {'fcp': 90, 'lcp': 60, 'tbt': 40, 'cls': 95, 'si': 70}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of weight a lighthouse-style performance score and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Multiplying each sub-score by its weight and summing reproduces Lighthouse's weighted-average; the result maps to the familiar green/orange/red bands.

```
subscores = {'fcp': 90, 'lcp': 60, 'tbt': 40, 'cls': 95, 'si': 70}
weights = {'fcp': 0.10, 'lcp': 0.25, 'tbt': 0.30, 'cls': 0.25, 'si': 0.10}
score = sum(subscores[k] * weights[k] for k in weights)
print(f'performance score = {round(score)}')
print('grade:', 'green' if score >= 90 else 'orange' if score >= 50 else 'red')
```

```
output
performance score = 67
grade: orange
```

How it works:

1. A subscores dict and a weights dict share keys fcp, lcp, tbt, cls, and si.
2. A generator multiplies each subscore by its weight and sum() combines them, rounding to 67.
3. A chained conditional grades the result orange because it falls between 50 and 90.

Try it:

1. Set tbt to 95 and watch the heavily weighted improvement push the score over 90 to green.
2. Print each sub-metric's weighted contribution so the biggest drag is obvious.
3. Assert that the weights sum to 1.0 before computing, to catch a misconfigured table.
4. Drop the TBT sub-score to 10 and watch the headline score collapse.

⚠ Common Mistakes

- Using weights that do not sum to 1.0 silently rescales the whole score.
- Averaging the sub-scores unweighted ignores that TBT and LCP matter most.
- Rounding each weighted term before summing accumulates rounding error.

Skills gained weighted average | Lighthouse scoring | generator sum

→ Where You'll Use This: Understanding the weighting explains why teams chase TBT and LCP first, since those levers move the headline Lighthouse score the most in audits and CI gates.

Mental Model

Like a course grade where the final exam counts far more than a quiz: ace the small stuff but bomb the heavy-weight piece and your overall mark still sinks.

Project 281 Enforce a Per-Resource-Type Budget

The Idea Behind It

A single page-wide budget hides which resource type actually blew it, so this project sets a separate kilobyte cap per type. It walks a budgets dict alongside parallel usage figures, computes overage per category, and labels each as ok or OVER by an amount. The per-type breakdown pinpoints that images and JS, not CSS or fonts, busted their limits.

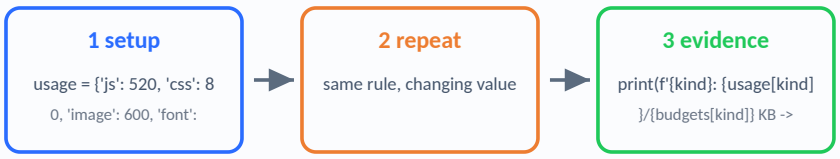
What You'll Build & Learn

Compare per-type usage against per-type budgets and report the overage for each resource category.

- Per-type budgets localise the problem
- Overage is usage minus the cap

- Parallel dicts share their keys

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 280: weight a lighthouse-style performance score. Project 282 changes the surface problem while preserving the underlying method. *progress check*

Reading target: enforce a per-resource-type budget is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `usage = {'js': 520, 'css': 80, 'image': 600, 'font': 140}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{kind}: {usage[kind]}/{budgets[kind]} KB -> {status}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`usage = {'js': 520, 'css': 80, 'image': 600, 'font': 140}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`status = f'OVER by {over}' if over > 0 else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f'{kind}: {usage[kind]}/{budgets[kind]} KB -> {status}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `status = f'OVER by {over}' if over > 0 else 'ok'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Enforce a Per-Resource-Type Budget: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: usage = {'js': 520, 'css': 80, 'image': 600, 'font': 140} | Core: status = f'OVER by {over}' if over > 0 else 'ok' | Evidence: print(f'{kind}: {usage[kind]}/{budgets[kind]} KB -> {status}')

Reader to Writer Bridge

1. Read: explain enforce a per-resource-type budget in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 280.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 282 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{kind}: {usage[kind]}/{budgets[kind]} KB -> {status}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `usage = {'js': 520, 'css': 80, 'image': 600, 'font': 140}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of enforce a per-resource-type budget and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing each type's usage to its own cap reports the overage per category, so an over-budget JS bundle cannot hide behind under-budget CSS.

```
usage = {'js': 520, 'css': 80, 'image': 600, 'font': 140}
budgets = {'js': 400, 'css': 100, 'image': 500, 'font': 150}
for kind in sorted(budgets):
    over = usage[kind] - budgets[kind]
    status = f'OVER by {over}' if over > 0 else 'ok'
    print(f'{kind}: {usage[kind]}/{budgets[kind]} KB -> {status}')
```

```
output
css: 80/100 KB -> ok
font: 140/150 KB -> ok
image: 600/500 KB -> OVER by 100
js: 520/400 KB -> OVER by 120
```

How it works:

1. usage and budgets dicts share keys js, css, image, and font.
2. For each sorted kind the code computes usage minus budget and labels it OVER by that amount when positive, else ok.
3. The output shows css and font ok but image OVER by 100 and js OVER by 120.

Try it:

1. Sum all the overages into a single total-over-budget figure.

2. Add a percentage-over column so a small absolute miss on a tight budget still stands out.
3. Only print the categories that are over, suppressing the ok lines for a focused report.
4. Tighten the image budget to 400 and watch a second type go over.

⚠ Common Mistakes

- Comparing total usage to the sum of budgets masks a single type's overage.
- Missing a key in either dict raises a KeyError mid-check.
- Reporting 'ok' for a type that exactly equals its budget if you use `>=` wrongly.

Skills gained per-type budgets | overage math | parallel dicts

→ Where You'll Use This: Granular budgets are how performance teams hold each asset category accountable, so this report is what a CI budget check prints when it needs to name the offending type.

Mental Model

Like a household budget split into rent, food, and fun: a single total only says you overspent, but the categories reveal it was the dining-out line all along.

Project 282 Flag Oversized Images Above a Limit

The Idea Behind It

Any single image past a kilobyte limit is a candidate for compression or resizing. This project filters an images dict with a comprehension that keeps entries above a threshold, then prints the offenders sorted descending by size using a negated key. The two oversized files become a prioritised fix list, heaviest first.

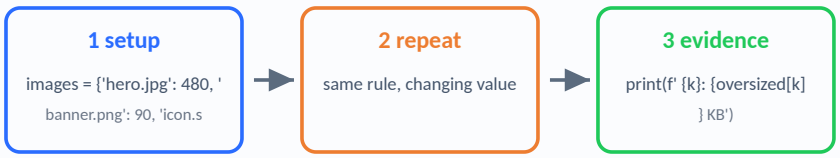
What You'll Build & Learn

Filter images above a kilobyte limit and list the offenders sorted heaviest-first as a fix list.

- A size limit flags fixable images
- Dict comprehension filters by value
- Negated key sorts descending

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 281: enforce a per-resource-type budget. Project 283 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag oversized images above a limit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `images = {'hero.jpg': 480, 'banner.png': 90, 'icon.svg': 4, 'photo.jpg': 310}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f' {k}: {oversized[k]} KB')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`images = {'hero.jpg': 480, 'banner.png': 90, 'icon.svg': 4, 'photo.jpg': 310}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`oversized = {k: v for k, v in images.items() if v > limit_kb}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f' {k}: {oversized[k]} KB')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the

behaviour.

CORE LINE `oversized = {k: v for k, v in images.items() if v > limit_kb}`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Oversized Images Above a Limit: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: images, hero, jpg, banner, png. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: images = {'hero.jpg': 480, 'banner.png': 90, 'icon.svg': 4, 'photo.jpg'... | Core: oversized = {k: v for k, v in images.items() if v > limit_kb} | Evidence: print(f' {k}: {oversized[k]} KB')

🛠️ Reader to Writer Bridge

1. Read: explain flag oversized images above a limit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 281.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 283 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f' {k}: {oversized[k]} KB')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `images = {'hero.jpg': 480, 'banner.png': 90, 'icon.svg': 4, 'photo.jpg': 310}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag oversized images above a limit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A dict comprehension keeps only images above the limit, and sorting the offenders by descending size puts the worst hog first.

```
images = {'hero.jpg': 480, 'banner.png': 90, 'icon.svg': 4, 'photo.jpg': 310}
limit_kb = 200
oversized = {k: v for k, v in images.items() if v > limit_kb}
print(f'oversized (> {limit_kb} KB): {len(oversized)}')
for k in sorted(oversized, key=lambda x: -oversized[x]):
    print(f'  {k}: {oversized[k]} KB')
```

```
output
oversized (> 200 KB): 2
  hero.jpg: 480 KB
  photo.jpg: 310 KB
```

How it works:

1. An images dict pairs four files with sizes, and limit_kb is 200.
2. A dict comprehension keeps only the entries whose size exceeds the limit, catching hero.jpg and photo.jpg.
3. Sorting the keys by negative size prints hero.jpg at 480 then photo.jpg at 310, heaviest first.

Try it:

1. Make the threshold depend on image type, allowing larger hero images than thumbnails.
2. Print the total kilobytes that all oversized images could potentially save.
3. Lower the limit to 50 KB and watch how many more images get flagged.
4. Lower the limit to 50 KB and watch banner.png join the list.

⚠ Common Mistakes

- Using `>=` instead of `>` flags an image sitting exactly on the limit.
- Sorting ascending buries the worst offender at the bottom of the list.
- Hard-coding 200 in two places so the limit and the message can drift apart.

Skills gained dict comprehension threshold filter descending sort

→ Where You'll Use This: Oversized-image warnings are standard in performance audits, and ordering them by weight tells you which file to compress first for the biggest single byte saving.

Mental Model

Like a bouncer turning away oversized bags at a venue: only the ones past the size line get pulled aside, biggest first, for repacking.

Project 283 Estimate Savings From Compression

The Idea Behind It

Each text asset has a typical compression ratio, and multiplying its size by that ratio estimates the kilobytes gzip or Brotli would shave off. This project loops a list of resource dicts, computes the saving per file, accumulates a running total, and reports both. The 161 KB total quantifies the payoff of enabling compression before you touch a server config.

What You'll Build & Learn

Estimate per-resource and total compression savings by multiplying each size by its compression ratio.

- Compression ratio estimates byte savings
- Size times ratio is the per-file saving
- An accumulator builds the running total

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 282: flag oversized images above a limit. Project 284 changes the surface problem while preserving the underlying method.

progress check

Reading target: estimate savings from compression is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

- Evidence: `print(f'total estimated saving = {round(total_saving, 1)} KB')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`for r in resources:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'total estimated saving = {round(total_saving, 1)} KB')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for r in resources:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Estimate Savings From Compression: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, url, app, js, size. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: resources = [| Core: for r in resources: | Evidence: print(f'total estimated saving = {round(total_saving, 1)} KB')

🛠️ Reader to Writer Bridge

1. Read: explain estimate savings from compression in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 282.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 284 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'total estimated saving = {round(total_saving, 1)} KB')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of estimate savings from compression and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Per-resource `size * ratio` estimates the saving, and accumulating them gives the total transfer reduction you could expect from enabling compression.

```
resources = [
    {'url': 'app.js', 'size': 300, 'ratio': 0.35},
    {'url': 'style.css', 'size': 80, 'ratio': 0.25},
    {'url': 'data.json', 'size': 120, 'ratio': 0.30},
]
total_saving = 0
for r in resources:
    saved = round(r['size'] * r['ratio'], 1)
    total_saving += saved
    print(f"{r['url']}: save {saved} KB")
print(f'total estimated saving = {round(total_saving, 1)} KB')
```

```
output
app.js: save 105.0 KB
style.css: save 20.0 KB
data.json: save 36.0 KB
total estimated saving = 161.0 KB
```

How it works:

1. resources is a list of dicts each with size and a compression ratio.
2. The loop multiplies size by ratio, rounds the saving, adds it to total_saving, and prints the per-file figure.
3. After the loop it prints the rounded total of 161.0 KB saved.

Try it:

1. Sort the resources so the biggest saving prints first.
2. Skip any resource whose estimated saving is under 5 KB as not worth the effort.
3. Express the total saving as a percentage of the combined original size.
4. Raise app.js's ratio to 0.7 and watch the total saving jump.

⚠ Common Mistakes

- Treating the ratio as the compressed size rather than the fraction saved.
- Applying a text-compression ratio to already-compressed binary assets.
- Summing unrounded floats then rounding only at the end can disagree with per-row rounding.

Skills gained savings estimate | accumulator pattern | round()

→ Where You'll Use This: Estimating compression savings helps you justify the effort of configuring Brotli, turning a vague best practice into a concrete kilobyte figure for stakeholders.

Mental Model

Like estimating how much a vacuum bag will shrink each pile of laundry: a quick multiply tells you the space you will reclaim before you start sealing bags.

Project 284 Count Requests by Resource Type

The Idea Behind It

A request waterfall is far easier to reason about when grouped by type. This project feeds the type field of each request dict into a Counter via a generator, then prints the total fetch count followed by a per-type tally. Seeing two scripts against one document, stylesheet, image, and font shows where the request count concentrates.

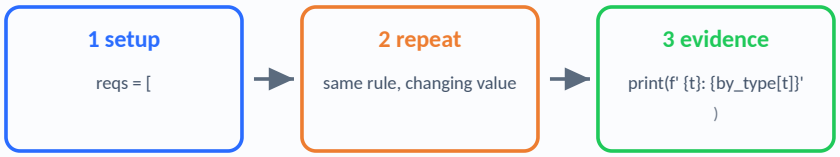
What You'll Build & Learn

Tally HTTP requests by their resource type to show where the fetch count concentrates.

- Grouping a waterfall by type clarifies it
- Counter tallies from a generator
- Total fetches is just the list length

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 283: estimate savings from compression. Project 285 changes the surface problem while preserving the underlying method.



progress check

Reading target: count requests by resource type is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `reqs = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f' {t}: {by_type[t]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`reqs = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`by_type = Counter(r['type'] for r in reqs)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f' {t}: {by_type[t]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `by_type = Counter(r['type'] for r in reqs)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Requests by Resource Type: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: reqs, url, page, html, type. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: reqs = [| Core: by_type = Counter(r['type'] for r in reqs) | Evidence: print(f' {t}: {by_type[t]}')

🛠️ Reader to Writer Bridge

1. Read: explain count requests by resource type in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 283.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 285 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f' {t}: {by_type[t]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `reqs = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count requests by resource type and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A Counter over the `type` field groups the waterfall, and sorting the types makes the breakdown deterministic; too many scripts is a classic smell.

```
reqs = [
    {'url': 'page.html', 'type': 'document'},
    {'url': 'app.js', 'type': 'script'},
    {'url': 'vendor.js', 'type': 'script'},
    {'url': 'style.css', 'type': 'stylesheet'},
    {'url': 'hero.jpg', 'type': 'image'},
    {'url': 'font.woff2', 'type': 'font'},
]
```

```
from collections import Counter
by_type = Counter(r['type'] for r in reqs)
print('total fetches:', len(reqs))
for t in sorted(by_type):
    print(f'  {t}: {by_type[t]}')
```

```
output
total fetches: 6
  document: 1
  font: 1
  image: 1
  script: 2
  stylesheet: 1
```

How it works:

1. reqs is a list of six dicts, each with a url and a type.
2. Counter is fed a generator of r['type'] values, building counts per type.
3. The code prints the total of six fetches, then loops the sorted Counter to show script at two and the rest at one each.

Try it:

1. Also report which type has the highest request count using the Counter's most_common.
2. Add a size field and sum bytes per type alongside the request count.
3. Flag when scripts exceed a chosen count, hinting at too many separate bundles.
4. Add a third script and watch the script tally rise to 3.

⚠ Common Mistakes

- Counting unique URLs instead of types answers a different question.
- Forgetting that one HTML document generates many sub-resource requests.
- Printing the Counter directly leaves the type order nondeterministic.

Skills gained Counter | request grouping | generator expression

→ Where You'll Use This: Grouping requests by type is the first cut of any waterfall analysis, helping you decide whether to bundle scripts, sprite images, or reduce font variants.

Mental Model

Like sorting a pile of mail into bills, ads, and letters: once the stacks are separate, you immediately see which kind is flooding your mailbox.

Project 285 Measure Critical Request Chain Depth

The Idea Behind It

The critical request chain is the dependency path from the HTML to the last blocking resource, and its depth caps how quickly rendering can begin. This project models the chain as a dict mapping each resource to the next it depends on, then walks from the start, following links until it hits None. Tracking the order and counting hops yields a chain depth of two.

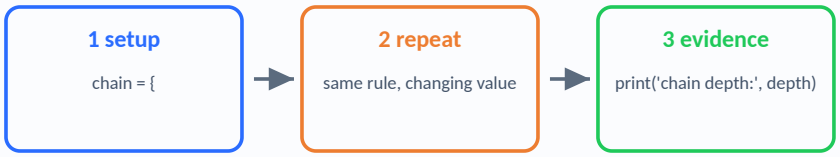
What You'll Build & Learn

Walk a dependency chain from the HTML to the final resource and report its order and depth.

- The critical chain caps render start
- A dict can model a dependency path
- Walk until the next link is None

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 284: count requests by resource type. Project 286 changes the surface problem while preserving the underlying method.



progress check

Reading target: measure critical request chain depth is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `chain = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('chain depth:', depth)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`chain = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`while chain.get(cur):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('chain depth:', depth)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `while chain.get(cur):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

2. Explain: point to `chain = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure critical request chain depth and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Walking the chain map until a resource has no dependency counts the hops; a deep chain (HTML waits on CSS waits on a font) serialises the critical path.

```
chain = {
    'page.html': 'style.css',
    'style.css': 'font.woff2',
    'font.woff2': None,
}
start = 'page.html'
depth, cur = 0, start
```

```
order = [start]
while chain.get(cur):
    cur = chain[cur]
    order.append(cur)
    depth += 1
print('critical chain:', ' -> '.join(order))
print('chain depth:', depth)
```

```
output
critical chain: page.html -> style.css -> font.woff2
chain depth: 2
```

How it works:

1. A chain dict maps page.html to style.css, style.css to font.woff2, and font.woff2 to None.
2. Starting at page.html, a while loop follows chain.get(cur), appending each next link and incrementing depth.
3. It prints the arrow-joined order and a depth of two, since two hops separate the HTML from the font.

Try it:

1. Add a fourth link to the chain and confirm the depth count rises accordingly.
2. Detect a cycle by tracking visited nodes so a self-referential chain cannot loop forever.
3. Return the order list from a function so other code can inspect the path.
4. Add a fourth link in the chain and watch the depth grow.

⚠ Common Mistakes

- Counting nodes instead of edges overstates the depth by one.
- No guard against a cyclic dependency would loop forever.
- Using `chain[cur]` instead of `chain.get(cur)` raises on the terminal node.

Skills gained chain traversal | while loop | dependency mapping

→ Where You'll Use This: Lighthouse reports critical request chains, and shortening the longest one, by preloading or removing a dependency, is a direct lever on how soon a page can render.

⚡ Mental Model

Like a relay race where each runner must finish before the next starts: the team can only be as quick as the full baton hand-off sequence allows.

Project 286 Compare Mobile and Desktop Vitals

💡 The Idea Behind It

Google indexes mobile-first, and mobile vitals are almost always worse thanks to slower CPUs and networks. This project pairs a mobile and a desktop metric dict on the same keys and, per metric, names which form factor is slower using a simple comparison. With mobile losing on all three, the output quantifies the mobile performance penalty.

What You'll Build & Learn

Compare mobile and desktop vitals per metric and name which form factor is slower each time.

- Google ranks on mobile-first indexing
- Mobile metrics are usually worse
- A comparison picks the slower side

🧭 Skill Roadmap

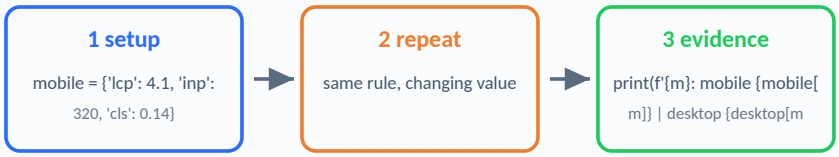
Skill step: moves you from recognition toward independent tracing. It builds on Project 285: measure critical request chain depth. Project 287 changes the surface problem while preserving the underlying method.

progress check

Reading target: compare mobile and desktop vitals is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens



- Setup: `mobile = {'lcp': 4.1, 'inp': 320, 'cls': 0.14}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{m}: mobile {mobile[m]} | desktop {desktop[m]} -> {worse} slower')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`mobile = {'lcp': 4.1, 'inp': 320, 'cls': 0.14}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`worse = 'mobile' if mobile[m] > desktop[m] else 'desktop'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{m}: mobile {mobile[m]} | desktop {desktop[m]} -> {worse} slower')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `worse = 'mobile' if mobile[m] > desktop[m] else 'desktop'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. 1. Read: explain compare mobile and desktop vitals in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 285.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 287 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{m}: mobile {mobile[m]} | desktop {desktop[m]} -> {worse} slower')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `mobile = {'lcp': 4.1, 'inp': 320, 'cls': 0.14}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare mobile and desktop vitals and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

Comparing each metric across the two device dicts names the slower form factor; mobile losing on every metric is the typical and concerning pattern.

```
mobile = {'lcp': 4.1, 'inp': 320, 'cls': 0.14}
desktop = {'lcp': 1.8, 'inp': 90, 'cls': 0.03}
for m in sorted(mobile):
    worse = 'mobile' if mobile[m] > desktop[m] else 'desktop'
    print(f'{m}: mobile {mobile[m]} | desktop {desktop[m]} -> {worse} slower')
```

```
output
cls: mobile 0.14 | desktop 0.03 -> mobile slower
inp: mobile 320 | desktop 90 -> mobile slower
lcp: mobile 4.1 | desktop 1.8 -> mobile slower
```

How it works:

1. Two dicts, mobile and desktop, carry lcp, inp, and cls readings.
2. For each sorted metric a conditional picks mobile when its value is higher, else desktop, as slower.
3. The output shows mobile slower on all three, with lcp 4.1 against desktop 1.8.

Try it:

1. Print the size of each gap, not just which device is slower.
2. Flag any metric where desktop is actually the slower one, which would be unusual.
3. Grade both readings into bands and show how often mobile drops a whole band below desktop.
4. Make desktop CLS worse than mobile and watch one row flip.

⚠ Common Mistakes

- Comparing only the overall pass hides which metric is worse on which device.
- Assuming higher is always worse; it is for these latency/shift metrics but not for scores.
- Iterating without sorting keys yields nondeterministic metric order.

Skills gained mobile-first | per-metric comparison | dict pairing

→ Where You'll Use This: Because rankings hinge on the mobile experience, this side-by-side is how you justify prioritising mobile fixes even when your desktop scores already look healthy.

⚡ Mental Model

Like timing the same recipe on a camp stove versus a full kitchen range: the underpowered burner finishes later on nearly every dish.

Project 287 Compute the p75 of LCP Samples

💡 The Idea Behind It

CrUX reports the 75th percentile rather than the average, so a handful of fast visits cannot hide many slow ones. This project sorts the LCP samples, computes a fractional rank at 0.75 of the last index, and linearly interpolates between the two bracketing values. Reproducing this p75 of 3.4s mirrors how the field metric is actually derived.

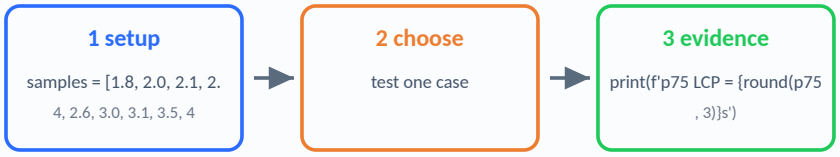
What You'll Build & Learn

Interpolate the 75th percentile of a list of LCP samples to reproduce the CrUX field metric.

- CrUX uses the 75th percentile
- Percentiles resist a few fast outliers
- Linear interpolation between ranks

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 286: compare mobile and desktop vitals. Project 288 changes the surface problem while preserving the underlying method.



progress check

Reading target: compute the p75 of lcp samples is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'p75 LCP = {round(p75, 3)}s')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

Move	Code to inspect	Why it matters
2. Apply the rule	`p75 = ordered[lo] + frac * (ordered[lo + 1] - ordered[lo]) if frac else ordered[lo]`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f'p75 LCP = {round(p75, 3)}s')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `p75 = ordered[lo] + frac * (ordered[lo + 1] - ordered[lo]) if frac else ordered[lo]`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Compute the p75 of LCP Samples: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: samples, ordered, sorted, rank, len. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2] | Core: p75 = ordered[lo] + frac * (ordered[lo + 1] - ordered[lo]) if frac else... | Evidence: print(f'p75 LCP = {round(p75, 3)}s')

🛠️ Reader to Writer Bridge

1. Read: explain compute the p75 of lcp samples in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 286.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 288 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'p75 LCP = {round(p75, 3)}s')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute the p75 of lcp samples and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Sorting the samples and linearly interpolating at rank `0.75 * (n-1)` gives the 75th percentile, the exact statistic Google grades Core Web Vitals against.

```
samples = [1.8, 2.0, 2.1, 2.4, 2.6, 3.0, 3.1, 3.5, 4.0, 4.2]
ordered = sorted(samples)
rank = 0.75 * (len(ordered) - 1)
lo = int(rank)
frac = rank - lo
p75 = ordered[lo] + frac * (ordered[lo + 1] - ordered[lo]) if frac else
ordered[lo]
print(f'p75 LCP = {round(p75, 3)}s')
```

```
output
p75 LCP = 3.4s
```

How it works:

1. The samples list is sorted, and rank is 0.75 times the last index, giving a fractional position.
2. lo is the integer part and frac the remainder used to interpolate between ordered[lo] and the next value.
3. Since frac is non-zero, the interpolation yields a p75 LCP printed as 3.4 seconds.

Try it:

1. Parameterise the percentile so the same code can compute p90 or the median.
2. Handle the edge case of a single-sample list without an index error.
3. Grade the resulting p75 into the LCP bands to give it a verdict.

4. Compute the p90 by changing 0.75 to 0.90.

⚠ Common Mistakes

- Reporting the mean instead of the p75 hides the slow tail Google penalises.
- Off-by-one in the rank index (`n` vs `n-1`) skews the percentile.
- Skipping the sort means the percentile is computed over unordered data.

Skills gained percentile interpolation | sorting | field metrics

→ Where You'll Use This: Knowing p75 is the reporting basis explains why Google cares about your worst quartile of visitors, shaping how you read CrUX dashboards and set targets.

⚡ Mental Model

Like a school reporting the mark three-quarters of students beat rather than the class average: it deliberately exposes the trailing group instead of hiding it.

Project 288 Detect a Budget Regression vs a Baseline

💡 The Idea Behind It

A budget that passes today can quietly bloat over time, so this project diffs current per-type sizes against a stored baseline. It loops the shared keys, computes each difference, records only the positive growths in a regressions dict, and prints a signed change per type. The result names image and js as the categories that grew since the baseline.

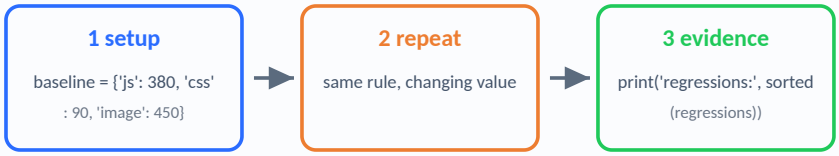
What You'll Build & Learn

Diff current per-type sizes against a baseline and flag the resource types that regressed upward.

- Budgets bloat without a baseline
- Positive diffs are regressions
- Record growth in a separate dict

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 287: compute the p75 of lcp samples. Project 289 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a budget regression vs a baseline is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `baseline = {'js': 380, 'css': 90, 'image': 450}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('regressions:', sorted(regressions))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`baseline = {'js': 380, 'css': 90, 'image': 450}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`if diff > 0:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('regressions:', sorted(regressions))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if diff > 0:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Budget Regression vs a Baseline: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: baseline, js, css, image, current. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: baseline = {'js': 380, 'css': 90, 'image': 450} | Core: if diff > 0: | Evidence: print('regressions:', sorted(regressions))

🛠️ Reader to Writer Bridge

1. Read: explain detect a budget regression vs a baseline in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 287.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 289 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('regressions:', sorted(regressions))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `baseline = {'js': 380, 'css': 90, 'image': 450}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect a budget regression vs a baseline and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting baseline from current per type signs each change, and collecting the positive diffs lists exactly which resource types regressed since the baseline.

```
baseline = {'js': 380, 'css': 90, 'image': 450}
current = {'js': 460, 'css': 85, 'image': 470}
regressions = {}
for k in sorted(baseline):
    diff = current[k] - baseline[k]
    if diff > 0:
        regressions[k] = diff
    print(f'{k}: {baseline[k]} -> {current[k]} ({"+" if diff >= 0 else ""}
{diff} KB)')
print('regressions:', sorted(regressions))
```

```
output
css: 90 -> 85 (-5 KB)
image: 450 -> 470 (+20 KB)
js: 380 -> 460 (+80 KB)
regressions: ['image', 'js']
```

How it works:

1. baseline and current dicts share keys js, css, and image.
2. For each sorted key the diff is current minus baseline; positive diffs are stored in regressions and every change prints signed.
3. css shrank by 5 while image grew 20 and js grew 80, so regressions lists image and js.

Try it:

1. Only count a regression when growth exceeds a tolerance, ignoring trivial jitter.
2. Print the total kilobytes gained across all regressed types.
3. Track improvements too and report which types shrank the most.
4. Make every type shrink and confirm zero regressions are reported.

⚠ Common Mistakes

- Flagging any change as a regression, including the CSS that actually shrank.
- Comparing totals instead of per type hides a JS gain offset by an image loss.

- Missing a key present in one dict but not the other raises a KeyError.

Skills gained regression detection baseline diffing signed change

→ Where You'll Use This: Comparing against a committed baseline is how CI catches creeping page-weight regressions, failing a pull request that quietly adds a heavy script or image.

Mental Model

Like weighing yourself against last month's number: the scale only flags the pounds that crept on, telling you exactly where the drift happened.

Project 289 Track a Performance Score Trend Across Builds

The Idea Behind It

CI can capture a Lighthouse score per build, and walking those scores in build order turns a column of numbers into a readable trend. This project iterates a sorted builds dict, comparing each score to the previous to print an up, down, or flat marker, then reports the net change from first to last. The build-101 to build-104 swing surfaces a noisy but net-positive trajectory.

What You'll Build & Learn

Walk per-build performance scores in order, mark each up, down, or flat, and report the net change.

- CI can log a score per build
- Compare each value to the previous
- Net change is last minus first

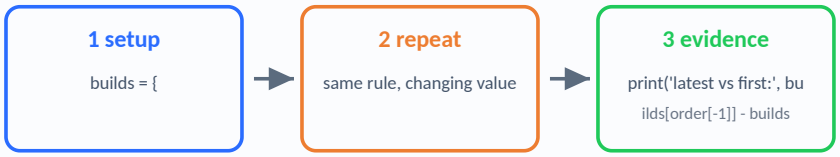
Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 288: detect a budget regression vs a baseline. Project 290 changes the surface problem while preserving the underlying method.

progress check

Reading target: track a performance score trend across builds is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `builds = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('latest vs first:', builds[order[-1]] - builds[order[0]])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`builds = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`arrow = '' if prev is None else (' up' if score > prev else ' down' if score < prev else ' flat')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('latest vs first:', builds[order[-1]] - builds[order[0]])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
arrow = '' if prev is None else (' up' if score > prev else ' down' if score < prev else ' flat')
```

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Track a Performance Score Trend Across Builds: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: builds, build, order, sorted, prev. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: builds = { | Core: arrow = '' if prev is None else (' up' if score > prev else ' down' if... | Evidence: print('latest vs first:', builds[order[-1]] - builds[order[0]])

🛠️ Reader to Writer Bridge

1. Read: explain track a performance score trend across builds in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 288.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 290 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('latest vs first:', builds[order[-1]] - builds[order[0]])`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `builds = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of track a performance score trend across builds and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Iterating the sorted build ids and comparing each score to the previous one annotates the direction of change, and the first-to-last delta summarises the overall trend.

```
builds = {
    'build-101': 78,
    'build-102': 82,
    'build-103': 71,
    'build-104': 88,
}
order = sorted(builds)
prev = None
for b in order:
    score = builds[b]
    arrow = '' if prev is None else (' up' if score > prev else ' down' if
score < prev else ' flat')
    print(f'{b}: {score}{arrow}')
    prev = score
print('latest vs first:', builds[order[-1]] - builds[order[0]])
```

```
output
build-101: 78
build-102: 82 up
build-103: 71 down
build-104: 88 up
latest vs first: 10
```

How it works:

1. A builds dict maps build labels to scores, iterated in sorted order.
2. A prev variable holds the last score; each iteration appends an up, down, or flat arrow based on the comparison.
3. After the loop it prints latest minus first, showing a net gain of 10 from build-101 to build-104.

Try it:

1. Print the per-step delta number alongside each arrow.
2. Find and flag the single build with the steepest drop.
3. Compute the average score across all builds as a stability summary.
4. Insert a regressing build between 102 and 103 and watch a 'down' appear.

⚠ Common Mistakes

- Iterating an unsorted dict scrambles the build order and the trend.
- Comparing each build to the first instead of the previous mislabels the arrows.
- Treating the very first build as 'down' instead of having no prior to compare.

Skills gained trend marking | previous-value compare | net change

→ Where You'll Use This: Tracking a Lighthouse score across builds is how teams spot the commit that regressed performance, making this walk the core of a CI trend report.

⚡ Mental Model

Like reading a fitness app's daily steps: each day shows an arrow versus yesterday, and the month-end figure tells you whether you really moved forward.

Project 290 Compute Total Blocking Time From Tasks

💡 The Idea Behind It

Total Blocking Time sums how long main-thread tasks ran past 50ms, since only that excess slice actually blocks user input. This project filters the task list to long tasks over the threshold, then sums each task's time minus 50 to get TBT. The resulting 250ms is the lab proxy that predicts poor INP in the field.

What You'll Build & Learn

Compute Total Blocking Time by summing each long task's milliseconds past the 50ms threshold.

- TBT counts only time past 50ms
- Long tasks block user input
- TBT is the lab proxy for INP

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 289: track a performance score trend across builds. Project 291 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute total blocking time from tasks is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `tasks = [50, 120, 30, 80, 200, 45]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'total blocking time = {tbt}ms')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`tasks = [50, 120, 30, 80, 200, 45]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`long_tasks = [t for t in tasks if t > threshold]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'total blocking time = {tbt}ms')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `long_tasks = [t for t in tasks if t > threshold]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute Total Blocking Time From Tasks: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: tasks, threshold, long_tasks, tbt, sum. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: tasks = [50, 120, 30, 80, 200, 45] | Core: long_tasks = [t for t in tasks if t > threshold] | Evidence: print(f'total blocking time = {tbt}ms')

🛠️ Reader to Writer Bridge

1. Read: explain compute total blocking time from tasks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 289.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 291 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'total blocking time = {tbt}ms')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `tasks = [50, 120, 30, 80, 200, 45]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of compute total blocking time from tasks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

For each task over 50ms only the excess counts toward TBT, so summing `duration - 50` over the long tasks reproduces the metric that predicts responsiveness.

```
tasks = [50, 120, 30, 80, 200, 45]
threshold = 50
long_tasks = [t for t in tasks if t > threshold]
tbt = sum(t - threshold for t in long_tasks)
print(f'long tasks (> {threshold}ms): {len(long_tasks)}')
print(f'total blocking time = {tbt}ms')
```

```
output
long tasks (> 50ms): 3
total blocking time = 250ms
```

How it works:

1. tasks is a list of durations and threshold is 50.
2. A comprehension keeps tasks over 50, then a generator sums each one's time minus 50.
3. It prints three long tasks and a total blocking time of 250 milliseconds.

Try it:

1. Report which single task contributed the most blocking time.
2. Make the 50ms threshold a parameter so you can experiment with stricter cutoffs.
3. Count how many tasks fall under the threshold and are therefore harmless.
4. Add a 60ms task and watch TBT rise by 10.

⚠ Common Mistakes

- Summing whole task durations instead of just the portion above 50ms.
- Including tasks at exactly 50ms, which contribute zero blocking time.
- Hard-coding 50 in two spots so the threshold and message can disagree.

Skills gained TBT calculation | threshold filter | generator sum

→ Where You'll Use This: Because TBT in the lab predicts INP in the field, reducing it, by splitting long JavaScript tasks, is a concrete way to improve real-user responsiveness.

Mental Model

Like measuring only the minutes a meeting runs past its scheduled end: short ones cost nothing, and it is the overruns that eat everyone's afternoon.

Project 291 Compute CLS From Layout Shift Records

The Idea Behind It

CLS is the sum of impact-fraction times distance-fraction across every unexpected layout shift on a page. This project builds the score directly from a list of shift records, multiplying each record's two fields and summing the products with a generator. Reconstructing CLS as 0.09 and grading it good shows exactly where the headline score comes from.

What You'll Build & Learn

Build a CLS score from layout-shift records by summing impact times distance, then grade it.

- CLS sums impact times distance
- Each shift contributes its own product
- Grade the sum against the bands

Skill Roadmap

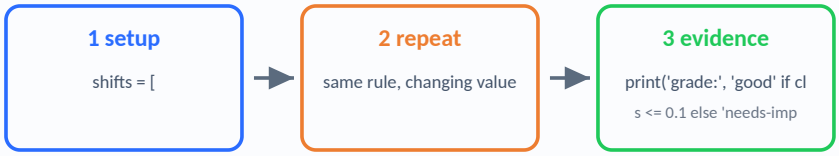
Skill step: pushes the same idea into a less automatic situation. It builds on Project 290: compute total blocking time from tasks. Project 292 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute cls from layout shift records is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `shifts = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25 else 'poor')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`shifts = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25 else 'poor')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25 else 'poor')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25 else 'poor')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute CLS From Layout Shift Records: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: shifts, impact, distance, cls, sum. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: shifts = [| Core: print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <=... | Evidence: print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <=...

🛠️ Reader to Writer Bridge

1. Read: explain compute cls from layout shift records in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 290.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 292 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25 else 'poor')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `shifts = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute cls from layout shift records and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each shift contributes `impact * distance`, and summing them yields the CLS that the banded grade then classifies.

```
shifts = [
    {'impact': 0.15, 'distance': 0.3},
    {'impact': 0.25, 'distance': 0.1},
    {'impact': 0.10, 'distance': 0.2},
]
cls = sum(s['impact'] * s['distance'] for s in shifts)
print(f'CLS = {round(cls, 4)}')
print('grade:', 'good' if cls <= 0.1 else 'needs-improvement' if cls <= 0.25
else 'poor')
```

```
output
CLS = 0.09
grade: good
```

How it works:

1. shifts is a list of dicts, each with an impact and a distance fraction.
2. A generator multiplies impact by distance per record and sum() combines them into 0.09.
3. A chained conditional grades the rounded score good because it stays at or under 0.1.

Try it:

1. Print the single shift that contributed the most to the score.
2. Add a shift large enough to push the total into needs-improvement and confirm the grade changes.
3. Round the per-shift contributions and show each one's percentage of the total.
4. Add a fourth large shift and watch CLS cross into needs-improvement.

⚠ Common Mistakes

- Adding impact and distance instead of multiplying them inflates the score.
- Counting expected (user-initiated) shifts that should be excluded from CLS.
- Printing the unrounded float gives a long, unstable decimal.

Skills gained CLS computation | generator sum | band grading

→ Where You'll Use This: Understanding CLS as a sum of shift products helps you trace a bad score to the specific elements moving, like a late-loading banner shoving content down.

Mental Model

Like scoring a clumsy dance routine by how big and how far each stumble was: many small trips add up to the same mark as one dramatic lurch.

Project 292 Flag Fonts Risking Invisible Text

The Idea Behind It

Without font-display: swap a web font can hide text entirely while it downloads, the flash of invisible text that delays LCP. This project scans a list of font dicts and collects any whose display value is not exactly swap, including block and None. Listing Roboto and Lora flags the declarations that risk invisible text on slow connections.

What You'll Build & Learn

List web fonts lacking font-display: swap, which risk a flash of invisible text and slow LCP.

- font-display swap avoids invisible text
- FOIT can delay LCP
- Filter fonts not set to swap

Skill Roadmap

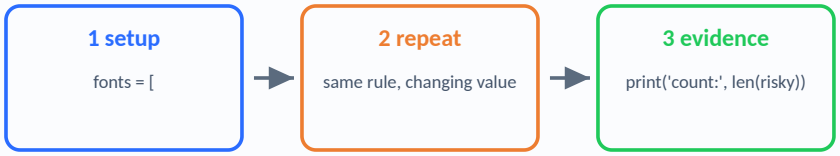
Skill step: pushes the same idea into a less automatic situation. It builds on Project 291: compute cls from layout shift records. Project 293 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag fonts risking invisible text is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `fonts = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('count:', len(risky))` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`fonts = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`risky = [f['family'] for f in fonts if f['display'] != 'swap']`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('count:', len(risky))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `risky = [f['family'] for f in fonts if f['display'] != 'swap']`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Fonts Risking Invisible Text: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: fonts, family, Inter, display, swap. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: fonts = [| Core: risky = [f['family'] for f in fonts if f['display'] != 'swap'] | Evidence: print('count:', len(risky))

Reader to Writer Bridge

1. Read: explain flag fonts risking invisible text in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 291.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 293 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('count:', len(risky))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `fonts = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag fonts risking invisible text and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

Filtering fonts whose `display` value is not 'swap' catches both 'block' and missing values, the two settings that can delay text rendering.

```
fonts = [
    {'family': 'Inter', 'display': 'swap'},
    {'family': 'Roboto', 'display': 'block'},
    {'family': 'Lora', 'display': None},
]
risky = [f['family'] for f in fonts if f['display'] != 'swap']
```

```
print('fonts risking invisible text:', sorted(risky))
print('count:', len(risky))
```

```
output
fonts risking invisible text: ['Lora', 'Roboto']
count: 2
```

How it works:

1. fonts is a list of dicts with a family and a display value of swap, block, or None.
2. A comprehension keeps the family where display is not equal to swap, catching Roboto and Lora.
3. It prints the sorted risky families and a count of two.

Try it:

1. Treat a display of optional as acceptable too, since it also avoids long invisible-text periods.
2. Report the total font count alongside the number at risk.
3. Add a fallback-font field and only flag fonts that lack both swap and a system fallback.
4. Set Roboto to 'swap' and watch the risky count fall to 1.

⚠ Common Mistakes

- Treating a missing `display` value as safe when the default can block rendering.
- Accepting 'optional' or 'fallback' as equivalent to 'swap' without deciding policy.
- Printing the offender set unsorted gives nondeterministic order.

Skills gained font-display audit | inequality filter | FOIT risk

→ Where You'll Use This: Auditing font-display is a routine LCP fix, since switching declarations to swap keeps text visible during font loads and is a quick rendering win.

⚡ Mental Model

Like a theatre that keeps the stage dark until the star arrives: swap turns on the work lights so the audience can at least read the program meanwhile.

Project 293 Pinpoint Which Vital To Fix First

💡 The Idea Behind It

When a page fails Core Web Vitals you need to know where to spend effort first. This project compares each metric to its threshold, collects the failing keys with a comprehension, and names the first one as the focus. Because only lcp exceeds its cap here, the output points work squarely at fixing LCP.

What You'll Build & Learn

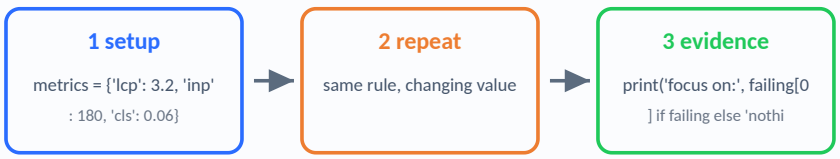
List the metrics that exceed their thresholds and name the first failing one as the focus.

- Failing metrics guide where to work
- Comprehension collects the over-limit keys
- Index zero names the first focus

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 292: flag fonts risking invisible text. Project 294 changes the surface problem while preserving the underlying method.

progress check



Reading target: pinpoint which vital to fix first is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `metrics = {'lcp': 3.2, 'inp': 180, 'cls': 0.06}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('focus on:', failing[0] if failing else 'nothing, all good')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`metrics = {'lcp': 3.2, 'inp': 180, 'cls': 0.06}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`failing = [m for m in thresholds if metrics[m] > thresholds[m]]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('focus on:', failing[0] if failing else 'nothing, all good')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `failing = [m for m in thresholds if metrics[m] > thresholds[m]]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pinpoint Which Vital To Fix First: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: metrics, lcp, inp, cls, thresholds. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: metrics = {'lcp': 3.2, 'inp': 180, 'cls': 0.06} | Core: failing = [m for m in thresholds if metrics[m] > thresholds[m]] | Evidence: print('focus on:', failing[0] if failing else 'nothing, all good')

Reader to Writer Bridge

1. Read: explain pinpoint which vital to fix first in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 292.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 294 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('focus on:', failing[0] if failing else 'nothing, all good')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `metrics = {'lcp': 3.2, 'inp': 180, 'cls': 0.06}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pinpoint which vital to fix first and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

From Concept to Code (Python)

Filtering the metrics that exceed their thresholds yields the failure list, and the first entry (in sorted order) becomes the recommended focus.

```
metrics = {'lcp': 3.2, 'inp': 180, 'cls': 0.06}
thresholds = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
failing = [m for m in thresholds if metrics[m] > thresholds[m]]
print('failing metrics:', sorted(failing))
print('focus on:', failing[0] if failing else 'nothing, all good')
```

```
output
failing metrics: ['lcp']
focus on: lcp
```

How it works:

1. metrics and a parallel thresholds dict share lcp, inp, and cls.
2. A comprehension keeps each metric whose value exceeds its threshold, capturing only lcp.
3. It prints the sorted failing list and names failing[0] as the focus, or a clean message when nothing fails.

Try it:

1. Order the failing metrics by how far each overshoots its threshold and focus on the biggest gap.
2. Handle the all-good case without indexing into an empty list.

3. Print a tailored fix hint for whichever metric is named as the focus.
4. Make `inp` also fail and confirm both appear in the list.

⚠ Common Mistakes

- Reporting all metrics rather than only the ones over threshold.
- Indexing `failing[0]` without first checking the list is non-empty raises on a passing page.
- Not sorting the failing list makes the recommended focus nondeterministic.

Skills gained failure prioritisation | threshold comparison | list indexing

→ Where You'll Use This: Naming the worst offending metric is how you turn a red Core Web Vitals report into a single actionable ticket rather than a vague directive to be faster.

Mental Model

Like a doctor reading a panel of test results and circling the one out-of-range number: that is where treatment starts, not the values already healthy.

Project 294 Break LCP Into Its Four Sub-Parts

The Idea Behind It

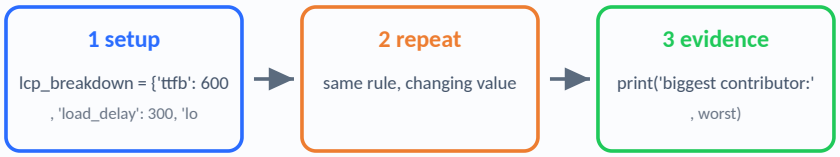
LCP decomposes into four sub-parts: TTFB, resource load delay, load time, and render delay, and splitting it reveals whether the server, network, or rendering is to blame. This project sums the breakdown to the total LCP, finds the largest component with max over a key, and prints each part's share. With load_time at 42 percent it names the dominant contributor.

What You'll Build & Learn

Split an LCP value into its four sub-parts, show each share, and name the biggest contributor.

- LCP has four diagnostic sub-parts
- Shares localise the bottleneck
- max with a key finds the largest part

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 293: pinpoint which vital to fix first. Project 295 changes the surface problem while preserving the underlying method. *progress check*

Reading target: break lcp into its four sub-parts is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `lcp_breakdown = {'ttfb': 600, 'load_delay': 300, 'load_time': 800, 'render_delay': 200}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('biggest contributor:', worst)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`lcp_breakdown = {'ttfb': 600, 'load_delay': 300, 'load_time': 800, 'render_delay': 200}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`for part in sorted(lcp_breakdown):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('biggest contributor:', worst)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for part in sorted(lcp_breakdown):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Break LCP Into Its Four Sub-Parts: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: lcp_breakdown, ttfb, load_delay, load_time, render_delay. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: lcp_breakdown = {'ttfb': 600, 'load_delay': 300, 'load_time': 800, 'ren... | Core: for part in sorted(lcp_breakdown): | Evidence: print('biggest contributor:', worst)

🛠️ Reader to Writer Bridge

1. Read: explain break lcp into its four sub-parts in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 293.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 295 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('biggest contributor:', worst)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `lcp_breakdown = {'ttfb': 600, 'load_delay': 300, 'load_time': 800, 'render_delay': 200}` and say why this line, value, import, or entry point

is needed before the rest of the Python can work.

3. Transfer: change one small part of break lcp into its four sub-parts and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Summing the four sub-parts reconstructs total LCP, and turning each into a percentage of the whole names the dominant phase to optimise.

```
lcp_breakdown = {'ttfb': 600, 'load_delay': 300, 'load_time': 800,
'render_delay': 200}
total = sum(lcp_breakdown.values())
worst = max(sorted(lcp_breakdown), key=lambda k: lcp_breakdown[k])
print(f'LCP = {total}ms ({round(total / 1000, 2)}s)')
for part in sorted(lcp_breakdown):
    pct = round(100 * lcp_breakdown[part] / total)
    print(f'  {part}: {lcp_breakdown[part]}ms ({pct}%)')
print('biggest contributor:', worst)
```

```
output
LCP = 1900ms (1.9s)
  load_delay: 300ms (16%)
  load_time: 800ms (42%)
  render_delay: 200ms (11%)
  ttfb: 600ms (32%)
biggest contributor: load_time
```

How it works:

1. An lcp_breakdown dict holds ttfb, load_delay, load_time, and render_delay in milliseconds.
2. sum() gives the 1900ms total, and max over the keys by value picks load_time as the worst.
3. A loop prints each part's milliseconds and rounded percentage before naming load_time as the biggest contributor.

Try it:

1. Suggest a fix tailored to whichever sub-part dominates, like preloading when load_delay wins.
2. Flag when two sub-parts are within a few percent of each other, signalling no single culprit.
3. Convert the breakdown into a small text bar chart of the shares.
4. Triple the TTFB and watch it become the biggest contributor.

⚠ Common Mistakes

- Computing percentages against a hard-coded 2500ms instead of the actual total.
- Picking the biggest part with `max(dict)` returns a key by name, not by value.

- Dividing integer milliseconds before multiplying by 100 floors the percentage.

Skills gained LCP breakdown | percentage shares | max with key

→ **Where You'll Use This:** Breaking down LCP is how performance engineers decide whether to tune the backend, preload the resource, or simplify rendering, rather than guessing at the cause.

Mental Model

Like a courier's delivery timeline split into pickup, transit, and doorstep wait: only by stage-timing the route do you learn where the package really sat.

Project 295 Score a Blocking Penalty Across Resources

The Idea Behind It

Render-blocking resources hurt more than deferred ones, so this project weights each resource type and doubles its penalty when it blocks. It loops a manifest of (url, type, blocking) tuples, looks up the type's weight, multiplies by two for blocking resources, and accumulates a single risk score. The 2.9 result compresses a whole manifest into one comparable number.

What You'll Build & Learn

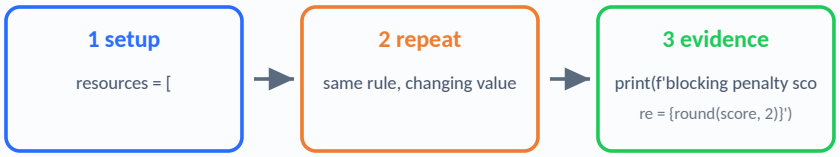
Turn a resource manifest into one risk score by weighting types and doubling the blocking ones.

- Blocking resources deserve a heavier penalty
- Per-type weights set base severity
- An accumulator sums into one score

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 294: break lcp into its four sub-parts. Project 296 changes the surface problem while preserving the underlying method.

progress check



Reading target: score a blocking penalty across resources is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'blocking penalty score = {round(score, 2)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`penalty = weights[kind] * (2 if blocking else 1)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'blocking penalty score = {round(score, 2)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `penalty = weights[kind] * (2 if blocking else 1)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score a Blocking Penalty Across Resources: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, app, js, hero, jpg. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: resources = [| Core: penalty = weights[kind] * (2 if blocking else 1) | Evidence: print(f'blocking penalty score = {round(score, 2)}')

🛠️ Reader to Writer Bridge

1. Read: explain score a blocking penalty across resources in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 294.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 296 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'blocking penalty score = {round(score, 2)}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score a blocking penalty across resources and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each resource adds its type weight, doubled when it blocks rendering, so the accumulated score rewards moving heavy critical resources off the critical path.

```
resources = [
    ('app.js', 'js', True),
    ('hero.jpg', 'image', False),
    ('style.css', 'css', True),
    ('analytics.js', 'js', False),
    ('font.woff2', 'font', True),
]
weights = {'js': 0.3, 'image': 0.2, 'css': 0.4, 'font': 0.5}
score = 0.0
for url, kind, blocking in resources:
    penalty = weights[kind] * (2 if blocking else 1)
    score += penalty
print(f'blocking penalty score = {round(score, 2)}')
```

```
output
blocking penalty score = 2.9
```

How it works:

1. resources is a list of tuples with url, type, and a blocking boolean, plus a weights dict per type.
2. The loop looks up each type's weight and multiplies by two when blocking, adding the penalty to score.
3. After the loop it prints the rounded blocking penalty score of 2.9.

Try it:

1. Also factor each resource's size into the penalty so heavy blockers score worse.
2. Print the per-resource penalty so the biggest contributor is visible.
3. Use a default weight so an unknown resource type does not raise a KeyError.
4. Make hero.jpg blocking and watch the penalty rise.

⚠ Common Mistakes

- Applying the doubling additively (weight + 2) instead of multiplicatively (weight * 2).
- Missing a resource type in the weights dict raises a KeyError.

- Summing into an int then printing a float-looking value without rounding.

Skills gained weighted scoring blocking penalty accumulator pattern

→ Where You'll Use This: A composite blocking score lets you rank pages or templates by render risk, turning a scattered list of resources into a single metric you can trend over time.

Mental Model

Like an insurance risk score: each factor carries a weight, and the dangerous ones, here the blockers, count double toward the final premium.

Project 296 Assess CrUX Good-Density Against 75 Percent

The Idea Behind It

In the field a metric passes only when at least 75 percent of samples fall in the good band, the CrUX good-density rule. This project sums a sample distribution across good, needs-improvement, and poor, computes the good share as a rounded percentage, and asserts PASS only above 75. With good at 72 percent the assessment is FAIL, just under the bar.

What You'll Build & Learn

Compute the good-sample density from a CrUX distribution and decide PASS or FAIL against 75 percent.

- Field pass needs 75 percent good
- Good-density comes from the distribution
- Just under the bar still fails

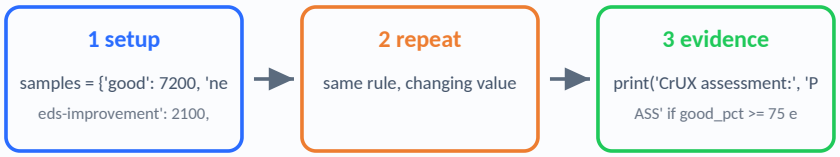
Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 295: score a blocking penalty across resources. Project 297 changes the surface problem while preserving the underlying method.

progress check

Reading target: assess crux good-density against 75 percent is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `samples = {'good': 7200, 'needs-improvement': 2100, 'poor': 700}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`samples = {'good': 7200, 'needs-improvement': 2100, 'poor': 700}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Assess CrUX Good-Density Against 75 Percent: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: samples, good, needs, improvement, poor. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: samples = {'good': 7200, 'needs-improvement': 2100, 'poor': 700} | Core: print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL') | Evidence: print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')

🛠️ Reader to Writer Bridge

1. Read: explain assess crux good-density against 75 percent in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 295.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 297 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `samples = {'good': 7200, 'needs-improvement': 2100, 'poor': 700}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of assess crux good-density against 75 percent and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Dividing the good count by the total gives the good-density percentage, and the 75% rule decides whether the metric passes for real users.

```
samples = {'good': 7200, 'needs-improvement': 2100, 'poor': 700}
total = sum(samples.values())
good_pct = round(100 * samples['good'] / total, 1)
print('field distribution:')
for k in ['good', 'needs-improvement', 'poor']:
    print(f"  {k}: {round(100 * samples[k] / total, 1)}%")
print('CrUX assessment:', 'PASS' if good_pct >= 75 else 'FAIL')
```

```
output
field distribution:
  good: 72.0%
  needs-improvement: 21.0%
  poor: 7.0%
CrUX assessment: FAIL
```

How it works:

1. A samples dict holds counts for good, needs-improvement, and poor, totalling 10000.
2. good_pct is the good count over the total times 100, rounded to 72.0.
3. A loop prints each band's percentage, then the assessment prints FAIL because 72 is below 75.

Try it:

1. Print how many more good samples would be needed to cross 75 percent.
2. Run the rule against several metric distributions and tally how many pass.
3. Combine the good and needs-improvement shares to report an at-or-better figure too.
4. Push the good count to 7600 and watch the assessment flip to PASS.

⚠ Common Mistakes

- Comparing the good count to a raw number instead of a percentage of the total.
- Using the 'poor' bucket for the pass test instead of the 'good' bucket.
- Rounding the three buckets independently so they fail to sum to 100%.

Skills gained good-density rule percentage math CrUX assessment

→ Where You'll Use This: The 75 percent threshold is exactly how Google decides whether a metric passes in the field, so this calculation mirrors the verdict behind a CrUX report.

Mental Model

Like a vote needing a supermajority: a clear plurality is not enough, and falling three points shy of seventy-five means the motion simply does not carry.

Project 297 Quantify Before-and-After Optimisation Gains

The Idea Behind It

After an optimisation pass you want a concrete number to prove the win. This project totals the before and after per-type sizes, subtracts to find the kilobytes saved, and expresses that saving as a percentage of the original weight. The 290 KB and 22.8 percent figures turn a vague faster into a quantified result.

What You'll Build & Learn

Diff total page weight before and after optimisation and report the saving in KB and percent.

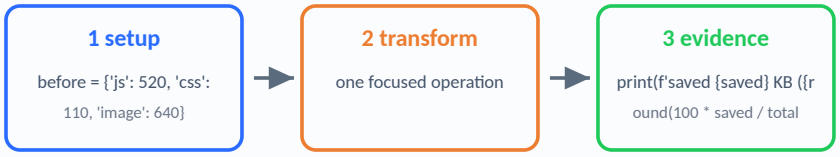
- Before-and-after proves an optimisation
- sum() totals each snapshot
- Saving as KB and as a percentage

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 296: assess crux good-density against 75 percent. Project 298 changes the surface problem while preserving the underlying method.

progress check

Reading target: quantify before-and-after optimisation gains is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `before = {'js': 520, 'css': 110, 'image': 640}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'saved {saved} KB ({round(100 * saved / total_before, 1)}%)')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`before = {'js': 520, 'css': 110, 'image': 640}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`saved = total_before - total_after`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. slow line
3. Check the evidence	`print(f'saved {saved} KB ({round(100 * saved / total_before, 1)}%)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `saved = total_before - total_after`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Quantify Before-and-After Optimisation Gains: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: before, js, css, image, after. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: before = {'js': 520, 'css': 110, 'image': 640} | Core: saved = total_before - total_after | Evidence: print(f'saved {saved} KB ({round(100 * saved / total_before, 1)}%)')

🛠️ Reader to Writer Bridge

1. Read: explain quantify before-and-after optimisation gains in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 296.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 298 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'saved {saved} KB ({round(100 * saved / total_before, 1)}%)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `before = {'js': 520, 'css': 110, 'image': 640}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of quantify before-and-after optimisation gains and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Summing each manifest and subtracting yields the bytes saved, and dividing by the original total expresses the improvement as a percentage.

```
before = {'js': 520, 'css': 110, 'image': 640}
after = {'js': 410, 'css': 90, 'image': 480}
total_before = sum(before.values())
```

```
    total_after = sum(after.values())
    saved = total_before - total_after
    print(f'before = {total_before} KB, after = {total_after} KB')
    print(f'saved {saved} KB ({round(100 * saved / total_before, 1)}%)')
```

```
output
before = 1270 KB, after = 980 KB
saved 290 KB (22.8%)
```

How it works:

1. before and after dicts share keys js, css, and image.
2. sum() totals each, giving 1270 and 980 KB, and the difference is 290 KB saved.
3. The print expresses the saving both as 290 KB and as 22.8 percent of the before total.

Try it:

1. Print the per-type saving so you can show which category improved most.
2. Guard against a zero before-total to avoid dividing by zero.
3. Flag any type that grew rather than shrank, which would be a regression hidden in the total.
4. Make the JS larger after the pass and watch the saving shrink.

⚠ Common Mistakes

- Dividing the saving by the after-total instead of the before-total overstates the gain.
- Reporting a negative saving as a win when a type actually grew.
- Forgetting to round the percentage gives a long, noisy decimal.

Skills gained before/after diff | savings percentage | summing values

→ Where You'll Use This: Quantifying a saving is how you report optimisation results to stakeholders, converting engineering effort into a percentage win that justifies the work.

Mental Model

Like stepping on the scale before and after a diet: the pounds lost and the percent of starting weight together make the result undeniable.

Project 298 Audit Core Web Vitals Across a Page Set

The Idea Behind It

A site passes Core Web Vitals when most of its pages pass individually. This project stores a metrics dict per page, runs the all-three-good test over each using all() against a shared thresholds dict, prints each page's verdict, then tallies the passers. Only /home clears all three, so the summary reads 1 of 3 pages passing.

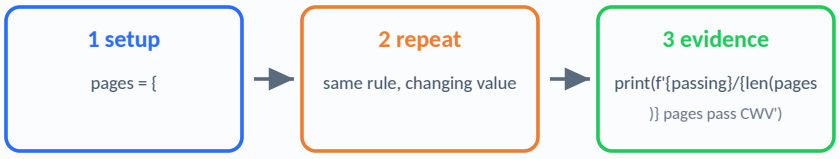
What You'll Build & Learn

Run the all-three-good test over a set of pages and tally how many pass Core Web Vitals.

- Site pass depends on per-page passes
- all() applies the three-good test
- Tally the passing pages

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 297: quantify before-and-after optimisation gains. Project 299 changes the surface problem while preserving the underlying method.



progress check

Reading target: audit core web vitals across a page set is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{passing}/{len(pages)} pages pass CWV')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Audit Core Web Vitals Across a Page Set: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: pages, home, lcp, inp, cls. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = { | Core: print(f'{path}: {"PASS" if passed else "FAIL"}') | Evidence: print(f'{passing}/{len(pages)} pages pass CWV')

🛠️ Reader to Writer Bridge

1. Read: explain audit core web vitals across a page set in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 297.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 299 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{passing}/{len(pages)} pages pass CWV')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of audit core web vitals across a page set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Looping the pages, applying the all-metrics-good test, and counting the passers turns per-page verdicts into a site coverage figure.

```
pages = {
    '/home': {'lcp': 2.2, 'inp': 160, 'cls': 0.05},
    '/blog': {'lcp': 3.8, 'inp': 220, 'cls': 0.08},
    '/shop': {'lcp': 4.5, 'inp': 540, 'cls': 0.31},
}
th = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
for path in sorted(pages):
    m = pages[path]
    passed = all(m[k] <= th[k] for k in th)
    print(f'{path}: {"PASS" if passed else "FAIL"}')
passing = sum(1 for m in pages.values() if all(m[k] <= th[k] for k in th))
print(f'{passing}/{len(pages)} pages pass CWV')
```

```
output
/blog: FAIL
/home: PASS
```

```
/shop: FAIL
1/3 pages pass CWV
```

How it works:

1. A pages dict maps three paths each to a metrics dict, with a shared thresholds dict th.
2. For each sorted path, all(m[k] <= th[k] for k in th) decides PASS or FAIL and prints it.
3. A generator counts the passing pages, printing 1 of 3 pass CWV.

Try it:

1. Print the pass rate as a percentage rather than a fraction.
2. List only the failing pages and the specific metrics that broke them.
3. Group pages by template prefix and report a pass rate per template.
4. Fix /blog's LCP to 2.4 and watch the passing count rise.

⚠ Common Mistakes

- Recomputing the per-page pass twice (once to print, once to count) risks them disagreeing.
- Iterating pages unsorted yields nondeterministic per-page output order.
- Counting any good metric as a page pass instead of requiring all three.

Skills gained page-set audit | all() test | pass tallying

→ Where You'll Use This: Auditing a whole page set is how SEO teams report site-level Core Web Vitals health, spotting which templates drag the overall pass rate down.

Mental Model

Like grading a class on how many students passed the exam: a few star scores mean nothing if most of the room failed the same test.

Project 299 Generate Targeted Optimisation Hints

The Idea Behind It

An audit only earns its keep if it tells you what to do next. This project scans a list of resource dicts and emits targeted hints: compress when an asset is compressible and over 100 KB, cache when it is uncached and over 200 KB. Collecting and printing the hints turns raw resource flags into a concrete, prioritised action list.

What You'll Build & Learn

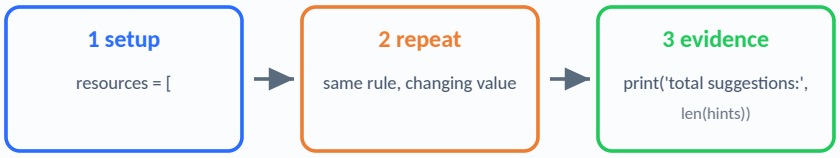
Scan resources for compressible-and-large or uncached-and-large cases and emit concrete fix hints.

- Audits should output actions

- Compound conditions trigger each hint
- Collect hints in a list to count them

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 298: audit core web vitals across a page set. Project 300 changes the surface problem while preserving the underlying method.



progress check

Reading target: generate targeted optimisation hints is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `resources = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('total suggestions:', len(hints))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`resources = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`if r['compressible'] and r['size'] > 100:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print('total suggestions:', len(hints))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if r['compressible'] and r['size'] > 100:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Generate Targeted Optimisation Hints: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: resources, url, app, js, size. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: resources = [| Core: if r['compressible'] and r['size'] > 100: | Evidence: print('total suggestions:', len(hints))

Reader to Writer Bridge

1. Read: explain generate targeted optimisation hints in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 298.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 300 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total suggestions:', len(hints))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `resources = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of generate targeted optimisation hints and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Two guarded conditions per resource emit a compress or cache hint only when it would actually help, so the suggestion list stays actionable and short.

```
resources = [
    {'url': 'app.js', 'size': 300, 'compressible': True, 'cached': False},
    {'url': 'hero.jpg', 'size': 480, 'compressible': False, 'cached': False},
    {'url': 'style.css', 'size': 90, 'compressible': True, 'cached': True},
]
hints = []
for r in resources:
    if r['compressible'] and r['size'] > 100:
        hints.append(f"compress {r['url']}")
    if not r['cached'] and r['size'] > 200:
        hints.append(f"cache {r['url']}")
for h in hints:
    print('-', h)
print('total suggestions:', len(hints))
```

```
output
- compress app.js
- cache app.js
- cache hero.jpg
total suggestions: 3
```

How it works:

1. resources is a list of dicts with size, compressible, and cached flags.

2. Per resource, a compressible-and-over-100 test appends a compress hint and an uncached-and-over-200 test appends a cache hint.
3. It prints each hint with a dash and the total of three suggestions.

Try it:

1. Add a resize hint for images above a width or size limit.
2. Sort the hints so the highest-impact fixes appear first.
3. Attach the estimated saving to each hint so the list is prioritised by payoff.
4. Mark hero.jpg as cached and watch one hint disappear.

⚠ Common Mistakes

- Suggesting compression for an already-compressed image yields a useless hint.
- Emitting a cache hint for a tiny asset where the win is negligible.
- Counting hints by resources scanned rather than hints actually produced.

Skills gained hint generation | compound conditions | actionable audit

→ Where You'll Use This: Generating targeted hints is the bridge from measurement to remediation, the part of an audit tool that hands developers a ready to-do list rather than raw numbers.

Mental Model

Like a car inspection that does not just list faults but writes the work order: rotate tyres, change oil, ready for the mechanic to act on directly.

Project 300 Chart a Vitals Trend Across Weeks

The Idea Behind It

Tracking how many of the three vitals are good each week shows whether optimisation work is paying off. This project iterates a weeks dict, counts the good metrics per week by testing each against a shared thresholds dict with a generator, and prints the running tally. The climb from 0 of 3 to 3 of 3 makes the improving trajectory visible.

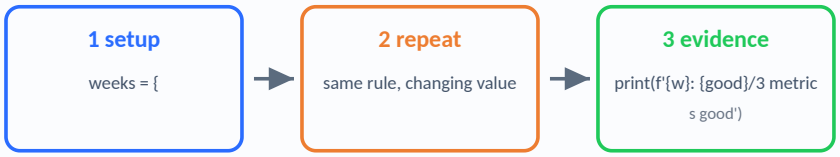
What You'll Build & Learn

Count how many of the three vitals are good per week to chart whether optimisation is working.

- Weekly good-counts show a trajectory
- Generator counts metrics under threshold
- Compare weeks at a glance

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 299: generate targeted optimisation hints. Project 301 changes the surface problem while preserving the underlying method.



progress check

Reading target: chart a vitals trend across weeks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `weeks = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print(f'{w}: {good}/3 metrics good')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`weeks = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`good = sum(1 for k in th if m[k] <= th[k])`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{w}: {good}/3 metrics good')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `good = sum(1 for k in th if m[k] <= th[k])`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Chart a Vitals Trend Across Weeks: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: weeks, w1, lcp, inp, cls. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: weeks = { | Core: good = sum(1 for k in th if m[k] <= th[k]) | Evidence: print(f'{w}: {good}/3 metrics good')

Reader to Writer Bridge

1. Read: explain chart a vitals trend across weeks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 299.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 301 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{w}: {good}/3 metrics good')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `weeks = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of chart a vitals trend across weeks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each week, counting the metrics that meet their threshold yields a 0-to-3 score, and reading the weeks in order reveals the improvement trend.

```
weeks = {
    'w1': {'lcp': 4.2, 'inp': 380, 'cls': 0.22},
    'w2': {'lcp': 3.6, 'inp': 300, 'cls': 0.15},
    'w3': {'lcp': 2.4, 'inp': 190, 'cls': 0.08},
}
th = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
for w in sorted(weeks):
    m = weeks[w]
    good = sum(1 for k in th if m[k] <= th[k])
    print(f'{w}: {good}/3 metrics good')
```

```
output
w1: 0/3 metrics good
w2: 0/3 metrics good
w3: 3/3 metrics good
```

How it works:

1. A weeks dict maps w1, w2, and w3 to per-metric readings, with a shared thresholds dict th.
2. For each sorted week a generator counts the metrics at or under their threshold.
3. It prints the good count out of three per week, climbing from 0 to 3 by w3.

Try it:

1. Also name which specific metrics turned good each week.
2. Print an arrow showing whether the count improved versus the prior week.
3. Add a fourth week that regresses and confirm the count drops.
4. Add a week 4 that is all good and watch the score hit 3/3.

⚠ Common Mistakes

- Iterating the weeks dict unsorted scrambles the chronological trend.

- Counting metrics below threshold instead of at-or-below flips the score.
- Hard-coding 3 as the denominator instead of `len(th)` breaks if a metric is added.

Skills gained `weekly trend` `good-metric count` `generator sum`

→ **Where You'll Use This:** Charting good-metric counts over time is how teams demonstrate that performance work is moving the needle, ideal for a recurring stakeholder report.

⚡ Mental Model

Like tracking how many of three new habits you kept each week: watching the count rise from zero toward three is proof the routine is finally sticking.

Project 301 Run a Full Page Performance Audit

💡 The Idea Behind It

This capstone ties the chapter together by combining a request manifest with a metrics snapshot into one audit. It totals transfer against a budget, counts render-blocking resources, lists the failing vitals against their thresholds, and prints a single verdict. The page busts its budget and fails all three vitals, so the overall verdict reads NEEDS WORK.

What You'll Build & Learn

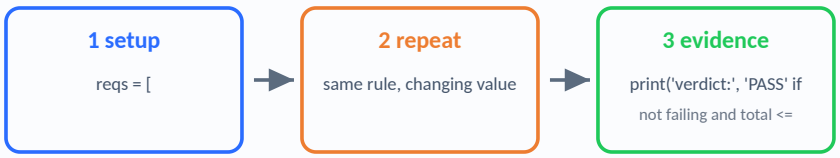
Combine a manifest and a metrics snapshot to total transfer, count blockers, list failing vitals, and decide a verdict.

- A full audit fuses bytes and vitals
- One verdict needs several checks to pass
- Manifest tuples carry size and a blocking flag

🧭 Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 300: chart a vitals trend across weeks. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full page performance audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `reqs = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
- Evidence: `print('verdict:', 'PASS' if not failing and total <= budget_kb else 'NEEDS WORK')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`reqs = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
2. Apply the rule	`blocking = sum(1 for _, _, _, b in reqs if b)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('verdict:', 'PASS' if not failing and total <= budget_kb else 'NEEDS WORK')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Site Speed and Core Web Vitals becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `blocking = sum(1 for _, _, _, b in reqs if b)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run a Full Page Performance Audit: connect the surface task to the chapter skill, score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.
Names	Watch these names first: reqs, page, html, document, app. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: reqs = [| Core: blocking = sum(1 for _, _, _, b in reqs if b) | Evidence: print('verdict:', 'PASS' if not failing and total <= budget_kb else 'NE...

🛠️ Reader to Writer Bridge

1. Read: explain run a full page performance audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 300.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('verdict:', 'PASS' if not failing and total <= budget_kb else 'NEEDS WORK')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `reqs = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full page performance audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A single pass over the manifest yields the request count, transfer weight and blocking count, while the vitals check supplies the failing list; the verdict combines both gates.

```
reqs = [
    ('page.html', 'document', 20, False),
    ('app.js', 'script', 300, True),
    ('vendor.js', 'script', 180, False),
    ('style.css', 'stylesheet', 80, True),
    ('hero.jpg', 'image', 480, False),
    ('font.woff2', 'font', 90, True),
]
metrics = {'lcp': 3.4, 'inp': 210, 'cls': 0.12}
th = {'lcp': 2.5, 'inp': 200, 'cls': 0.1}
budget_kb = 1000
total = sum(s for _, _, s, _ in reqs)
blocking = sum(1 for _, _, _, b in reqs if b)
failing = [k for k in th if metrics[k] > th[k]]
print('=== Performance Audit ===')
print(f'fetches: {len(reqs)}, transfer: {total} KB / {budget_kb} KB')
print(f'render-blocking: {blocking}')
print(f'failing CWV: {sorted(failing) if failing else "none"}')
print('verdict:', 'PASS' if not failing and total <= budget_kb else 'NEEDS
WORK')
```

```
output
=== Performance Audit ===
fetches: 6, transfer: 1150 KB / 1000 KB
render-blocking: 3
failing CWV: ['cls', 'inp', 'lcp']
verdict: NEEDS WORK
```

How it works:

1. reqs is a list of tuples with url, type, size, and a blocking boolean, plus a metrics snapshot and thresholds.
2. It sums transfer to 1150 KB, counts three blocking resources, and lists every failing vital against th.
3. The verdict prints NEEDS WORK because the page is over budget and all three vitals fail.

Try it:

1. Add the per-type budget breakdown so the report names which category overshot.
2. Print the specific render-blocking URLs, not just the count.

3. Return a structured result dict instead of printing, so a caller can act on it programmatically.
4. Shrink hero.jpg so transfer drops under budget and re-check the verdict.

⚠ Common Mistakes

- Passing the audit while still over the transfer budget because only vitals were checked.
- Counting blocking resources but never feeding them into the final verdict.
- Reporting failing vitals unsorted so the audit output varies run to run.

Skills gained full audit | transfer total | verdict logic

→ Where You'll Use This: A combined audit like this is the heart of a real performance-monitoring script, the single function that ingests a page snapshot and returns a ship-or-fix decision.

Mental Model

Like a pre-flight checklist that touches fuel, weight, and instruments: every line must clear before the plane is cleared for takeoff, and one red item grounds it.

✅ Chapter Progress Checkpoint

What this chapter added: after 38 mini-projects, Site Speed and Core Web Vitals should feel like a reusable Python move: score lcp, inp and cls against thresholds, set performance budgets, and weigh page resources.

chapter checkpoint

1 Read
Open any project from Projects 264-301 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 9 (Structured Data and Rich Results) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

9 questions · 4 categories · graded

3 Recall | 2 Meaning | 2 Structure | 2 Transfer

8.1.Q1 Recall MEDIUM Turn back to Project 274 (Grade Time To First Byte). Without running it, what exactly does it print?

8.1.Q2 Meaning MEDIUM Turn back to Project 269 (Check Total Transfer Against a Budget). Without running it, what exactly does it print?

8.1.Q3 Structure MEDIUM Turn back to Project 267 (Decide the Overall Core Web Vitals Pass). Without running it, what exactly does it print?

8.1.Q4 Transfer MEDIUM Turn back to Project 290 (Compute Total Blocking Time From Tasks). Without running it, what exactly does it print?

8.1.Q5 Recall MEDIUM Which Core Web Vital measures how quickly a page visibly responds to a user interaction such as a tap or click?

A LCP

B INP

C CLS

D TTFB

8.1.Q6 Meaning MEDIUM A page reports LCP 2.4s (good), INP 150ms (good) and CLS 0.30 (poor). Does it pass Core Web Vitals?

A Yes — two of three are good

B Yes — the average is fine

C No — all three must be in the good band

D Only on desktop

8.1.Q7 Structure EASY Why does Google grade the field data at the 75th percentile (p75) rather than the average?

A Averages are harder to compute

B p75 ensures a slow tail of real visits cannot be hidden by a few fast loads

C p75 is always lower than the average

D It matches the Lighthouse algorithm

8.1.Q8 Transfer MEDIUM A page is 100 KB over its total transfer budget and three resources in the head are render-blocking. Which gives the most reliable picture of why LCP is poor?

8.1.Q9 Recall EASY State the good-band thresholds for all three Core Web Vitals.

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 8 – Site Speed and Core Web Vitals

8.1.Q1. `TTFB 640ms -> slow`

8.1.Q2. `total transfer = 1000 KB, budget = 900 KB -> OVER budget` then `headroom = -100 KB`

8.1.Q3. `Core Web Vitals: PASS`

8.1.Q4. `long tasks (> 50ms): 3` then `total blocking time = 250ms`

8.1.Q5. B Interaction to Next Paint (INP) measures responsiveness in milliseconds; it replaced FID in March 2024. LCP is load speed, CLS is visual stability.

8.1.Q6. C passing requires every vital in the good band at once, so the poor CLS fails the whole assessment.

8.1.Q7. B the average can be flattered by fast visits; the p75 reflects the experience of the slower three-quarters, the visits most likely to bounce.

8.1.Q8. Both the per-type weight breakdown (which category blew the budget) and the count of render-blocking resources (what delays first paint) — vitals are symptoms, while weight and blocking resources are the cause you can act on.

8.1.Q9. LCP ⩽ 2.5s, INP ⩽ 200ms, and CLS ⩽ 0.1. (The needs-improvement upper bounds are 4.0s, 500ms and 0.25 respectively.)

Chapter 9 · Structured Data and Rich Results

Generate and validate JSON-LD for Article, Product, FAQ, LocalBusiness and Breadcrumb.

Chapter Skill Map

What this chapter adds: In Structured Data and Rich Results, the focus is generate and validate json-ld for article, product, faq, localbusiness and breadcrumb. You practise it across 37 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples.

chapter arc

What it builds on: Chapter 9 assumes the reading habits from Chapter 8: Site Speed and Core Web Vitals. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 10, International SEO and hreflang, reuses this chapter's discipline with a new kind of problem.

1 **Projects 302-313**	2 **Projects 314-325**	3 **Projects 326-338**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Structured data is a fact sheet for robots: a JSON object that says *what* this page is.

@context names the vocabulary, @type names the thing

A crawler reads your prose the way a stranger skims a poster — it can guess that "$89.99" is probably a price and "Jane Doe" is probably a name, but it is guessing. Structured data removes the guessing by attaching a small, machine-readable fact sheet to the page: a labelled object that states *this is a Product, its name is Trail Runner Shoe, its price is 89.99 USD, and it is in stock.*

Today that fact sheet is almost always written as JSON-LD — JSON for Linked Data — a plain JSON object dropped into a `<script type="application/ld+json">` tag in the page. Because it is just JSON, you build it the same way you build any dictionary. In Python a Product fact sheet is a `dict`, and `json.dumps` is the entire publishing step:

```
import json
article = {
    "@context": "https://schema.org",
    "@type": "Article",
    "headline": "How Crawlers Work",
    "author": "Jane Doe",
    "datePublished": "2026-01-15",
}
print(json.dumps(article, indent=2))
```

```
output
{
  "@context": "https://schema.org",
  "@type": "Article",
  "headline": "How Crawlers Work",
  "author": "Jane Doe",
  "datePublished": "2026-01-15"
}
```

Two keys make this more than an ordinary dictionary. `@context` tells the engine which vocabulary the field names come from — for SEO that is always `"https://schema.org"`, the shared dictionary Google, Bing and others agree on. `@type` tells the engine *what kind of thing* the object describes, drawn from that vocabulary: `Article`, `Product`, `FAQPage`, and so on. Once the engine knows the context and the type, every other key (`headline`, `author`, `price`) has an agreed meaning.

without @type the engine has labels but no idea what they label

Each type publishes a small contract: some properties are `required` (omit one and the block is rejected) and some are `recommended` (omit one and you simply qualify for a plainer result). Satisfy the required set and your page becomes eligible for a `rich result` — the enhanced listing with stars, prices, FAQ accordions or breadcrumbs instead of a bare blue link. Structured data does not improve your ranking directly; it changes what your listing *looks like*, and a richer listing earns more clicks.

STRUCTURED DATA

A machine-readable description of a page's content, written in an agreed vocabulary so a search engine reads facts (price, author, rating) instead of inferring them from prose.

JSON-LD

JSON for Linked Data: the format Google recommends for structured data. A JSON object placed in a `<script type="application/ld+json">` tag, kept separate from the visible HTML.

@CONTEXT

The key that names the vocabulary the field names come from. For SEO it is always the string `"https://schema.org"`.

@TYPE

The key that names what the object is — `Article`, `Product`, `FAQPage`, `BreadcrumbList`, `LocalBusiness`, etc. An unknown or misspelled type is silently ignored.

SCHEMA.ORG

The shared vocabulary of types and properties maintained jointly by the major search engines. It defines, per type, which properties exist and which are required.

RICH RESULT

An enhanced search listing — stars, prices, FAQ accordion, breadcrumb trail — granted to a page whose structured data is valid and carries the required properties for its type.

Every block declares a context and a type

A JSON-LD block is checked for two keys before anything else. `@context` says which vocabulary the names belong to; `@type` says what the object is. Miss either and the engine cannot interpret the rest, so the very first audit is a presence check on those two keys:

```
data = {
    "@context": "https://schema.org",
    "@type": "Article",
    "headline": "How Crawlers Work",
}
has_ctx = "@context" in data
has_type = "@type" in data
ok = has_ctx and has_type
print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")
```

```
output
@context=True @type=True -> valid
```

The type also has to be a *real* type. A typo like `Artical` or `Prodcut` is not an error — the engine simply does not recognise it and throws the whole block away. Validating `@type` against a set of known types catches the silent failure:

```
KNOWN = {"Article", "Product", "FAQPage", "BreadcrumbList", "LocalBusiness"}
docs = [{"@type": "Article"}, {"@type": "Artical"}, {"@type": "Prodcut"}]
for d in docs:
    t = d["@type"]
    print(f"{t}: {'known' if t in KNOWN else 'unknown type'}")
```

```
output
Article: known
Artical: unknown type
Prodcut: unknown type
```

Required vs recommended: the contract per type

Each schema type ships a contract. `Required` properties must be present or the block earns no rich result at all; `recommended` properties are optional but unlock a richer display. A data-driven validator keeps each type's required list in one table and checks any block by looking up its `@type` — so one function scales to dozens of types:

```
SCHEMAS = {
    "Article": ["headline", "author", "datePublished"],
    "Product": ["name", "offers"],
}
article = {"@context": "https://schema.org", "@type": "Article",
           "author": "Jane Doe"}
required = SCHEMAS[article["@type"]]
missing = [f for f in required if f not in article]
print("missing required:", missing)
```

```
output
missing required: ['headline', 'datePublished']
```

Recommended fields are audited the same way, but a miss is advice rather than a failure. Reporting the absent recommended fields tells an author exactly what to add next to upgrade from a basic to a richer result — an image, a description, a brand, a rating:

required = pass/fail · recommended = better/worse

```
product = {"@type": "Product", "name": "Widget",
           "offers": {"price": "5.00", "priceCurrency": "USD"}}
recommended = ["image", "description", "brand", "aggregateRating"]
missing = sorted(f for f in recommended if f not in product)
print("recommended missing:", missing)
```

```
output
recommended missing: ['aggregateRating', 'brand', 'description', 'image']
```

Nesting: properties whose values are themselves typed objects

Many properties do not take a plain string — they take another typed object. A Product's `offers` is an `Offer` with its own `price`, `priceCurrency` and `availability`; a LocalBusiness's `address` is a nested `PostalAddress`. The rule is simple: whenever a value has its own structure, it gets its own `@type` and becomes a sub-dictionary. Here a Product earns shopping eligibility by carrying a complete Offer:

```
import json
product = {
    "@context": "https://schema.org",
    "@type": "Product",
    "name": "Trail Runner Shoe",
    "offers": {
        "@type": "Offer",
```

```
        "price": "89.99",
        "priceCurrency": "USD",
        "availability": "https://schema.org/InStock",
    },
}
print(json.dumps(product["offers"], indent=2))
```

```
output
{
  "@type": "Offer",
  "price": "89.99",
  "priceCurrency": "USD",
  "availability": "https://schema.org/InStock"
}
```

The same nesting pattern builds the common list-shaped types. An `FAQPage` holds a `mainEntity` list where each entry is a `Question` whose `acceptedAnswer` is an `Answer`. A `BreadcrumbList` holds an `itemListElement` list of `ListItem` objects, each carrying a 1-based `position` so the engine can order the trail. A `LocalBusiness` feeds the map pack with a name, a nested address, a phone and opening hours. Build the breadcrumb from a plain Python list and the positions fall out of `enumerate`:

```
import json
trail = ["Home", "Catalog", "Shoes"]
crumbs = {
    "@context": "https://schema.org",
    "@type": "BreadcrumbList",
    "itemListElement": [
        {"@type": "ListItem", "position": i + 1, "name": name}
        for i, name in enumerate(trail)
    ],
}
for item in crumbs["itemListElement"]:
    print(item["position"], item["name"])
```

```
output
1 Home
2 Catalog
3 Shoes
```

Validating values, not just presence

A key being present is not enough — its *value* has to obey the schema's rules, or the rich result is dropped. Prices must be bare numbers (the currency lives in `priceCurrency`), currencies must be uppercase ISO 4217 codes, `availability` must be one of schema.org's fixed enum URLs, and dates must be ISO-8601 `YYYY-MM-DD`. These are the checks a validator runs after the presence pass. Availability is a good example — free text like `SoldOut` is rejected because it is not in the allowed enum:

```
allowed = {
    "https://schema.org/InStock",
    "https://schema.org/OutOfStock",
    "https://schema.org/PreOrder",
}
offers = [
    {"availability": "https://schema.org/InStock"},
    {"availability": "https://schema.org/SoldOut"},
]
for o in offers:
    a = o["availability"]
    print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")
```

```
output
InStock -> ok
SoldOut -> invalid enum
```

Pull it all together and a single audit decides `rich-result eligibility`: it confirms the context, the type, the required content fields, and at least one validated value, then reports an overall verdict. That combined check is exactly what tools like Google's Rich Results Test perform on a live page.

eligible only when every required check passes

```
product = {
    "@context": "https://schema.org",
    "@type": "Product",
    "name": "Trail Runner Shoe",
    "image": "https://example.com/shoe.jpg",
    "offers": {"@type": "Offer", "price": "89.99", "priceCurrency": "USD"},
}
checks = {
    "@context": product.get("@context") == "https://schema.org",
    "@type": product.get("@type") == "Product",
    "name": bool(product.get("name")),
    "image": bool(product.get("image")),
    "offer price": "price" in product.get("offers", {}),
}
for k, ok in checks.items():
    print(f"{k}: {'PASS' if ok else 'FAIL'}")
print("eligible:", all(checks.values()))
```

```
output
@context: PASS
@type: PASS
name: PASS
image: PASS
offer price: PASS
eligible: True
```

Example 1

You have the Q&A pairs ("What is JSON-LD?", "A way to embed structured data as JSON.") and ("Where does it go?", "In a script tag in the page head."). Build the first Question node of an FAQPage.

SOLUTION

1. An FAQPage carries a `mainEntity` list, and every entry is a `Question` object — so each pair becomes one node.
2. The question text goes in the Question's `name`; the answer is not a plain string but a nested `Answer` object under `acceptedAnswer`, holding the `text`.
3. So the first node is `{"@type": "Question", "name": "What is JSON-LD?", "acceptedAnswer": {"@type": "Answer", "text": "A way to embed structured data as JSON."}}`.

The Question wraps the answer in a typed Answer sub-object.

each Q&A pair → one Question whose acceptedAnswer is an Answer

Example 2

An Article block has @context, @type Article and an author, but no headline and no datePublished. The required set for Article is headline, author, datePublished. Is it rich-result eligible, and what must you add?

SOLUTION

1. Look up the required list for the type `Article`: `headline, author, datePublished`.
2. Diff it against the block — `author` is present; `headline` and `datePublished` are `absent`.
3. A type is eligible only when *every* required property is present, so a non-empty missing list means not eligible.

Not eligible — it is missing headline and datePublished; add both (a non-empty title and an ISO-8601 date) to qualify. *required is all-or-nothing*

Example 3

A BreadcrumbList has items at positions 1, 2 and 4. The trail should be a continuous 1-based sequence. Is the ordering valid, and what is wrong?

SOLUTION

1. A valid BreadcrumbList numbers its items 1, 2, 3, … with no skips or repeats.
2. The full expected range up to the highest position is {1, 2, 3, 4}; the present positions are {1, 2, 4}.
3. Subtract the present set from the expected set: {1,2,3,4} − {1,2,4} = `{3}`, so position 3 is missing.

Invalid — there is a gap at position 3; the third crumb was dropped, breaking the chain.

compare present positions to the full expected range to find the gap

⚡ Mental-Math Shortcut

Name it, then describe it, then prove it. Every block answers three questions in order: *which vocabulary?* (`@context` = schema.org), *what is this?* (`@type`), and *what is true of it?* (the properties). A block fails at the earliest unanswered question — a missing `@type` makes the properties meaningless, and a missing *required* property makes the whole block ineligible no matter how rich the rest is. Audit context and type first, required fields next, value formats last.

⚠ Common Mistakes

- Misspelling @type (Artical, Prodcut) — the engine does not error, it silently ignores the unknown type and the whole block is dropped.
- Putting a currency symbol in price ("$19.99") — price must be a bare number; the symbol belongs to priceCurrency, which must be an uppercase ISO 4217 code like USD.
- Using free text for an enum field such as availability ("SoldOut") instead of the exact schema.org URL (https://schema.org/OutOfStock), so the value is rejected.
- Marking up content with structured data that is not actually visible on the page — search engines require the JSON-LD to match what the user sees, or they treat it as spam.

This chapter contains 37 hands-on mini-projects (Projects 302–338). Type each one out, run it, and experiment.

Project 302 Build an Article JSON-LD Object

💡 The Idea Behind It

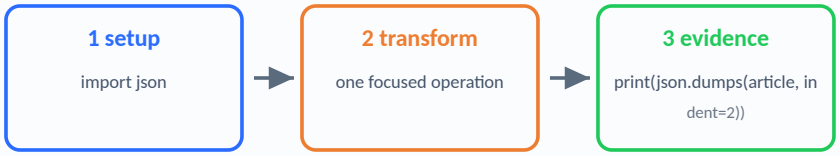
Structured data starts as an ordinary Python dictionary. Here you assemble an Article with the two magic keys @context and @type alongside plain content fields like headline, author, and datePublished. Feeding that dict to json.dumps with indent=2 turns it into the exact JSON-LD text a page embeds, which is what makes the page eligible for an article rich result.

What You'll Build & Learn

Build a minimal Article JSON-LD object and serialize it to readable JSON.

- A JSON-LD block is just a dict
- The @context and @type keys
- Serializing with json.dumps and indent

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 303 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build an article json-ld object is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(json.dumps(article, indent=2))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(json.dumps(article, indent=2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build an Article JSON-LD Object: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, article, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(json.dumps(article, indent=2))

🛠️ Reader to Writer Bridge

1. Read: explain build an article json-ld object in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 303 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(json.dumps(article, indent=2))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of build an article json-ld object and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A JSON-LD block is just a dict with `@context` pointing at schema.org and an `@type`; `json.dumps(..., indent=2)` renders the exact text a `<script type="application/ld+json">` tag would carry.

```
import json
article = {
    "@context": "https://schema.org",
    "@type": "Article",
    "headline": "How Crawlers Work",
    "author": "Jane Doe",
    "datePublished": "2026-01-15",
}
print(json.dumps(article, indent=2))
```

```
output
{
  "@context": "https://schema.org",
  "@type": "Article",
  "headline": "How Crawlers Work",
  "author": "Jane Doe",
  "datePublished": "2026-01-15"
}
```

How it works:

1. The article dict declares @context as the schema.org URL and @type as Article.
2. Three content fields follow: headline, author, and a datePublished string.
3. json.dumps with indent=2 prints the dict as nicely formatted JSON-LD text ready to paste into a page.

Try it:

1. Add an image field with an absolute URL and re-serialize the block
2. Swap @type to NewsArticle and add a publisher organization
3. Wrap the build in a function that takes headline and author as arguments
4. Add an `image` key and re-dump to see the block grow.

⚠ Common Mistakes

- Writing `@context` as `http://schema.org` trips network filters and looks unsafe; always use the `https://` form.
- Dumping without `indent` produces one long line that is valid but hard to eyeball in a review.

- By default `json.dumps` preserves insertion order, so the printed key order matches the dict literal, not alphabetical.

Skills gained `json.dumps` `dict literals` `JSON-LD` `schema.org`

→ Where You'll Use This: Every rich-result project starts from a dict like this; you generate article markup for blog posts and news pages so Google can show headline and byline.

⚡ Mental Model

The dict is the recipe and json.dumps is the printer that types the recipe onto the page in the format search engines read.

Project 303 Validate Context and Type Are Present

💡 The Idea Behind It

Before trusting any JSON-LD block you confirm it announces its vocabulary and its subject. This snippet uses the in operator to test whether @context and @type are present, stores the two booleans, ANDs them into a single ok flag, and prints a verdict. It mirrors the very first gate a structured-data validator applies to incoming markup.

What You'll Build & Learn

Check that a block declares both @context and @type before deeper validation.

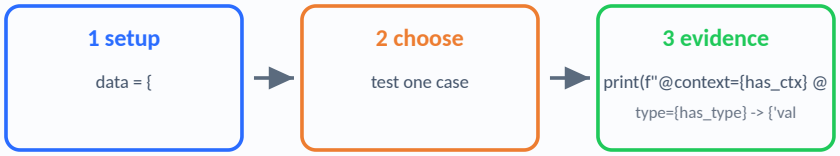
- The in operator tests dict key membership
- Both @context and @type are mandatory
- Combining booleans with and

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 302: build an article json-ld object. Project 304 changes the surface problem while preserving the underlying method.

progress check

Reading target: validate context and type are present is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `data = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.

- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`data = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Validate Context and Type Are Present: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: data, context, https, schema, org. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: data = { | Core: print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'inv... | Evidence: print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'inv...

🛠️ Reader to Writer Bridge

1. Read: explain validate context and type are present in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 302.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 304 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `data = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate context and type are present and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Membership tests on the two mandatory keys are the cheapest possible structured-data check; a block missing either is ignored entirely by search engines.

```
data = {
    "@context": "https://schema.org",
    "@type": "Article",
    "headline": "How Crawlers Work",
}
has_ctx = "@context" in data
has_type = "@type" in data
ok = has_ctx and has_type
print(f"@context={has_ctx} @type={has_type} -> {'valid' if ok else 'invalid'}")
```

```
output
@context=True @type=True -> valid
```

How it works:

1. The data dict holds @context, @type, and a headline.
2. has_ctx and has_type each test key presence with the in operator.
3. ok ANDs the two flags, and an f-string with a conditional expression prints valid or invalid.

Try it:

1. Wrap the two checks in a function that returns the ok boolean
2. Loop over a list of blocks and count how many pass
3. Print which specific key is missing rather than a single verdict
4. Delete the `@type` key and confirm the verdict flips to invalid.

⚠ Common Mistakes

- Testing `data['@context']` instead of `'@context' in data` raises KeyError when the key is absent, which defeats the validation.
- Treating an empty-string `@type` as present passes the `in` check but is still invalid data.
- Checking only `@type` and forgetting `@context` lets a context-free block slip through.

Skills gained `in operator` `boolean logic` `f-strings` `key presence`

→ **Where You'll Use This:** This is the smoke test you run across a crawl of pages, flagging any JSON-LD missing its context or type before you bother checking the richer required fields.

⚡ Mental Model

Like checking a letter has both a language and a subject line before reading the body; without them the recipient cannot route it.

Project 304 Build a Product With an Offer

💡 The Idea Behind It

A Product earns a shopping rich result only when it carries pricing detail, and that detail lives in a nested Offer. This code builds a Product dict whose offers value is itself a dict with @type Offer, a price string, a priceCurrency, and a schema.org availability URL. Printing just the offers sub-dict shows the self-contained block that drives the price snippet.

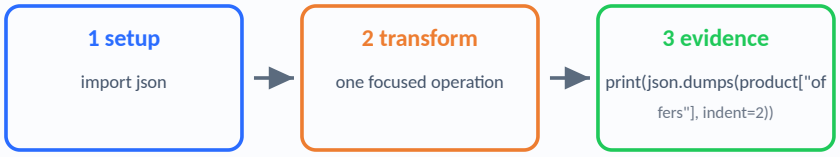
What You'll Build & Learn

Build a Product whose nested Offer carries price, currency, and availability.

- Offers nest as a dict inside a Product
- Price, currency, and availability fields
- Availability uses a schema.org URL

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 303: validate context and type are present. Project 305 changes the surface problem while preserving the underlying method. *progress check*



Reading target: build a product with an offer is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

- Evidence: `print(json.dumps(product["offers"], indent=2))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(json.dumps(product["offers"], indent=2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build a Product With an Offer: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, product, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(json.dumps(product["offers"], indent=2))

🛠️ Reader to Writer Bridge

1. Read: explain build a product with an offer in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 303.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 305 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(json.dumps(product["offers"], indent=2))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a product with an offer and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The `offers` value is itself a typed dict (`@type: Offer`) whose price, priceCurrency and availability are the trio Google needs for a price-rich result.

```
import json
product = {
    "@context": "https://schema.org",
    "@type": "Product",
    "name": "Trail Runner Shoe",
    "offers": {
        "@type": "Offer",
        "price": "89.99",
        "priceCurrency": "USD",
        "availability": "https://schema.org/InStock",
    },
}
print(json.dumps(product["offers"], indent=2))
```

```
output
{
  "@type": "Offer",
  "price": "89.99",
  "priceCurrency": "USD",
  "availability": "https://schema.org/InStock"
}
```

How it works:

1. The product dict has name and an offers key holding a nested Offer dict.
2. The Offer declares @type Offer, a price string, priceCurrency USD, and an InStock availability URL.
3. json.dumps prints only product['offers'], isolating the Offer block.

Try it:

1. Add a priceValidUntil date to the Offer and re-print
2. Make offers a list of two Offers for two sellers
3. Add a seller field pointing to a nested Organization
4. Add a `priceValidUntil` date to the offer.

⚠ Common Mistakes

- Encoding `price` as the float `89.99` instead of the string `"89.99"` is technically allowed but loses control over trailing-zero formatting.
- Writing `availability` as the bare word `InStock` instead of the full `https://schema.org/InStock` enum URL fails validation.
- Omitting `priceCurrency` makes the price meaningless and disqualifies the rich result.

Skills gained `nested dicts` `Offer schema` `json.dumps` `availability enum`

→ **Where You'll Use This:** On e-commerce product pages you generate exactly this Offer shape so the search result can show the price, currency symbol, and an in-stock badge beside the listing.

Mental Model

The Offer is the price tag clipped onto the product; the Product describes the item, the tag tells the shopper what it costs and whether it is on the shelf.

Project 305 Validate Required Product Fields

The Idea Behind It

Search engines only grant a Product rich result when its required fields are present. This snippet lists the required names, then uses a list comprehension to collect any that are not in the product dict. An empty missing list means the block passes; otherwise the names reveal what to add. It is required-field validation expressed in one comprehension.

What You'll Build & Learn

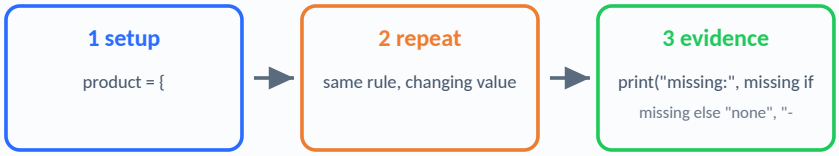
Detect which required Product fields are missing using a comprehension.

- A required-fields list drives validation
- List comprehension with an in filter
- Empty list means valid

Skill Roadmap

`Skill step:` adds one small variation while the chapter pattern is still new. It builds on Project 304: build a product with an offer. Project 306 changes the surface problem while preserving the underlying method.

progress check



`Reading target:` validate required product fields is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- `Setup:` `product = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The comprehension compresses a loop into a readable noun phrase: `make this` for `each item` if `it qualifies`. Expand it mentally when it feels dense.
- `Writing move:` this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

- Evidence: `print("missing:", missing if missing else "none", "->", "valid" if not missing else "invalid")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`product = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = [f for f in required if f not in product]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print("missing:", missing if missing else "none", "->", "valid" if not missing else "invalid")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [f for f in required if f not in product]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate Required Product Fields: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: product, type, Product, name, Trail. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: product = { | Core: missing = [f for f in required if f not in product] | Evidence: print("missing:", missing if missing else "none", "->", "valid" if not...

🛠️ Reader to Writer Bridge

1. Read: explain validate required product fields in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 304.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 306 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("missing:", missing if missing else "none", "->", "valid" if not missing else "invalid")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `product = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate required product fields and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the required-field list down to keys not present in the dict yields the missing set; an empty result means the block satisfies the schema's minimum.

```
product = {
    "@type": "Product",
    "name": "Trail Runner Shoe",
    "offers": {"price": "89.99", "priceCurrency": "USD"},
}
required = ["name", "offers"]
missing = [f for f in required if f not in product]
print("missing:", missing if missing else "none", "->", "valid" if not missing
else "invalid")
```

```
output
missing: none -> valid
```

How it works:

1. The product dict has name and a small offers dict.
2. required lists the field names name and offers.
3. The comprehension keeps each name not in product, and the print reports the missing names or none plus a valid/invalid verdict.

Try it:

1. Add price and priceCurrency to the required list and test against the nested offer
2. Return the missing list from a function instead of printing
3. Run the check across a list of three product dicts
4. Remove the `name` key and watch the verdict turn invalid.

⚠ Common Mistakes

- Checking `if not product[f]` instead of `if f not in product` raises KeyError on the very field you are testing for.
- Listing `price` as a top-level required field misses that it lives nested inside `offers`.
- Reporting the count of missing fields but not which ones leaves the author guessing.

Skills gained list comprehension | required fields | validation | membership test

→ Where You'll Use This: When auditing a catalog of product pages you run this to flag listings that will silently fail to earn a price snippet because a mandatory field never made it into the markup.

Mental Model

Like a checklist at a checkpoint: every box must be ticked or the product is turned away before it can appear with rich detail.

Project 306 Build an FAQPage From Q&A Pairs

The Idea Behind It

An FAQPage converts question and answer pairs into structured data so Google can show the answers as expandable entries. This code holds the pairs as tuples, then a list comprehension builds the mainEntity array, turning each tuple into a Question node whose acceptedAnswer is an Answer dict carrying the text. Printing the first node shows the nested Question/Answer shape.

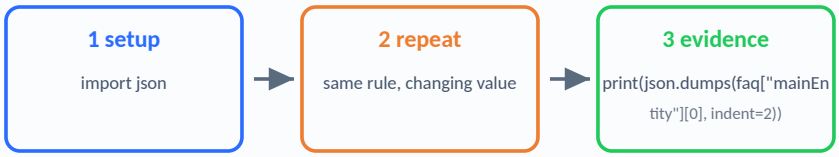
What You'll Build & Learn

Transform a list of Q&A tuples into FAQPage mainEntity nodes.

- FAQPage holds a mainEntity list
- Each pair becomes a Question with an acceptedAnswer
- Comprehension over (q, a) tuples

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 305: validate required product fields. Project 307 changes the surface problem while preserving the underlying method.



progress check

Reading target: build an faqpage from q&a pairs is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(json.dumps(faq["mainEntity"][0], indent=2))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`for q, a in qa`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(json.dumps(faq["mainEntity"][0], indent=2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for q, a in qa`

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build an FAQPage From Q&A Pairs: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, qa, What, is, LD. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: for q, a in qa | Evidence: print(json.dumps(faq["mainEntity"][0], indent=2))

🛠️ Reader to Writer Bridge

1. Read: explain build an faqpage from q&a pairs in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 305.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 307 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(json.dumps(faq["mainEntity"][0], indent=2))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build an faqpage from q&a pairs and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A list comprehension maps each `(question, answer)` tuple to a `Question` dict with a nested `Answer`, building the `mainEntity` array that an FAQPage requires.

```
import json
qa = [
    ("What is JSON-LD?", "A way to embed structured data as JSON."),
    ("Where does it go?", "In a script tag in the page head."),
]
faq = {
    "@context": "https://schema.org",
    "@type": "FAQPage",
```

```
    "mainEntity": [
        {"@type": "Question", "name": q,
         "acceptedAnswer": {"@type": "Answer", "text": a}}
        for q, a in qa
    ],
}
print(json.dumps(faq["mainEntity"][0], indent=2))
```

```
output
{
  "@type": "Question",
  "name": "What is JSON-LD?",
  "acceptedAnswer": {
    "@type": "Answer",
    "text": "A way to embed structured data as JSON."
  }
}
```

How it works:

1. qa is a list of (question, answer) tuples.
2. The faq dict declares FAQPage and builds mainEntity with a comprehension unpacking q, a from each tuple.
3. Each item is a Question node whose acceptedAnswer is an Answer dict holding the text; the first node is printed.

Try it:

1. Add a third Q&A tuple and confirm mainEntity grows
2. Read the pairs from a CSV instead of hard-coded tuples
3. Strip whitespace from each question and answer before building the node
4. Add a third tuple and confirm `mainEntity` grows.

⚠ Common Mistakes

- Putting the answer text directly on the Question instead of inside `acceptedAnswer` produces an FAQ that renders no answer.
- Naming the array `mainEntities` (plural) instead of `mainEntity` breaks the schema key.
- Reusing the same Question name for two pairs makes duplicate, confusing FAQ entries.

Skills gained tuple unpacking | list comprehension | FAQPage | nested nodes

→ Where You'll Use This: Support and help-center pages feed their FAQ content into this shape so the questions surface directly in search, capturing space and clicks for common queries.

Mental Model

The tuples are raw interview notes; the comprehension formats each exchange into a tidy question-and-answer card the engine can display.

Project 307 Count Question and Answer Pairs

The Idea Behind It

An FAQPage with a blank answer silently loses that entry, so an audit counts both questions and answers. This snippet pulls the mainEntity list, reports its length as the question count, then uses a generator inside sum with .get to count how many acceptedAnswer dicts actually carry text. Matching counts mean every question is answered.

What You'll Build & Learn

Count questions and verify each one carries a non-empty answer.

- len gives the question count
- sum over a generator counts matches
- dict.get guards a missing key

Skill Roadmap

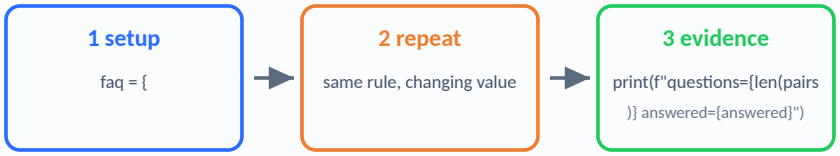
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 306: build an faqpage from q&a pairs. Project 308 changes the surface problem while preserving the underlying method.

progress check

Reading target: count question and answer pairs is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `faq = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"questions={len(pairs)} answered={answered}")` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`faq = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`answered = sum(1 for q in pairs if q["acceptedAnswer"].get("text"))`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"questions={len(pairs)} answered={answered}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `answered = sum(1 for q in pairs if q["acceptedAnswer"].get("text"))`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Question and Answer Pairs: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: faq, type, FAQPage, mainEntity, Question. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: faq = { | Core: answered = sum(1 for q in pairs if q["acceptedAnswer"].get("text")) | Evidence: print(f"questions={len(pairs)} answered={answered}")

Reader to Writer Bridge

1. Read: explain count question and answer pairs in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 306.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 308 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"questions={len(pairs)} answered={answered}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `faq = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count question and answer pairs and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

Counting `mainEntity` entries gives the question total, while summing those whose `acceptedAnswer.text` is truthy confirms none was left blank.

```
faq = {
    "@type": "FAQPage",
    "mainEntity": [
        {"@type": "Question", "name": "Q1", "acceptedAnswer": {"text": "A1"}},
        {"@type": "Question", "name": "Q2", "acceptedAnswer": {"text": "A2"}},
```

```
        {"@type": "Question", "name": "Q3", "acceptedAnswer": {"text": "A3"}},
    ],
}
pairs = faq["mainEntity"]
answered = sum(1 for q in pairs if q["acceptedAnswer"].get("text"))
print(f"questions={len(pairs)} answered={answered}")
```

```
output
questions=3 answered=3
```

How it works:

1. The faq dict's mainEntity holds three Question nodes, each with an acceptedAnswer.
2. pairs aliases that list and len(pairs) is the question count.
3. sum with a generator counts questions whose acceptedAnswer.get('text') is truthy, and the f-string prints both numbers.

Try it:

1. Print the name of any question whose answer is empty
2. Treat a whitespace-only answer as missing by stripping first
3. Fail loudly with an assert when answered is less than the question count
4. Blank out Q2's answer text and watch `answered` drop to 2.

⚠ Common Mistakes

- Using `q['acceptedAnswer']['text']` instead of `.get('text')` raises KeyError on a question that has no answer node.
- Counting a question with an empty-string answer as answered, since `''` is falsy but `'text' in dict` would be true.
- Iterating the FAQPage dict itself rather than its `mainEntity` list counts top-level keys.

Skills gained len | generator sum | dict.get | truthiness

→ Where You'll Use This: Before publishing an FAQ block you run this to catch a copy-paste slip where a question shipped with an empty answer, which would drop it from the rich result.

Mental Model

Like counting chairs and counting people seated: a mismatch means someone is standing, here a question with no answer attached.

Project 308 Build a BreadcrumbList With Positions

The Idea Behind It

A BreadcrumbList shows the path from the homepage down to the current page in the search snippet. This code takes a trail of names and builds itemListElement with a comprehension that enumerates them, giving each a ListItem with a 1-based position via i + 1. Looping the result prints each position next to its name, the ordering the engine relies on.

What You'll Build & Learn

Build a BreadcrumbList with correctly numbered ListItem positions.

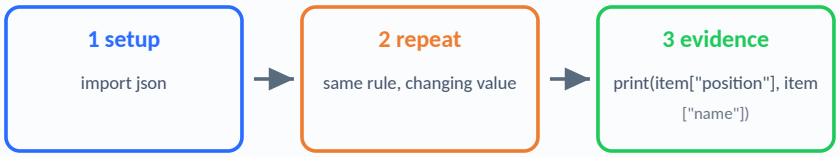
- Breadcrumbs are an itemListElement list
- enumerate plus i + 1 gives 1-based positions
- Each crumb is a ListItem

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 307: count question and answer pairs. Project 309 changes the surface problem while preserving the underlying method.

progress check

Reading target: build a breadcrumblist with positions is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(item["position"], item["name"])` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`for i, name in enumerate(trail)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(item["position"], item["name"])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for i, name in enumerate(trail)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a BreadcrumbList With Positions: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, trail, Home, Catalog, Shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import json | Core: for i, name in enumerate(trail) | Evidence: print(item["position"], item["name"])

Reader to Writer Bridge

1. Read: explain build a breadcrumblist with positions in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 307.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 309 should feel like a variation, not a brand-new mystery.

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a breadcrumblist with positions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

From Concept to Code (Python)

`enumerate` over the trail yields a zero-based index that becomes the 1-based `position` each ListItem needs, building an ordered breadcrumb array.

```
import json
trail = ["Home", "Catalog", "Shoes"]
crumbs = {
    "@context": "https://schema.org",
    "@type": "BreadcrumbList",
    "itemListElement": [
        {"@type": "ListItem", "position": i + 1, "name": name}
```

```
            for i, name in enumerate(trail)
        ],
    }
    for item in crumbs["itemListElement"]:
        print(item["position"], item["name"])
```

```
output
1 Home
2 Catalog
3 Shoes
```

How it works:

1. trail is the list of page names from Home to Shoes.
2. The comprehension uses enumerate so each name gets a ListItem with position i + 1 and the name.
3. A for loop prints each item's position and name, showing 1 Home, 2 Catalog, 3 Shoes.

Try it:

1. Add an item URL to each ListItem alongside name and position
2. Build the trail from a URL path split on slashes
3. Reverse the trail and confirm positions still start at one
4. Pass `enumerate(trail, 1)` and drop the `+ 1` for the same result.

⚠ Common Mistakes

- Using the raw `enumerate` index (starting at 0) gives a first position of 0, but schema.org positions start at 1.
- Passing `start=1` to `enumerate` and then also adding 1 double-counts the offset.
- Naming the array `itemListElements` (plural) breaks the required key.

Skills gained enumerate | list comprehension | BreadcrumbList | 1-based indexing

→ Where You'll Use This: Category and product pages generate breadcrumb markup so search results display the site hierarchy, helping users see where a page sits and improving click context.

Mental Model

Like numbering the steps of a staircase from the front door up; the engine needs the count so it can lay the crumbs in the right order.

Project 309 Validate Breadcrumb Position Ordering

The Idea Behind It

Breadcrumb positions must run 1, 2, 3 without skips or repeats or the engine may reject the trail. This snippet extracts the positions into a list, builds the expected sequence with range, and compares the two lists for exact equality. A True result confirms the numbering is clean; any deviation prints broken instead of ordered.

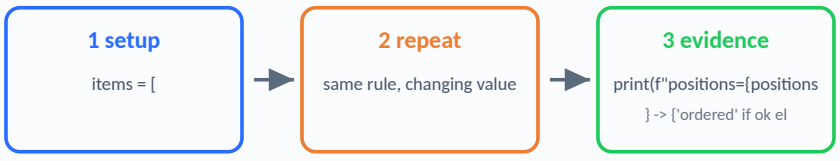
What You'll Build & Learn

Confirm breadcrumb positions form an unbroken 1-based sequence.

- Pull positions into a list
- range builds the expected sequence
- List equality compares order and values

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 308: build a breadcrumblist with positions. Project 310 changes the surface problem while preserving the underlying method. *progress check*



Reading target: validate breadcrumb position ordering is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `items = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"positions={positions} -> {'ordered' if ok else 'broken'}")` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`items = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"positions={positions} -> {'ordered' if ok else 'broken'}")`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"positions={positions} -> {'ordered' if ok else 'broken'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f"positions={positions} -> {'ordered' if ok else 'broken'}")`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate Breadcrumb Position Ordering: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: items, position, name, Home, Catalog. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: items = [| Core: print(f"positions={positions} -> {'ordered' if ok else 'broken'}") | Evidence: print(f"positions={positions} -> {'ordered' if ok else 'broken'}")

🛠️ Reader to Writer Bridge

1. Read: explain validate breadcrumb position ordering in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 308.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 310 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"positions={positions} -> {'ordered' if ok else 'broken'}")`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `items = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate breadcrumb position ordering and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Building the expected list `[1..n]` and comparing it for equality to the extracted positions verifies the breadcrumb is both complete and in order in one step.

```
items = [
    {"position": 1, "name": "Home"},
    {"position": 2, "name": "Catalog"},
    {"position": 3, "name": "Shoes"},
]
positions = [it["position"] for it in items]
expected = list(range(1, len(items) + 1))
ok = positions == expected
print(f"positions={positions} -> {'ordered' if ok else 'broken'}")
```

```
output
positions=[1, 2, 3] -> ordered
```

How it works:

1. items holds three crumbs with positions 1, 2, 3.
2. positions is a comprehension collecting each it['position'].

3. expected is list(range(1, len+1)), and comparing positions == expected yields the ordered or broken verdict.

Try it:

1. Sort the items by position before comparing in case they arrive out of order
2. Report the first index where actual and expected diverge
3. Test against a list whose positions are 1, 3, 2 and observe broken
4. Swap two items and watch the verdict turn broken.

⚠ Common Mistakes

- Comparing `sorted(positions)` to `expected` would call a shuffled `[3, 1, 2]` valid because sorting hides the disorder.
- Using `range(len(items))` (0-based) makes the expected list start at 0 and never match.
- Checking only the maximum position misses a missing middle item.

Skills gained range | list comparison | list comprehension | validation

→ Where You'll Use This: After generating breadcrumb markup at scale you verify each list is sequentially numbered, since a templating bug that repeats or skips a position quietly disqualifies the breadcrumb display.

⚡ Mental Model

Like checking a deck of numbered tickets is in order before the show; one missing or duplicate number and the sequence is invalid.

Project 310 Build a LocalBusiness Entity

💡 The Idea Behind It

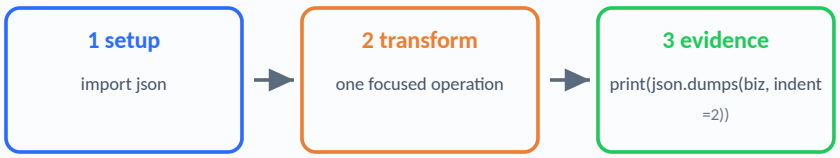
A LocalBusiness block supplies the map pack and knowledge panel with the essentials of a storefront. This code assembles a dict with name, telephone, and an openingHours string, plus an address that is itself a nested PostalAddress object holding street, locality, and postal code. Serializing with json.dumps shows the full nested structure a local listing needs.

What You'll Build & Learn

Build a LocalBusiness with a nested PostalAddress, phone, and hours.

- LocalBusiness feeds local search features
- Address nests as a PostalAddress object
- openingHours uses a compact day-time string

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 309: validate breadcrumb position ordering. Project 311 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build a localbusiness entity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(json.dumps(biz, indent=2))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(json.dumps(biz, indent=2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build a LocalBusiness Entity: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, biz, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(json.dumps(biz, indent=2))

🛠️ Reader to Writer Bridge

1. Read: explain build a localbusiness entity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 309.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 311 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(json.dumps(biz, indent=2))`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a localbusiness entity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The `address` is a typed `PostalAddress` sub-dict, and `openingHours` uses schema.org's compact `Mo-Fr 08:00-18:00` day/time notation that map listings parse directly.

```
import json
biz = {
    "@context": "https://schema.org",
    "@type": "LocalBusiness",
    "name": "Corner Cafe",
    "address": {
        "@type": "PostalAddress",
        "streetAddress": "12 Market St",
        "addressLocality": "Springfield",
        "postalCode": "10001",
    },
    "telephone": "+1-555-0100",
    "openingHours": "Mo-Fr 08:00-18:00",
}
print(json.dumps(biz, indent=2))
```

```
output
{
  "@context": "https://schema.org",
  "@type": "LocalBusiness",
  "name": "Corner Cafe",
  "address": {
    "@type": "PostalAddress",
    "streetAddress": "12 Market St",
    "addressLocality": "Springfield",
    "postalCode": "10001"
  },
  "telephone": "+1-555-0100",
  "openingHours": "Mo-Fr 08:00-18:00"
}
```

How it works:

1. The biz dict declares LocalBusiness with a name.
2. Its address key holds a nested PostalAddress with streetAddress, addressLocality, and postalCode.
3. telephone and openingHours follow, then json.dumps prints the whole nested block.

Try it:

1. Add geo coordinates as a nested GeoCoordinates object
2. Make openingHours a list covering weekend hours separately
3. Add a priceRange field and re-serialize the block
4. Add a `geo` object with latitude and longitude.

⚠ Common Mistakes

- Writing the address as one flat string instead of a `PostalAddress` object loses the structured locality and postcode.
- Using a human phrase like `Mon to Fri 8am` instead of the `Mo-Fr 08:00-18:00` format means opening hours will not parse.
- Storing `telephone` without a country code (`+1`) weakens the click-to-call match.

Skills gained nested objects | PostalAddress | LocalBusiness | json.dumps

→ Where You'll Use This: Multi-location businesses generate one of these per branch so each storefront can appear in the map pack with its address, phone number, and hours visible.

⚡ Mental Model

Like the storefront window display: name, address, phone, and hours all visible at a glance so a passerby knows where you are and when you open.

Project 311 Build an Organization With sameAs Links

💡 The Idea Behind It

An Organization block links a brand to its verified presence elsewhere through the sameAs array, helping engines assemble a knowledge panel. This code builds the org dict with name and url, then a sameAs list of canonical profile URLs. It prints the array and reports its length with len, the count of authoritative profiles the brand claims.

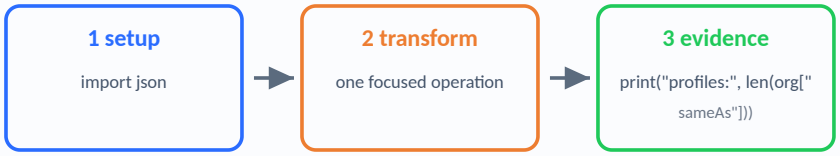
What You'll Build & Learn

Build an Organization that links to social profiles via sameAs.

- sameAs is an array of profile URLs
- It supports knowledge-panel assembly
- len counts the linked profiles

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 310: build a localbusiness entity. Project 312 changes the surface problem while preserving the underlying method.



progress check

Reading target: build an organization with sameas links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("profiles:", len(org["sameAs"]))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print("profiles:", len(org["sameAs"]))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build an Organization With sameAs Links: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, org, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print("profiles:", len(org["sameAs"]))

Reader to Writer Bridge

1. Read: explain build an organization with sameas links in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 310.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 312 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("profiles:", len(org["sameAs"]))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build an organization with sameas links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The `sameAs` array is a list of authoritative URLs for the same entity; counting its length tells you how many external profiles reinforce the brand's identity.

```
import json
org = {
    "@context": "https://schema.org",
    "@type": "Organization",
    "name": "Acme Inc",
    "url": "https://acme.example",
    "sameAs": [
        "https://twitter.com/acme",
        "https://www.linkedin.com/company/acme",
    ],
}
print(json.dumps(org["sameAs"], indent=2))
print("profiles:", len(org["sameAs"]))
```

```
output
[
  "https://twitter.com/acme",
  "https://www.linkedin.com/company/acme"
]
profiles: 2
```

How it works:

1. The org dict declares Organization with name and url.
2. sameAs is a list of two canonical profile URLs for Twitter and LinkedIn.
3. json.dumps prints the sameAs array and len reports profiles: 2.

Try it:

1. Add a logo field pointing to an absolute image URL
2. Append a Wikipedia URL to the sameAs list
3. Validate each sameAs entry starts with https before counting

4. Append a Facebook profile URL and watch the count rise.

⚠ Common Mistakes

- Putting a single profile as a bare string rather than a one-element list makes `len()` count characters, not profiles.
- Listing a non-canonical or redirecting profile URL weakens the entity link.
- Confusing `url` (the org's own site) with `sameAs` (external profiles) muddles the two fields.

Skills gained sameAs | Organization | list length | json.dumps

→ Where You'll Use This: Brand and about pages carry an Organization block whose sameAs entries point to official social and Wikipedia profiles, reinforcing entity identity for the knowledge graph.

⚡ Mental Model

sameAs is the brand saying these other accounts are also me; the engine connects the dots into one entity panel.

Project 312 Build a Recipe With Ingredients and Steps

💡 The Idea Behind It

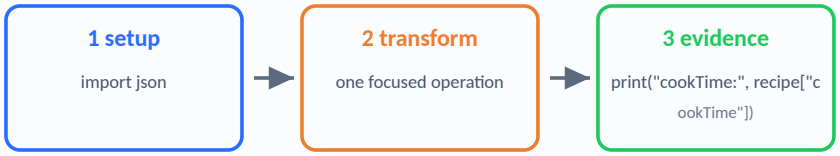
A Recipe rich result wants three things together: an ingredient list, ordered steps, and a cook time in ISO-8601 duration form. This code builds the recipe dict with recipeIngredient as a list of strings and recipeInstructions as HowToStep objects so each step renders alone. It then prints the ingredient count, step count, and the cookTime value PT15M.

What You'll Build & Learn

Build a Recipe with ingredients, HowToStep instructions, and a cook time.

- recipeIngredient is a list of strings
- Steps are individual HowToStep objects
- cookTime uses ISO-8601 duration

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 311: build an organization with sameas links. Project 313 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build a recipe with ingredients and steps is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("cookTime:", recipe["cookTime"])` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

🛠️ Reader to Writer Bridge

1. Read: explain build a recipe with ingredients and steps in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 311.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 313 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("cookTime:", recipe["cookTime"])`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of build a recipe with ingredients and steps and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`recipeIngredient` is a flat string list while `recipeInstructions` is a list of typed `HowToStep` objects, and `cookTime` uses the ISO duration `PT15M` (15 minutes).

```
import json
recipe = {
    "@context": "https://schema.org",
    "@type": "Recipe",
    "name": "Pancakes",
    "recipeIngredient": ["2 cups flour", "1 egg", "1 cup milk"],
    "recipeInstructions": [
        {"@type": "HowToStep", "text": "Mix the batter."},
        {"@type": "HowToStep", "text": "Cook on a griddle."},
    ],
    "cookTime": "PT15M",
}
print("ingredients:", len(recipe["recipeIngredient"]))
print("steps:", len(recipe["recipeInstructions"]))
print("cookTime:", recipe["cookTime"])
```

```
output
ingredients: 3
steps: 2
cookTime: PT15M
```

How it works:

1. The recipe dict declares Recipe with a name.
2. recipeIngredient is a three-item string list and recipeInstructions is a list of two HowToStep dicts.
3. len reports the ingredient and step counts, and cookTime PT15M is printed directly.

Try it:

1. Add a recipeYield field and print it
2. Add a nutrition object with calories
3. Convert each instruction to include a step name as well as text
4. Add a `prepTime` of `PT5M`.

⚠ Common Mistakes

- Writing `cookTime` as `15 minutes` instead of the ISO `PT15M` duration fails the rich-result test.

- Using the singular `recipeIngredient` for the list is correct schema.org naming; pluralizing it to `recipeIngredients` breaks it.
- Storing steps as plain strings instead of `HowToStep` objects loses per-step structure.

Skills gained HowToStep | Recipe schema | len | ISO-8601 duration

→ Where You'll Use This: Food and cooking sites markup each recipe this way so search can show the dish with its prep steps and total time, often with an image carousel.

Mental Model

The recipe card with three sections: a shopping list, a numbered method, and a clock for how long it takes.

Project 313 Build an Event With Date and Location

The Idea Behind It

An Event block puts dates and venues into search and maps. This code builds the event dict with a name and a startDate in ISO date-time form, then pairs it with a nested Place object describing the venue by name and address. Serializing with json.dumps reveals the typed nesting: an Event whose location is a Place, the shape an event listing needs.

What You'll Build & Learn

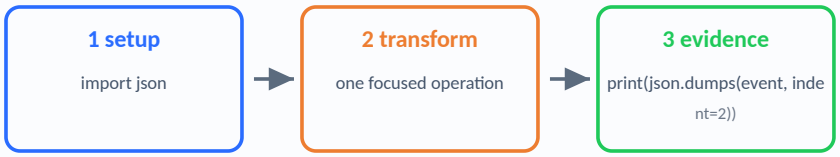
Build an Event with an ISO startDate and a nested Place location.

- Event surfaces date and venue
- startDate uses ISO date-time
- location nests as a Place object

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 312: build a recipe with ingredients and steps. Project 314 changes the surface problem while preserving the underlying method.

progress check



Reading target: build an event with date and location is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.

- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(json.dumps(event, indent=2))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(json.dumps(event, indent=2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build an Event With Date and Location: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, event, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(json.dumps(event, indent=2))

🛠️ Reader to Writer Bridge

1. Read: explain build an event with date and location in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 312.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 314 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(json.dumps(event, indent=2))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build an event with date and location and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

The `startDate` is an ISO-8601 datetime string and `location` is a typed `Place`, the minimum pair that lets an Event show its when and where.

```
import json
event = {
    "@context": "https://schema.org",
    "@type": "Event",
    "name": "SEO Summit",
    "startDate": "2026-09-01T09:00",
    "location": {
        "@type": "Place",
        "name": "Convention Center",
        "address": "500 Expo Blvd",
    },
}
print(json.dumps(event, indent=2))
```

```
output
{
  "@context": "https://schema.org",
  "@type": "Event",
  "name": "SEO Summit",
  "startDate": "2026-09-01T09:00",
  "location": {
    "@type": "Place",
    "name": "Convention Center",
    "address": "500 Expo Blvd"
  }
}
```

How it works:

1. The event dict declares Event with a name.
2. startDate is an ISO date-time string and location is a nested Place with its own name and address.
3. json.dumps prints the full block showing the Place nested inside the Event.

Try it:

1. Add an endDate and an eventStatus field
2. Make location a VirtualLocation with a url for an online event
3. Add an offers block so tickets show a price
4. Add an `endDate` to make it a two-day event.

⚠ Common Mistakes

- Omitting the time and writing `startDate` as just `2026-09-01` is allowed but loses the start hour shown in results.
- Using a bare address string for `location` instead of a `Place` object skips the venue name.

- Forgetting `endDate` on a multi-day event makes it look like a single instant.

Skills gained Event schema | Place | ISO date-time | nested objects

→ Where You'll Use This: Concert, conference, and webinar pages emit Event markup so listings show the date and venue, and qualify for the dedicated events experience in search.

Mental Model

Like a calendar invite: a when (startDate) and a where (the nested Place), the two facts a listing must answer.

Project 314 Serialize JSON-LD as a Pretty String

The Idea Behind It

Auditors want a stable rendering of a block so diffs stay meaningful run to run. This snippet builds a WebSite dict and calls json.dumps with both indent=2 and sort_keys=True. Sorting keys plus fixed indentation yields canonical text: the same dict always produces byte-identical output, which makes change detection across crawls reliable.

What You'll Build & Learn

Serialize a block to canonical, diff-friendly JSON with sorted keys.

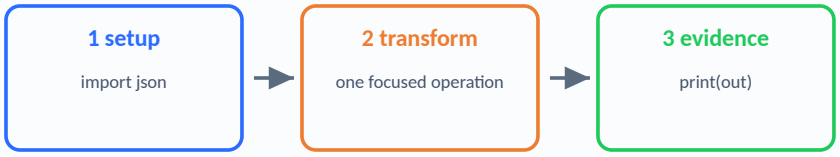
- sort_keys makes output order deterministic
- indent makes it readable
- Canonical text enables stable diffs

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 313: build an event with date and location. Project 315 changes the surface problem while preserving the underlying method.

progress check

Reading target: serialize json-ld as a pretty string is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

- Evidence: `print(out)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(out)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Serialize JSON-LD as a Pretty String: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, data, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(out)

🛠️ Reader to Writer Bridge

1. Read: explain serialize json-ld as a pretty string in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 313.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 315 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(out)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of serialize json-ld as a pretty string and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`sort_keys=True` orders keys alphabetically (so `@` symbols sort before letters), giving a canonical form ideal for diffing two versions of a block.

```
import json
data = {
    "@context": "https://schema.org",
    "@type": "WebSite",
    "name": "My Blog",
    "url": "https://blog.example",
```

```
}
out = json.dumps(data, indent=2, sort_keys=True)
print(out)
```

```
output
{
  "@context": "https://schema.org",
  "@type": "WebSite",
  "name": "My Blog",
  "url": "https://blog.example"
}
```

How it works:

1. The data dict declares WebSite with name and url.
2. json.dumps is called with indent=2 and sort_keys=True.
3. The result is printed; key order is alphabetical regardless of insertion order, so identical data prints identically every time.

Try it:

1. Compare output with and without sort_keys on the same dict
2. Hash the canonical string with hashlib to fingerprint the block
3. Add nested keys and confirm inner dicts also sort
4. Drop `sort_keys` and compare the key order.

⚠ Common Mistakes

- Leaving out `sort_keys` makes the output depend on insertion order, which breaks byte-for-byte diffs.
- Setting `indent=0` still adds newlines; only `indent=None` produces a single compact line.
- Assuming `@context` sorts after `name`, when in fact `@` (0x40) sorts before lowercase letters.

Skills gained json.dumps | sort_keys | canonical output | serialization

→ Where You'll Use This: When you snapshot a site's structured data over time, canonical serialization lets you diff today's markup against yesterday's and spot exactly what a deploy changed.

Mental Model

Like alphabetizing a filing cabinet: once everything has a fixed place, you can instantly see if a single file moved.

Project 315 Detect a Missing Required Property

The Idea Behind It

Each schema type carries a small set of required properties, and this snippet looks them up by type. The required table maps Article to its three mandatory fields; the comprehension reads the block's @type, fetches its required list, and collects any field not in the block. The printed missing list names exactly the mandatory fields that are absent.

What You'll Build & Learn

Report which required fields a typed block is missing via a lookup table.

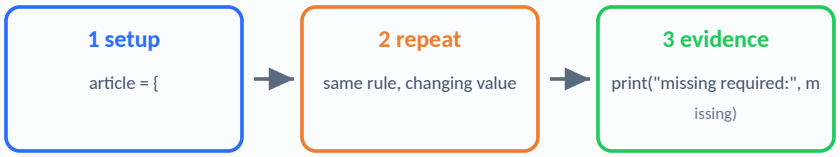
- A dict maps types to required fields
- Look up requirements by @type
- Comprehension finds absent fields

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 314: serialize json-ld as a pretty string. Project 316 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a missing required property is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `article = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("missing required:", missing)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`article = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = [f for f in required[article["@type"]] if f not in article]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print("missing required:", missing)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [f for f in required[article["@type"]] if f not in article]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Missing Required Property: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: article, context, https, schema, org. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: article = { | Core: missing = [f for f in required[article["@type"]] if f not in article] | Evidence: print("missing required:", missing)

🛠️ Reader to Writer Bridge

1. Read: explain detect a missing required property in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 314.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 316 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("missing required:", missing)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `article = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a missing required property and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Indexing the requirements table by the block's own `@type` keeps the rule lookup data-driven, and the comprehension lists each required field the block lacks.

```
article = {
    "@context": "https://schema.org",
    "@type": "Article",
    "author": "Jane Doe",
}
required = {"Article": ["headline", "author", "datePublished"]}
```

```
missing = [f for f in required[article["@type"]] if f not in article]
print("missing required:", missing)
```

```
output
missing required: ['headline', 'datePublished']
```

How it works:

1. The article dict has @context, @type, and author but no headline or datePublished.
2. required maps Article to headline, author, datePublished.
3. The comprehension iterates required[article['@type']] and keeps any field not in article, printing the two missing names.

Try it:

1. Add a Recipe entry to required and test a Recipe block
2. Raise a KeyError-safe message when @type is unknown
3. Return a tuple of present and missing fields
4. Add `headline` to the article and watch the list shrink.

⚠ Common Mistakes

- Hard-coding the Article rules instead of keying by `@type` means the check cannot be reused for other types.
- A KeyError fires if the block's `@type` is not in the requirements table; unknown types need a fallback.
- Listing fields present rather than absent inverts the report.

Skills gained dict lookup | list comprehension | required fields | @type

→ Where You'll Use This: A reusable validator keys its required-field rules off @type, so one function can audit Articles, Products, and Recipes by consulting the matching entry in the table.

⚡ Mental Model

Like a clerk pulling the right form for your visa type, then ticking which mandatory boxes you left blank.

Project 316 Detect a Missing Recommended Property

💡 The Idea Behind It

Beyond mandatory fields, schemas list recommended ones that unlock richer displays such as images, ratings, and brand. This code defines a recommended list, then uses sorted around a comprehension to collect, alphabetically, the recommended fields the product lacks. The output guides incremental improvement: add these to upgrade an eligible block into a fuller result.

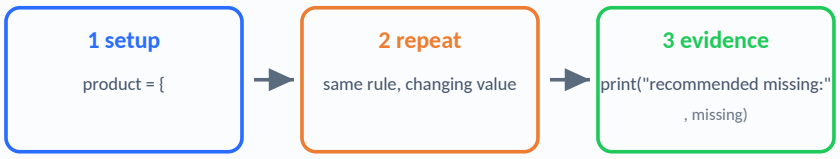
What You'll Build & Learn

List the recommended Product fields that are absent, sorted alphabetically.

- Recommended fields differ from required
- They unlock richer results
- sorted orders the missing names

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 315: detect a missing required property. Project 317 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a missing recommended property is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `product = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("recommended missing:", missing)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`product = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus:

Move	Code to inspect	Why it matters
		generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = sorted(f for f in recommended if f not in product)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print("recommended missing:", missing)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = sorted(f for f in recommended if f not in product)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Missing Recommended Property: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: product, type, Product, name, Widget. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: product = { | Core: missing = sorted(f for f in recommended if f not in product) | Evidence: print("recommended missing:", missing)

Reader to Writer Bridge

1. Read: explain detect a missing recommended property in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 315.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 317 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("recommended missing:", missing)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `product = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a missing recommended property and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Recommended fields are non-blocking, so they are reported separately from required ones; sorting the missing list keeps the audit output deterministic.

```
product = {
    "@type": "Product",
    "name": "Widget",
    "offers": {"price": "5.00", "priceCurrency": "USD"},
}
recommended = ["image", "description", "brand", "aggregateRating"]
missing = sorted(f for f in recommended if f not in product)
print("recommended missing:", missing)
```

```
output
recommended missing: ['aggregateRating', 'brand', 'description', 'image']
```

How it works:

1. The product dict has name and a minimal offers dict.
2. recommended lists image, description, brand, aggregateRating.
3. sorted wraps a comprehension keeping each recommended field not in product, printing the four absent names alphabetically.

Try it:

1. Weight the recommendations and report the highest-impact missing field first
2. Combine with a required check into one report
3. Count how many recommended fields are present versus absent
4. Add an `image` to the product and watch it drop from the list.

⚠ Common Mistakes

- Treating recommended fields as required would wrongly fail an otherwise valid block.
- Forgetting to sort the comprehension lets the printed order vary across runs.
- Checking nested fields like `offers.priceValidUntil` with a flat `in` test misses them.

Skills gained sorted | recommended fields | list comprehension | membership test

→ Where You'll Use This: After a block passes required-field validation you run this to produce a prioritized to-do list, telling content teams which optional fields would earn star ratings or image enhancements.

Mental Model

Required fields get you in the door; recommended fields are the upgrades that get you the corner office, and this lists which upgrades you skipped.

Project 317 Validate an AggregateRating Value

The Idea Behind It

An AggregateRating must sit within its declared scale or the star widget is rejected. This snippet pulls ratingValue, then checks it lies between worstRating and bestRating using Python's chained comparison. A passing value prints valid; a stray figure like 6 out of 5 would print out of range. It is a one-line bounds guard on the rating.

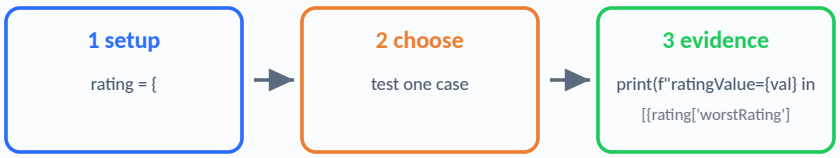
What You'll Build & Learn

Verify an AggregateRating value falls within its worst-to-best bounds.

- Chained comparison checks a range
- ratingValue must respect worst and best
- Out-of-range stars are rejected

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 316: detect a missing recommended property. Project 318 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate an aggregaterating value is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `rating = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"ratingValue={val} in [{rating['worstRating']}, {rating['bestRating']}] -> {'valid' if ok else 'out of range'}")` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`rating = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"ratingValue={val} in [{rating['worstRating']}, {rating['bestRating']}] -> {'valid' if ok else 'out of range'}")`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f"ratingValue={val} in [{rating['worstRating']}, {rating['bestRating']}] -> {'valid' if ok else 'out of range'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
print(f"ratingValue={val} in [{rating['worstRating']},{rating['bestRating']}] ->
{'valid' if ok else 'out of range'}")
```

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Validate an AggregateRating Value: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: rating, type, AggregateRating, ratingValue, bestRating. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: rating = { | Core: print(f"ratingValue={val} in [{rating['worstRating']},{rating['bestRati... | Evidence: print(f"ratingValue={val} in [{rating['worstRating']},{rating['bestRati...

Reader to Writer Bridge

1. Read: explain validate an aggregaterating value in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 316.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 318 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"ratingValue={val} in [{rating['worstRating']},{rating['bestRating']}] -> {'valid' if ok else 'out of range'}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `rating = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate an aggregaterating value and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Python's chained comparison `worst <= val <= best` reads like the math interval and confirms the rating falls inside the block's own declared bounds.

```
rating = {
    "@type": "AggregateRating",
    "ratingValue": 4.6,
    "bestRating": 5,
    "worstRating": 1,
    "ratingCount": 128,
}
val = rating["ratingValue"]
ok = rating["worstRating"] <= val <= rating["bestRating"]
print(f"ratingValue={val} in [{rating['worstRating']},{rating['bestRating']}] -
> {'valid' if ok else 'out of range'}")
```

```
output
ratingValue=4.6 in [1,5] -> valid
```

How it works:

1. The rating dict holds ratingValue 4.6, bestRating 5, worstRating 1, and ratingCount.
2. The short name val is bound to ratingValue so the comparison reads cleanly.
3. ok uses the chained comparison worstRating <= val <= bestRating, and the f-string prints the value, the bounds, and a valid or out-of-range verdict.

Try it:

1. Default worstRating to 1 when the field is absent
2. Also assert ratingCount is a positive integer
3. Loop the check over a list of rating dicts
4. Set `ratingValue` to 5.5 and watch it fail.

⚠ Common Mistakes

- Assuming a fixed 1-5 scale instead of reading the block's own `bestRating`/`worstRating` misjudges custom scales.
- Comparing strings (`'4.6' <= '5'`) instead of numbers gives lexical, not numeric, results.
- Forgetting that `ratingValue` of exactly `bestRating` is valid (inclusive bound).

Skills gained chained comparison | AggregateRating | range check | f-strings

→ Where You'll Use This: Review-aggregation pages compute an average star rating from many reviews; this guards against an arithmetic slip producing a value outside the declared scale and losing the star snippet.

Mental Model

Like a thermometer that must read between freezing and boiling; a value off the dial means the instrument is broken and gets ignored.

Project 318 Validate an Offer Availability Enum

The Idea Behind It

The Offer availability field must be one of schema.org's fixed enum URLs, never free text. This code defines the allowed set of availability URLs, then loops over a few offers checking each value's membership. It also splits the URL on the last slash to print a short label. A made-up value like SoldOut fails the set check and prints invalid enum.

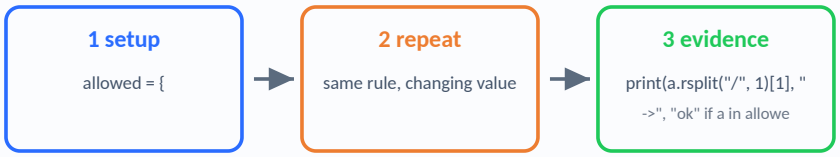
What You'll Build & Learn

Validate each Offer availability against the allowed schema.org enum set.

- Availability is a fixed enum of URLs
- Set membership validates the value
- rsplit extracts the short label

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 317: validate an aggregaterating value. Project 319 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate an offer availability enum is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `allowed = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`allowed = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate an Offer Availability Enum: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: allowed, https, schema, org, InStock. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: allowed = { | Core: print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enu... | Evidence: print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enu...

🛠️ Reader to Writer Bridge

1. Read: explain validate an offer availability enum in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 317.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 319 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `allowed = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate an offer availability enum and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

An enum field has a closed set of legal values; a set-membership test is the validation, and `rsplit('/', 1)[1]` peels off the short label for a readable report.

```
allowed = {
    "https://schema.org/InStock",
    "https://schema.org/OutOfStock",
    "https://schema.org/PreOrder",
    "https://schema.org/Discontinued",
}
offers = [
    {"availability": "https://schema.org/InStock"},
    {"availability": "https://schema.org/SoldOut"},
]
for o in offers:
    a = o["availability"]
    print(a.rsplit("/", 1)[1], "->", "ok" if a in allowed else "invalid enum")
```

```
output
InStock -> ok
SoldOut -> invalid enum
```

How it works:

1. allowed is a set of the four valid availability URLs.
2. The loop reads each offer's availability into a.
3. a.rsplit('/', 1)[1] prints the trailing label, and a in allowed decides ok or invalid enum, catching SoldOut.

Try it:

1. Map common phrases like 'sold out' to the correct enum URL
2. Add LimitedAvailability and BackOrder to the allowed set
3. Report all invalid offers as a list at the end
4. Add `BackOrder` to the allowed set and test it.

⚠ Common Mistakes

- Matching on the bare label `InStock` instead of the full enum URL accepts an unqualified value the schema rejects.

- Using `OutOfStock` spelling drift like `SoldOut` is a frequent real mistake this catches.
- Splitting with `split('/')[-1]` works too, but assuming a fixed index breaks on a trailing slash.

Skills gained set membership | rsplit | enum validation | loop

→ Where You'll Use This: When generating product markup from a catalog feed, the stock status often arrives as words like sold out; this validation forces it onto the canonical schema.org URLs Google accepts.

⚡ Mental Model

Like a drop-down menu with fixed choices: you may pick InStock or OutOfStock, but typing your own option simply does not register.

Project 319 Nest an Author as a Person

💡 The Idea Behind It

An author can be a bare string, but a nested Person object is richer because it can carry a URL and tie the byline to an entity. This code sets the Article's author to a Person dict with name and url, then reads back author['@type'] and author['name']. The byline becomes a typed sub-dict rather than loose text.

What You'll Build & Learn

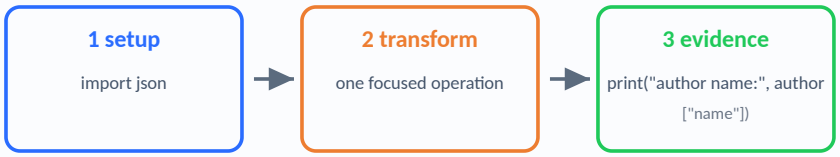
Express an Article author as a nested Person with a linking URL.

- Author may be a string or a Person
- A Person can carry a url
- The author value becomes a typed sub-dict

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 318: validate an offer availability enum. Project 320 changes the surface problem while preserving the underlying method.

progress check



Reading target: nest an author as a person is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.

- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("author name:", author["name"])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print("author name:", author["name"])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Nest an Author as a Person: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, article, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print("author name:", author["name"])

🛠️ Reader to Writer Bridge

1. Read: explain nest an author as a person in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 318.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 320 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("author name:", author["name"])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of nest an author as a person and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Replacing a string author with a `Person` dict lets the byline carry its own `@type`, name, and profile URL, which strengthens entity association.

```python
import json
article = {
    "@context": "https://schema.org",
    "@type": "Article",
    "headline": "Inside the Index",
    "author": {
        "@type": "Person",
        "name": "Sam Lee",
        "url": "https://example.com/sam",
    },
}
author = article["author"]
print("author type:", author["@type"])
print("author name:", author["name"])
```

```
output
author type: Person
author name: Sam Lee
```

How it works:

1. The article dict declares Article with a headline.
2. Its author key holds a nested Person dict with @type Person, name, and url.
3. author aliases that sub-dict, and the prints show the author type Person and the name Sam Lee.

Try it:

1. Add a sameAs list to the Person linking to social profiles
2. Support a list of two co-authors
3. Fall back to a string author when no url is available
4. Change the author to an `Organization` instead of a `Person`.

⚠ Common Mistakes

- Reading `article['author']` as a string and calling `.upper()` breaks once the author is a dict.
- Omitting `@type: Person` on the nested object leaves the author untyped.
- Putting the author URL on the Article instead of inside the Person mislinks it.

Skills gained nested Person | entity linking | dict access | Article schema

→ Where You'll Use This: Author bio and article pages use a Person author with a url to a profile, strengthening author authority signals and connecting the byline across a site's content.

Mental Model

A string byline is a printed name; a Person object is a name badge with a link back to the person's full file.

Project 320 Validate a Review Rating Is 1 to 5

The Idea Behind It

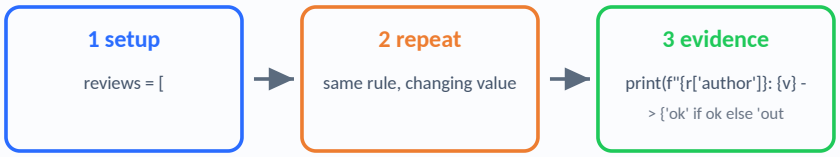
A Review's rating normally lives on a 1-to-5 star scale, so a batch audit flags anything outside that band. This code loops over a list of review dicts, reads each ratingValue into v, and tests 1 <= v <= 5 with a chained comparison. A zero or a six prints out of 1-5 while valid scores print ok, catching corrupt ratings before they ship.

What You'll Build & Learn

Scan a batch of reviews and flag ratings outside the 1-to-5 band.

- Reviews use a 1-to-5 star scale
- Chained comparison bounds the value
- Loop audits a batch

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 319: nest an author as a person. Project 321 changes the surface problem while preserving the underlying method. *progress check*

Reading target: validate a review rating is 1 to 5 is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `reviews = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{r['author']}: {v} -> {'ok' if ok else 'out of 1–5'}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate a Review Rating Is 1 to 5: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: reviews, author, ratingValue, ok, of. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: reviews = [| Core: print(f"{r['author']}: {v} -> {'ok' if ok else 'out of 1-5'}") | Evidence: print(f"{r['author']}: {v} -> {'ok' if ok else 'out of 1-5'}")

🛠️ Reader to Writer Bridge

1. Read: explain validate a review rating is 1 to 5 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 319.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 321 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{r['author']}: {v} -> {'ok' if ok else 'out of 1–5'}")`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `reviews = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate a review rating is 1 to 5 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A chained `1 <= v <= 5` comparison per review separates valid star values from impossible ones such as a zero rating.

```
reviews = [
    {"author": "A", "ratingValue": 5},
    {"author": "B", "ratingValue": 0},
    {"author": "C", "ratingValue": 3},
]
for r in reviews:
```

```
    v = r["ratingValue"]
    ok = 1 <= v <= 5
    print(f"{r['author']}: {v} -> {'ok' if ok else 'out of 1-5'}")
```

```
output
A: 5 -> ok
B: 0 -> out of 1-5
C: 3 -> ok
```

How it works:

1. reviews is a list of three dicts each with an author and a ratingValue.
2. The loop reads v from each review.
3. ok uses 1 <= v <= 5, and the f-string prints the author, value, and ok or out of 1-5, flagging the zero.

Try it:

1. Collect the offending authors into a list instead of printing inline
2. Allow a configurable max so a 1-to-10 scale also works
3. Skip reviews missing the ratingValue key without crashing
4. Add a review with rating 4.5 and confirm fractional values pass.

⚠ Common Mistakes

- Allowing 0 because a falsy check (`if v`) treats zero specially instead of using a range test.
- Hard-coding 1-5 when a block declares its own `bestRating` of, say, 10.
- Comparing a string rating to integers without converting first.

Skills gained chained comparison | loop | Review rating | batch validation

→ Where You'll Use This: When importing reviews from a third-party feed you run this gate so a malformed rating, like a zero placeholder, never reaches the markup and triggers a structured-data error.

⚡ Mental Model

Like a referee checking every scorecard reads between one and five stars; a zero or a six means someone mis-marked the card.

Project 321 Check a Type Against a Schema Dict

The Idea Behind It

A data-driven validator stores each type's required fields in one table and validates any block by looking up its @type. This code defines SCHEMAS mapping three types to their requirements, reads the document's type,

fetches the matching list, and collects missing fields with a comprehension. Adding a new type means adding a table row, so the design scales cleanly.

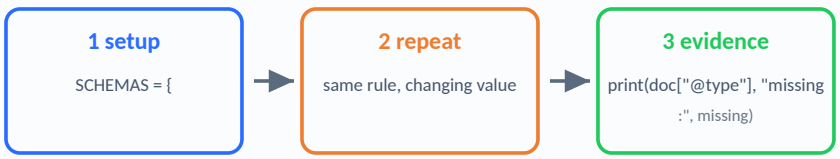
What You'll Build & Learn

Validate any typed block against a central schema-to-fields table.

- One table holds many types' requirements
- Look up requirements by @type
- Comprehension finds missing fields

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 320: validate a review rating is 1 to 5. Project 322 changes the surface problem while preserving the underlying method.



progress check

Reading target: check a type against a schema dict is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `SCHEMAS = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(doc["@type"], "missing:", missing)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`SCHEMAS = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = [f for f in req if f not in doc]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(doc["@type"], "missing:", missing)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [f for f in req if f not in doc]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check a Type Against a Schema Dict: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: Article, headline, author, datePublished, Product. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: SCHEMAS = { | Core: missing = [f for f in req if f not in doc] | Evidence: print(doc["@type"], "missing:", missing)

Reader to Writer Bridge

1. Read: explain check a type against a schema dict in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 320.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 322 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(doc["@type"], "missing:", missing)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `SCHEMAS = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check a type against a schema dict and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Keying the requirements table by `@type` lets one comprehension validate Article, Product or Recipe blocks identically, the heart of a generic schema linter.

```
SCHEMAS = {
    "Article": ["headline", "author", "datePublished"],
    "Product": ["name", "offers"],
    "Recipe": ["name", "recipeIngredient", "recipeInstructions"],
}
doc = {"@type": "Recipe", "name": "Soup", "recipeIngredient": ["water"]}
req = SCHEMAS[doc["@type"]]
missing = [f for f in req if f not in doc]
print(doc["@type"], "missing:", missing)
```

```
output
Recipe missing: ['recipeInstructions']
```

How it works:

1. SCHEMAS maps Article, Product, and Recipe to their required field lists.
2. The doc declares Recipe with name and one ingredient but no instructions.
3. req fetches SCHEMAS[doc['@type']] and the comprehension prints the single missing field recipeInstructions.

Try it:

1. Add Event and LocalBusiness rows to SCHEMAS
2. Handle an unknown @type gracefully with dict.get
3. Load the SCHEMAS table from an external JSON file
4. Add the missing `recipeInstructions` and watch the list empty.

⚠ Common Mistakes

- A block whose `@type` is not a key in `SCHEMAS` raises KeyError; unknown types need an explicit branch.
- Storing required fields as a comma string instead of a list breaks the `in` iteration.
- Mutating `req` (the shared list) inside the loop would corrupt the table for later blocks.

Skills gained dict-driven design | list comprehension | schema table | @type lookup

→ Where You'll Use This: A production structured-data linter is built exactly this way: a registry of types and their rules so one engine validates an entire site's mixed markup from a single table.

Mental Model

Like a rulebook indexed by category: look up the entry for your kind of thing and the required checklist comes back, no special-casing per type.

Project 322 Check Rich-Result Eligibility

The Idea Behind It

A block earns a rich result only when it has every required field for its type. This code stores Product's requirements, then iterates a small catalog computing each entry's missing fields. A product with no gaps prints eligible; one lacking image prints needs ['image']. It scales the single-block check across many products in one loop.

What You'll Build & Learn

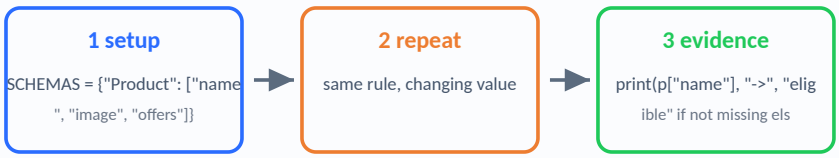
Report rich-result eligibility for each product in a small catalog.

- Eligibility means no missing required fields
- Loop applies the check per product
- Report the specific gaps

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 321: check a type against a schema dict. Project 323 changes the surface problem while preserving the underlying method.

progress check



Reading target: check rich-result eligibility is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `SCHEMAS = {"Product": ["name", "image", "offers"]}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(p["name"], "->", "eligible" if not missing else f"needs {missing}")` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`SCHEMAS = {"Product": ["name", "image", "offers"]}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = [f for f in req if f not in p]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(p["name"], "->", "eligible" if not missing else f"needs {missing}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [f for f in req if f not in p]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Intent	Check Rich-Result Eligibility: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: Product, name, image, offers, products. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: SCHEMAS = {"Product": ["name", "image", "offers"]} | Core: missing = [f for f in req if f not in p] | Evidence: print(p["name"], "->", "eligible" if not missing else f"needs {missing}...

Reader to Writer Bridge

1. Read: explain check rich-result eligibility in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 321.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 323 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(p["name"], "->", "eligible" if not missing else f"needs {missing}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `SCHEMAS = {"Product": ["name", "image", "offers"]}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check rich-result eligibility and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Eligibility is just an empty missing-field list; reporting the gap for ineligible products tells the author exactly what to add.

```
SCHEMAS = {"Product": ["name", "image", "offers"]}
products = [
    {"@type": "Product", "name": "A", "image": "a.jpg", "offers": {}},
    {"@type": "Product", "name": "B", "offers": {}},
]
req = SCHEMAS["Product"]
for p in products:
    missing = [f for f in req if f not in p]
    print(p["name"], "->", "eligible" if not missing else f"needs {missing}")
```

```
output
A -> eligible
B -> needs ['image']
```

How it works:

1. SCHEMAS maps Product to name, image, offers.
2. products is a two-item list; A has all three, B lacks image.
3. The loop computes missing per product and prints eligible or needs plus the missing list, marking B as needing image.

Try it:

1. Count how many products are eligible overall
2. Write the failing products to a separate report list
3. Add a second type and dispatch each block by its @type
4. Give product B an `image` and watch it become eligible.

⚠ Common Mistakes

- Treating an empty `offers` dict as missing would wrongly disqualify product A; presence of the key, not its contents, is checked here.
- Calling a product eligible when it merely has the keys but with empty values is a deeper trap to watch for.
- Sharing the `req` list and appending to it inside the loop pollutes later iterations.

Skills gained loop eligibility check list comprehension catalog audit

→ **Where You'll Use This:** Before a deploy you sweep the whole product catalog and get a list of which pages will earn price snippets and which need a field added, turning validation into an action list.

Mental Model

Like a bouncer with a guest list: each product is checked against the requirements and either waved through or told what credential it is missing.

Project 323 Detect a Wrong @type Value

The Idea Behind It

A typo in @type silently disables structured data because engines ignore types they do not recognize. This code holds a set of known type names, then loops over documents checking each @type for membership. Article passes as known while Artical and Prodcut, simple misspellings, print unknown type, surfacing errors that would otherwise vanish without warning.

What You'll Build & Learn

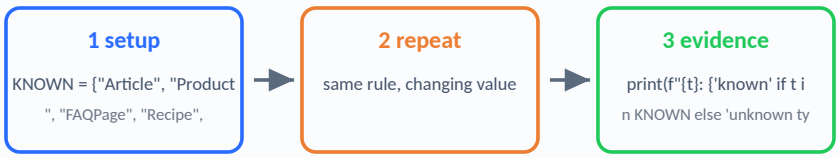
Catch misspelled @type values by checking against a known-types set.

- Unknown types are silently ignored
- A known-types set catches typos
- Set membership is the test

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 322: check rich-result eligibility. Project 324 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect a wrong @type value is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `KNOWN = {"Article", "Product", "FAQPage", "Recipe", "Event", "LocalBusiness"}` gives the program its first fact, tool, or entry point. Use it as the anchor for the

later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{t}: {'known' if t in KNOWN else 'unknown type'}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`KNOWN = {"Article", "Product", "FAQPage", "Recipe", "Event", "LocalBusiness"}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

🛠️ Reader to Writer Bridge

1. Read: explain detect a wrong @type value in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 322.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 324 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{t}: {'known' if t in KNOWN else 'unknown type'}")`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `KNOWN = {"Article", "Product", "FAQPage", "Recipe", "Event", "LocalBusiness"}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a wrong @type value and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Validating the `@type` against a curated set of known types catches the silent failures that come from misspelling a schema name.

```
KNOWN = {"Article", "Product", "FAQPage", "Recipe", "Event", "LocalBusiness"}
docs = [
    {"@type": "Article"},
    {"@type": "Artical"},
    {"@type": "Prodcut"},
]
for d in docs:
    t = d["@type"]
    print(f"{t}: {'known' if t in KNOWN else 'unknown type'}")
```

```
output
Article: known
Artical: unknown type
Prodcut: unknown type
```

How it works:

1. KNOWN is a set of six valid schema type names.
2. docs holds three blocks: Article plus the typos Artical and Prodcut.
3. The loop reads each @type into t and prints known or unknown type via t in KNOWN, flagging both misspellings.

Try it:

1. Suggest the closest known type using difflib for a near miss
2. Pull KNOWN from a complete list of schema.org types
3. Also flag a block missing the @type key entirely
4. Add `WebPage` to the known set and test it.

⚠ Common Mistakes

- Case-folding mismatches: `article` (lowercase) would be flagged unknown because schema types are PascalCase.
- Maintaining the known-types set by hand means a real new type can be wrongly rejected.

- Checking only that `@type` exists, not that its value is recognised, misses typos entirely.

Skills gained set membership | @type validation | loop | typo detection

→ Where You'll Use This: Hand-edited or template-generated markup easily introduces a type typo that breaks rich results invisibly; this check is a cheap guard that runs across every page's @type.

Mental Model

Like spell-checking a destination on a parcel: Artical is not on the route map, so the package quietly goes nowhere.

Project 324 Validate a Date Field With strptime

The Idea Behind It

Schema date fields must be ISO-8601 YYYY-MM-DD, and parsing is the cleanest way to validate them. This code loops over candidate strings inside a try block, calling datetime.strptime with the ISO format. A successful parse means valid ISO; a ValueError is caught and reported as bad format, so an impossible date or a slashed US format both fail clearly.

What You'll Build & Learn

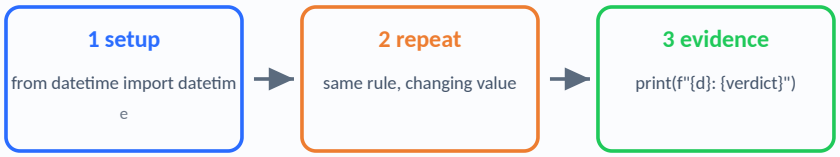
Validate date strings as ISO-8601 by parsing with strptime.

- Schema dates use YYYY-MM-DD
- strptime parses against a format
- A ValueError signals a bad date

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 323: detect a wrong @type value. Project 325 changes the surface problem while preserving the underlying method.

progress check



Reading target: validate a date field with strptime is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from datetime import datetime` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{d}: {verdict}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from datetime import datetime`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`for d in dates:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{d}: {verdict}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for d in dates:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate a Date Field With strptime: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: datetime, dates, strptime, verdict, valid. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from datetime import datetime | Core: for d in dates: | Evidence: print(f"{d}: {verdict}")

🛠️ Reader to Writer Bridge

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 323.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 325 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{d}: {verdict}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from datetime import datetime` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of validate a date field with strptime and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`strptime` with the `%Y-%m-%d` pattern both checks the shape and the real calendar bounds, so month 13 and a US-style slash date are both rejected.

```
from datetime import datetime
dates = ["2026-01-15", "2026-13-40", "01/15/2026"]
for d in dates:
    try:
        datetime.strptime(d, "%Y-%m-%d")
        verdict = "valid ISO"
    except ValueError:
        verdict = "bad format"
    print(f"{d}: {verdict}")
```

```
output
2026-01-15: valid ISO
2026-13-40: bad format
01/15/2026: bad format
```

How it works:

1. dates lists a valid date, an impossible 2026-13-40, and a US-style 01/15/2026.
2. The loop tries datetime.strptime(d, '%Y-%m-%d') inside a try.
3. A clean parse sets valid ISO; the except ValueError sets bad format, so only the first date passes.

Try it:

1. Add ISO date-time support by trying a second format on failure
2. Return the parsed datetime object on success
3. Reject future dates for a datePublished field
4. Accept a full datetime by switching the pattern to include `T%H:%M`.

⚠ Common Mistakes

- Catching a bare `except` instead of `ValueError` would also swallow unrelated bugs.
- A loose regex like `\d{4}-\d{2}-\d{2}` would accept the impossible `2026-13-40` that strptime correctly rejects.
- Relying on `datetime.now` for a reference date is forbidden and unnecessary; format validation needs no clock.

Skills gained `strptime` `try/except` `ISO-8601 date` `ValueError`

→ **Where You'll Use This:** datePublished, uploadDate, and startDate must all parse as ISO dates; this validation catches a content team pasting a localized or impossible date that would invalidate the block.

Mental Model

Like handing a date to a strict clerk who only accepts one form; if they can fill it in, it is valid, if they choke, it is rejected.

Project 325 Find Gaps in Breadcrumb Positions

The Idea Behind It

A breadcrumb numbered 1, 2, 4 has a hole that breaks the chain. This code sorts the present positions, builds the full expected range up to the maximum as a set, and subtracts to find the gaps. The set difference pinpoints the missing 3. It detects skips that simple ordering checks would miss because the sequence still rises.

What You'll Build & Learn

Find skipped positions in a breadcrumb using set difference.

- Set difference finds missing numbers
- range to the max builds the full set
- Sorting normalizes the input

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 324: validate a date field with strptime. Project 326 changes the surface problem while preserving the underlying method.

progress check

Reading target: find gaps in breadcrumb positions is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `items = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

- Evidence: `print("gaps:", gaps if gaps else "none")` exposes the result; match it against the output before changing the program. *output proves the trace*

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("gaps:", gaps if gaps else "none")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `items = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find gaps in breadcrumb positions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Building the full expected set from 1 to the maximum position and subtracting the present positions leaves exactly the missing numbers.

```
items = [
    {"position": 1, "name": "Home"},
    {"position": 2, "name": "Blog"},
    {"position": 4, "name": "Post"},
]
```

```
positions = sorted(it["position"] for it in items)
expected = set(range(1, max(positions) + 1))
gaps = sorted(expected - set(positions))
print("positions:", positions)
print("gaps:", gaps if gaps else "none")
```

```
output
positions: [1, 2, 4]
gaps: [3]
```

How it works:

1. items holds positions 1, 2, 4.
2. positions sorts the values and expected is set(range(1, max+1)).
3. gaps is sorted(expected - set(positions)), printing the present positions and the missing 3.

Try it:

1. Also report duplicate positions using a Counter
2. Detect gaps when positions do not start at 1
3. Return the gaps from a function for use in a larger linter
4. Add the missing position-3 item and watch gaps clear.

⚠ Common Mistakes

- Using `len(items)` instead of `max(positions)` as the range top hides a gap that pushes the max beyond the count.
- Forgetting to sort the gap set makes the printed order nondeterministic.
- Subtracting in the wrong direction (`present - expected`) reports extras, not gaps.

Skills gained set difference | range | sorted | gap detection

→ Where You'll Use This: When a CMS drops a middle breadcrumb level, the positions still ascend so a strict ordering check passes; this set-based audit is what actually catches the missing rung.

Mental Model

Like checking a numbered fence for missing pickets: lay out every slot from one to the highest, then see which numbers have no picket.

Project 326 Combine Multiple Types in a Graph

The Idea Behind It

A single page often describes several entities at once, and the @graph array lets one block hold many typed nodes under one shared context. This code builds a graph dict with @context plus an @graph list of Organization, WebSite, and BreadcrumbList nodes. It collects each node's @type with a comprehension and reports the node count, showing how multiple entities coexist.

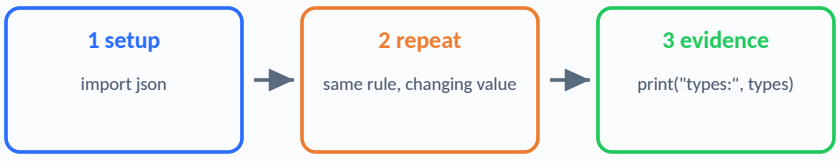
What You'll Build & Learn

Combine several typed entities into one block using @graph.

- @graph holds multiple typed nodes
- One @context covers them all
- Comprehension lists the node types

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 325: find gaps in breadcrumb positions. Project 327 changes the surface problem while preserving the underlying method.



progress check

Reading target: combine multiple types in a graph is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("types:", types)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`types = [node["@type"] for node in graph["@graph"]]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print("types:", types)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `types = [node["@type"] for node in graph["@graph"]]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Combine Multiple Types in a Graph: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, graph, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.

Layer	What to read
Evidence	Entry: import json | Core: types = [node["@type"] for node in graph["@graph"]] | Evidence: print("types:", types)

🛠️ Reader to Writer Bridge

1. Read: explain combine multiple types in a graph in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 325.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 327 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("types:", types)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of combine multiple types in a graph and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`@graph` is an array of independent typed nodes sharing one `@context`, the idiomatic way to declare multiple entities on a page without repeating the context.

```python
import json
graph = {
    "@context": "https://schema.org",
    "@graph": [
        {"@type": "Organization", "name": "Acme"},
        {"@type": "WebSite", "name": "Acme Blog"},
        {"@type": "BreadcrumbList", "itemListElement": []},
    ],
}
types = [node["@type"] for node in graph["@graph"]]
print("nodes:", len(graph["@graph"]))
print("types:", types)
```

```
output
```

```
nodes: 3
types: ['Organization', 'WebSite', 'BreadcrumbList']
```

How it works:

1. The graph dict has @context and an @graph list of three nodes.
2. The nodes declare Organization, WebSite, and BreadcrumbList.
3. types collects each node's @type via a comprehension, and the prints report 3 nodes and the three type names.

Try it:

1. Add an @id to each node so they can cross-reference
2. Append a WebPage node to the graph
3. Count how many distinct types the graph contains using a set
4. Add a `WebPage` node and watch the count rise.

⚠ Common Mistakes

- Giving each node its own `@context` inside `@graph` is redundant and bloats the block.
- Reading `graph['@type']` fails because the top-level object has none; the types live on the nodes.
- Mixing a single-entity layout with a `@graph` layout on the same page confuses parsers.

Skills gained `@graph` `list comprehension` `multiple entities` `shared context`

→ Where You'll Use This: Real homepages emit one @graph describing the organization, the site, the search box, and breadcrumbs together, which is the recommended way to package related markup on a page.

⚡ Mental Model

Like one envelope holding several documents that all share the same letterhead; @context is the letterhead, @graph is the stack inside.

Project 327 Build a HowTo With Steps

💡 The Idea Behind It

A HowTo turns a tutorial into numbered, individually displayable steps in search. This code builds the howto dict with a step list of HowToStep objects, each carrying its own text. Looping with enumerate starting at 1 restores the human numbering and prints Step 1, Step 2, Step 3, mirroring how the engine renders each step as a distinct instruction.

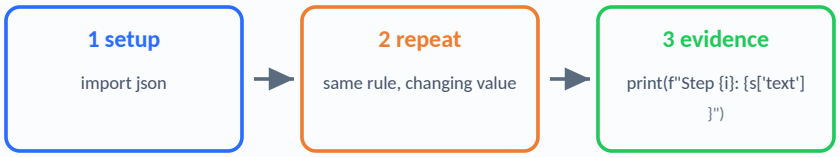
What You'll Build & Learn

Build a HowTo whose ordered HowToStep objects print as numbered steps.

- HowTo holds a step list
- Each step is a HowToStep with text
- enumerate from 1 restores numbering

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 326: combine multiple types in a graph. Project 328 changes the surface problem while preserving the underlying method.



progress check

Reading target: build a howto with steps is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"Step {i}: {s['text']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

Move	Code to inspect	Why it matters
2. Apply the rule	`for i, s in enumerate(howto["step"], 1):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"Step {i}: {s['text']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for i, s in enumerate(howto["step"], 1):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a HowTo With Steps: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, howto, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: for i, s in enumerate(howto["step"], 1): | Evidence: print(f"Step {i}: {s['text']}")

Reader to Writer Bridge

1. Read: explain build a howto with steps in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 326.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 328 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"Step {i}: {s['text']}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a howto with steps and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The `step` array holds ordered `HowToStep` objects; `enumerate(..., 1)` numbers them for display while the array order itself defines the sequence.

```
import json
howto = {
    "@context": "https://schema.org",
    "@type": "HowTo",
    "name": "Change a Tire",
    "step": [
        {"@type": "HowToStep", "text": "Loosen the lug nuts."},
        {"@type": "HowToStep", "text": "Jack up the car."},
        {"@type": "HowToStep", "text": "Swap the tire."},
    ],
}
for i, s in enumerate(howto["step"], 1):
    print(f"Step {i}: {s['text']}")
```

```
output
Step 1: Loosen the lug nuts.
Step 2: Jack up the car.
Step 3: Swap the tire.
```

How it works:

1. The howto dict declares HowTo with a name.
2. step is a list of three HowToStep dicts, each with a text instruction.
3. The loop uses enumerate(howto['step'], 1) and prints Step i and the step text for all three.

Try it:

1. Add an image to each HowToStep
2. Add a tool or supply list to the HowTo
3. Wrap groups of steps in HowToSection objects
4. Add a fourth step and confirm the numbering continues.

⚠ Common Mistakes

- Using the key `steps` (plural) instead of the schema's `step` breaks the HowTo.
- Relying on a `position` field for ordering when HowTo derives order from array index instead.
- Storing steps as raw strings loses the per-step `@type` that lets each render separately.

Skills gained HowTo schema | HowToStep | enumerate | loop

→ Where You'll Use This: Tutorial and instructional pages markup their procedures as HowTo so search can present the steps individually, sometimes with a step-by-step visual carousel.

Mental Model

Like an IKEA instruction sheet: each panel is a self-contained step, numbered so you know the order to follow.

Project 328 Build a VideoObject Entity

The Idea Behind It

A VideoObject lets a video appear as a rich result with a thumbnail and upload date. This code builds the video dict with name, description, thumbnailUrl, uploadDate, and duration, then validates by listing the four required fields and collecting any not in the dict. Since all four are present, the audit prints none, confirming eligibility.

What You'll Build & Learn

Build a VideoObject and confirm its four required fields are present.

- VideoObject enables a video rich result
- Required: name, description, thumbnailUrl, uploadDate
- Comprehension audits presence

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 327: build a howto with steps. Project 329 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build a videoobject entity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("VideoObject missing:", missing if missing else "none")` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`missing = [f for f in required if f not in video]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print("VideoObject missing:", missing if missing else "none")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [f for f in required if f not in video]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a VideoObject Entity: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, video, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: missing = [f for f in required if f not in video] | Evidence: print("VideoObject missing:", missing if missing else "none")

🛠️ Reader to Writer Bridge

1. Read: explain build a videoobject entity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 327.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 329 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("VideoObject missing:", missing if missing else "none")`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a videoobject entity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

VideoObject has four required fields beyond context and type; listing any that are absent confirms eligibility for a video rich result in one check.

```
import json
video = {
    "@context": "https://schema.org",
    "@type": "VideoObject",
    "name": "Intro to SEO",
    "description": "A short primer.",
    "thumbnailUrl": "https://example.com/thumb.jpg",
    "uploadDate": "2026-02-01",
    "duration": "PT3M30S",
}
required = ["name", "description", "thumbnailUrl", "uploadDate"]
missing = [f for f in required if f not in video]
print("VideoObject missing:", missing if missing else "none")
```

```
output
VideoObject missing: none
```

How it works:

1. The video dict declares VideoObject with name, description, thumbnailUrl, uploadDate, and a duration.
2. required lists the four mandatory fields.
3. The comprehension keeps any required field not in video, and the print reports none since all four exist.

Try it:

1. Add a contentUrl and embedUrl to the block
2. Validate uploadDate parses as an ISO date
3. Add a duration regex check for the ISO-8601 form
4. Remove `description` and watch it appear in the missing list.

⚠ Common Mistakes

- Spelling `thumbnailUrl` as `thumbnailURL` (wrong casing) makes the required field appear missing.
- Providing `duration` but omitting `uploadDate` still fails, since duration is optional and uploadDate is required.

- Writing `duration` as `3:30` rather than the ISO `PT3M30S` breaks any duration-based feature.

Skills gained VideoObject | required fields | list comprehension | audit

→ Where You'll Use This: Pages hosting or embedding video emit VideoObject markup so the clip can show with a thumbnail and date in search and the dedicated video results, driving extra visibility.

⚡ Mental Model

Like a video's poster frame and release date on a streaming tile: the four required fields are the tile's caption and image.

Project 329 Build a Review With an Author

💡 The Idea Behind It

A standalone Review names what it reviews, the star rating given, and who wrote it, each as a nested typed object. This code builds the review dict where itemReviewed is a Product, reviewRating is a Rating with ratingValue and bestRating, and author is a Person. The prints reach into each sub-dict to surface the reviewed item, the score, and the author name.

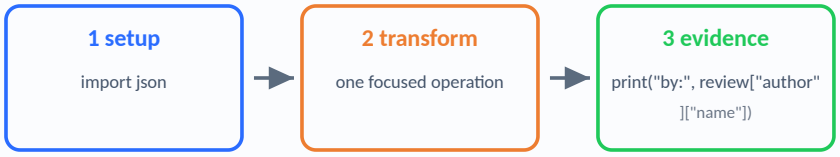
What You'll Build & Learn

Build a Review linking a reviewed item, a rating, and an author.

- itemReviewed, reviewRating, author all nest
- Each is a typed sub-object
- Reach into sub-dicts to read values

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 328: build a videoobject entity. Project 330 changes the surface problem while preserving the underlying method. *progress check*



Reading target: build a review with an author is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

- Evidence: `print("by:", review["author"]["name"])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print("by:", review["author"]["name"])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Build a Review With an Author: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, review, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print("by:", review["author"]["name"])

🛠️ Reader to Writer Bridge

1. Read: explain build a review with an author in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 328.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 330 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("by:", review["author"]["name"])`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a review with an author and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A Review threads together three typed sub-objects: the `itemReviewed` Product, the `reviewRating` Rating, and the `author` Person, each addressed by drilling into nested keys.

```python
import json
review = {
    "@context": "https://schema.org",
    "@type": "Review",
    "itemReviewed": {"@type": "Product", "name": "Blender"},
    "reviewRating": {"@type": "Rating", "ratingValue": 4, "bestRating": 5},
    "author": {"@type": "Person", "name": "Pat Kim"},
}
print("reviewed:", review["itemReviewed"]["name"])
print("rating:", review["reviewRating"]["ratingValue"])
print("by:", review["author"]["name"])
```

```
output
reviewed: Blender
rating: 4
by: Pat Kim
```

How it works:

1. The review dict declares Review.
2. itemReviewed is a nested Product, reviewRating is a Rating with ratingValue 4 and bestRating 5, and author is a Person.
3. The prints read review['itemReviewed']['name'], the ratingValue, and the author name.

Try it:

1. Add a reviewBody field with the prose
2. Add a datePublished to the review
3. Include a worstRating on the Rating and validate the range
4. Add a `reviewBody` with the prose of the review.

⚠ Common Mistakes

- Confusing `reviewRating` (one reviewer's score) with `aggregateRating` (the average of many).
- Putting the rating number directly on the Review instead of inside a `Rating` object.
- Naming the field `itemReviewed` is required; `reviewedItem` will not parse.

Skills gained Review schema | nested objects | Rating | dict access

→ Where You'll Use This: Editorial and product-review pages emit a Review block so the star rating and reviewer can show in search, distinct from aggregated ratings drawn from many reviewers.

⚡ Mental Model

Like a movie review byline: the film reviewed, the stars awarded, and the critic's name, here each filed as its own labeled card.

Project 330 Build a Sitelinks Searchbox

💡 The Idea Behind It

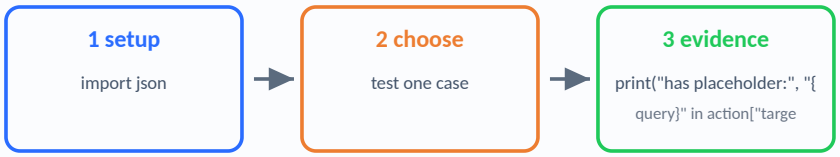
A WebSite block with a SearchAction can grant a search box directly in Google's results. This code builds the site dict whose potentialAction is a SearchAction with a target URL and a query-input spec. The target embeds a {query} placeholder the engine fills with the user's term. The code reads the action type and confirms the placeholder is present.

What You'll Build & Learn

Build a WebSite SearchAction enabling a sitelinks search box.

- potentialAction holds a SearchAction
- target embeds a {query} placeholder
- query-input names the bound parameter

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 329: build a review with an author. Project 331 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build a sitelinks searchbox is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("has placeholder:", "{query}" in action["target"])` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. slow line
3. Check the evidence	`print("has placeholder:", "{query}" in action["target"])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Build a Sitelinks Searchbox: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, site, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print("has placeholder:", "{query}" in action["target"])

🛠️ Reader to Writer Bridge

1. Read: explain build a sitelinks searchbox in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 329.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 331 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("has placeholder:", "{query}" in action["target"])`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a sitelinks searchbox and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The `potentialAction` is a `SearchAction` whose `target` must contain a `{query}` token matching the name declared in `query-input`, wiring the results-page search box to your site search.

```
import json
site = {
    "@context": "https://schema.org",
    "@type": "WebSite",
    "url": "https://example.com",
    "potentialAction": {
```

```
        "@type": "SearchAction",
        "target": "https://example.com/search?q={query}",
        "query-input": "required name=query",
    },
}
action = site["potentialAction"]
print("action:", action["@type"])
print("has placeholder:", "{query}" in action["target"])
```

```
output
action: SearchAction
has placeholder: True
```

How it works:

1. The site dict declares WebSite with a url.
2. potentialAction is a SearchAction with a target URL containing {query} and a query-input string.
3. action aliases it, printing the action type SearchAction and confirming {query} is in the target via membership.

Try it:

1. Add a urlTemplate-style EntryPoint object for the target
2. Validate the query-input names the same parameter as the placeholder
3. Support a second SearchAction for an app deep link
4. Change the placeholder name to `{search_term}` and update `query-input` to match.

⚠ Common Mistakes

- Forgetting the `{query}` placeholder in `target` means the engine has nowhere to inject the search term.
- Mismatching the placeholder name and the `name=` in `query-input` breaks the binding.
- Using `potentialActions` (plural) instead of the singular key fails the schema.

Skills gained SearchAction | potentialAction | string membership | WebSite schema

→ Where You'll Use This: Site-search-enabled homepages add this so Google can show a search box in the brand's result, letting users query the site straight from the SERP.

Mental Model

Like handing the search engine a fill-in-the-blank form: {query} is the blank, and the engine writes the visitor's words into it.

Project 331 Mark Text as Speakable

The Idea Behind It

The speakable property tells voice assistants which parts of a page to read aloud, chosen by CSS selectors. This code builds a WebPage whose speakable is a SpeakableSpecification listing a cssSelector array targeting the headline and summary. The code reads that selector list, reports its length, and joins the selectors into a readable line for inspection.

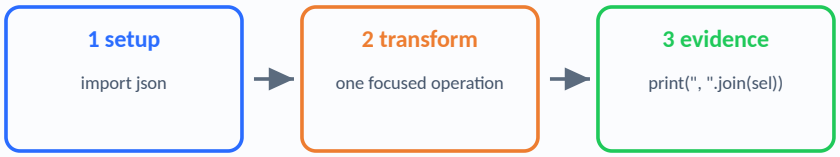
What You'll Build & Learn

Mark a WebPage's headline and summary as speakable via CSS selectors.

- speakable targets voice assistants
- SpeakableSpecification holds cssSelector
- Selectors choose readable regions

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 330: build a sitelinks searchbox. Project 332 changes the surface problem while preserving the underlying method.



progress check

Reading target: mark text as speakable is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(", ".join(sel))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`"@context": "https://schema.org",`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(", ".join(sel))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `"@context": "https://schema.org",`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Mark Text as Speakable: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, page, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: "@context": "https://schema.org", | Evidence: print(", ".join(sel))

🛠️ Reader to Writer Bridge

1. Read: explain mark text as speakable in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 330.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 332 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(", ".join(sel))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of mark text as speakable and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`speakable` is a `SpeakableSpecification` whose `cssSelector` array points at the on-page elements an assistant should voice, joined here for a readable summary.

```
import json
page = {
    "@context": "https://schema.org",
    "@type": "WebPage",
    "name": "Daily News",
    "speakable": {
        "@type": "SpeakableSpecification",
        "cssSelector": [".headline", ".summary"],
    },
}
sel = page["speakable"]["cssSelector"]
print("speakable selectors:", len(sel))
print(", ".join(sel))
```

```
output
speakable selectors: 2
.headline, .summary
```

How it works:

1. The page dict declares WebPage with a name.
2. speakable is a SpeakableSpecification whose cssSelector lists .headline and .summary.
3. sel aliases that list, len reports 2 selectors, and join prints them comma-separated.

Try it:

1. Support xpath instead of cssSelector as an alternative
2. Validate each selector starts with a dot or hash
3. Add a third selector for the article lede
4. Add a `.byline` selector and watch the count rise.

⚠ Common Mistakes

- Putting a single selector as a bare string instead of a list makes `len()` count characters.
- Using an `xpath` array and a `cssSelector` array together when only one addressing scheme should be chosen.
- Selecting a hidden or boilerplate element that should not be read aloud.

Skills gained `speakable` `SpeakableSpecification` `cssSelector` `str.join`

→ Where You'll Use This: News and article pages mark their key passages speakable so voice assistants can read the headline and summary aloud in audio search and smart-speaker results.

⚡ Mental Model

Like highlighting the lines an audiobook narrator should read; the CSS selectors are the highlighter marking what gets voiced.

Project 332 Validate Price Is a Numeric String

💡 The Idea Behind It

An Offer price must be a bare number because priceCurrency carries the unit separately. This code loops over offers, pulls each price, and tries float on it inside a try block. A clean parse prints valid; a value with a currency symbol or the word free raises ValueError and prints not numeric, catching the two common mistakes that break the price.

What You'll Build & Learn

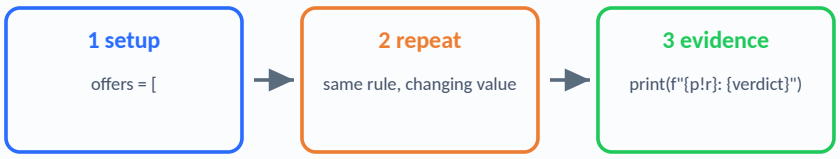
Validate that each Offer price is a parseable bare number.

- Price must be a bare numeric string
- priceCurrency carries the unit

- float parsing flags bad prices

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 331: mark text as speakable. Project 333 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate price is a numeric string is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `offers = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{p!r}: {verdict}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`offers = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`for o in offers:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f"{p!r}: {verdict}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for o in offers:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate Price Is a Numeric String: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: offers, price, priceCurrency, free, verdict. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: offers = [| Core: for o in offers: | Evidence: print(f"{p!r}: {verdict}")

Reader to Writer Bridge

1. Read: explain validate price is a numeric string in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 331.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 333 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{p!r}: {verdict}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `offers = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate price is a numeric string and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`float()` succeeds only on a clean numeric string, so wrapping it in a try/except cleanly separates schema-legal prices from ones polluted by symbols or words.

```
offers = [
    {"price": "19.99", "priceCurrency": "USD"},
    {"price": "$19.99", "priceCurrency": "USD"},
    {"price": "free", "priceCurrency": "USD"},
]
for o in offers:
    p = o["price"]
    try:
        float(p)
        verdict = "valid"
    except ValueError:
        verdict = "not numeric"
    print(f"{p!r}: {verdict}")
```

```
output
'19.99': valid
'$19.99': not numeric
'free': not numeric
```

How it works:

1. offers lists prices 19.99, $19.99, and free.
2. The loop reads each price into p.
3. float(p) inside a try sets valid; the except ValueError sets not numeric, so the symbol and the word both fail while the bare number passes.

Try it:

1. Strip a leading currency symbol then re-validate
2. Reject negative prices even though they parse
3. Report the offending offers as a list at the end
4. Add a thousands-separated price like `1,299.00` and see it rejected.

⚠ Common Mistakes

- Embedding a currency symbol in `price` (`$19.99`) duplicates what `priceCurrency` already states and fails validation.
- Using a comma decimal separator (`19,99`) also fails `float()` and needs locale handling.
- Catching every exception instead of `ValueError` would hide real bugs.

Skills gained float parsing | try/except | Offer price | ValueError

→ Where You'll Use This: Feeds often arrive with currency symbols glued to the price; this validation forces the markup to use a clean numeric price with the currency declared separately as Google requires.

Mental Model

Like a scale that weighs only the goods, not the packaging; the price field holds the number alone and the currency rides separately.

Project 333 Validate a Currency Code Is ISO 4217

The Idea Behind It

The priceCurrency must be a three-letter ISO 4217 code in uppercase, such as USD or EUR. This code holds a set of valid codes, then loops over offers checking each currency for membership. A correct code passes while a symbol like US$ or a lowercase eur fails, catching both symbol intrusion and case drift in one membership test.

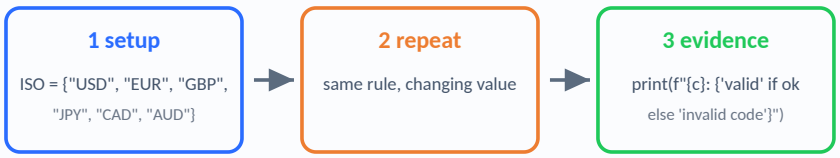
What You'll Build & Learn

Validate each priceCurrency against a set of ISO 4217 codes.

- priceCurrency is an ISO 4217 code
- It must be uppercase three letters
- Set membership rejects symbols and case drift

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 332: validate price is a numeric string. Project 334 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate a currency code is iso 4217 is the surface task; the transferable Python move is to mark setup, rule, and output before running. setup -> rule -> result

🔎 Logic Lens

- Setup: `ISO = {"USD", "EUR", "GBP", "JPY", "CAD", "AUD"}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. repeat, test, update
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{c}: {'valid' if ok else 'invalid code'}")` exposes the result; match it against the output before changing the program. output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`ISO = {"USD", "EUR", "GBP", "JPY", "CAD", "AUD"}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"{c}: {'valid' if ok else 'invalid code'}")`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"{c}: {'valid' if ok else 'invalid code'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the

behaviour.

CORE LINE `print(f"{c}: {'valid' if ok else 'invalid code'}")`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate a Currency Code Is ISO 4217: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: offers, priceCurrency, US, eur, ok. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: ISO = {"USD", "EUR", "GBP", "JPY", "CAD", "AUD"} | Core: print(f"{c}: {'valid' if ok else 'invalid code'}") | Evidence: print(f"{c}: {'valid' if ok else 'invalid code'}")

🛠️ Reader to Writer Bridge

1. Read: explain validate a currency code is iso 4217 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 332.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 334 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{c}: {'valid' if ok else 'invalid code'}")`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `ISO = {"USD", "EUR", "GBP", "JPY", "CAD", "AUD"}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate a currency code is iso 4217 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A set-membership test enforces the closed ISO 4217 vocabulary, catching both the symbol `US$` and the lowercase `eur` that schema.org would not accept.

```
ISO = {"USD", "EUR", "GBP", "JPY", "CAD", "AUD"}
offers = [
    {"priceCurrency": "USD"},
    {"priceCurrency": "US$"},
    {"priceCurrency": "eur"},
]
for o in offers:
    c = o["priceCurrency"]
    ok = c in ISO
    print(f"{c}: {'valid' if ok else 'invalid code'}")
```

```
output
USD: valid
US$: invalid code
eur: invalid code
```

How it works:

1. ISO is a set of six valid uppercase currency codes.
2. offers lists USD, the symbol US$, and lowercase eur.
3. The loop reads each c, tests c in ISO, and prints valid or invalid code, rejecting both the symbol and the lowercase value.

Try it:

1. Uppercase each code before checking to tolerate case drift
2. Load the full ISO 4217 list rather than six codes
3. Map a symbol like $ to USD before validating
4. Uppercase the value first so `eur` passes.

⚠ Common Mistakes

- Allowing lowercase by not normalising means `eur` slips through if you `.upper()` before checking but forget the codes are case-sensitive in the data.
- Confusing the currency symbol (`$`) with the ISO code (`USD`).

- Maintaining only a partial ISO set rejects valid but uncommon codes.

Skills gained set membership ISO 4217 currency validation loop

→ Where You'll Use This: Catalog feeds sometimes carry currency symbols or lowercase codes; this gate enforces the exact uppercase three-letter codes the structured-data spec demands before the price ships.

Mental Model

Like an international form that only accepts the airport-style three-letter code; a dollar sign or lowercase entry is simply not recognized.

Project 334 Validate an ISO 8601 Duration

The Idea Behind It

Schema durations such as cookTime use ISO-8601's PnYnMnDTnHnMnS form, most often the simple PT15M. This code compiles a regex anchoring the PT prefix with optional hour, minute, and second groups, then matches each candidate. A guard rejects a bare PT with no components. Valid durations pass while a phrase like 15 min fails, enforcing the format.

What You'll Build & Learn

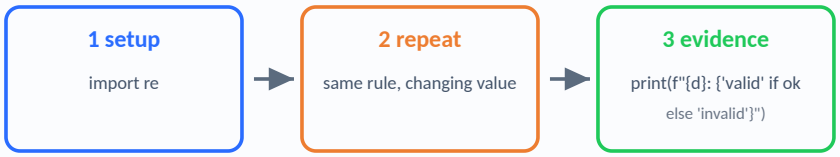
Validate duration strings against the ISO-8601 PT pattern with a regex.

- Durations use the PT prefix form
- A regex anchors optional H, M, S groups
- Guard against an empty PT

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 333: validate a currency code is iso 4217. Project 335 changes the surface problem while preserving the underlying method.

progress check



Reading target: validate an iso 8601 duration is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"{d}: {'valid' if ok else 'invalid'}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"{d}: {'valid' if ok else 'invalid'}")`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate an ISO 8601 Duration: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: re, durations, min, pattern, compile. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: print(f"{d}: {'valid' if ok else 'invalid'}") | Evidence: print(f"{d}: {'valid' if ok else 'invalid'}")

🛠️ Reader to Writer Bridge

1. Read: explain validate an iso 8601 duration in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 333.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 335 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{d}: {'valid' if ok else 'invalid'}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of validate an iso 8601 duration and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The pattern anchors on `PT` and accepts optional hour/minute/second groups; the extra `d != 'PT'` guard rejects an empty duration that the optional groups would otherwise allow.

```
import re
durations = ["PT15M", "PT1H30M", "15 min", "PT0S"]
pattern = re.compile(r"^PT(?:\d+H)?(?:\d+M)?(?:\d+S)?$")
for d in durations:
    ok = bool(pattern.match(d)) and d != "PT"
    print(f"{d}: {'valid' if ok else 'invalid'}")
```

```
output
PT15M: valid
PT1H30M: valid
15 min: invalid
PT0S: valid
```

How it works:

1. durations lists PT15M, PT1H30M, the phrase 15 min, and PT0S.
2. pattern compiles a regex requiring PT then optional digit-H, digit-M, digit-S groups.
3. ok combines a successful match with a check that d is not bare PT, so 15 min fails and the rest pass.

Try it:

1. Extend the pattern to allow the date portion like P1DT2H
2. Capture the components and convert to total seconds
3. Reject PT0S as a zero-length duration
4. Add a day component by extending the pattern with `(?:\\d+D)?` after `PT` handling.

⚠ Common Mistakes

- Without the `d != 'PT'` guard the bare `PT` (no components) matches and is wrongly accepted.
- Forgetting to anchor with `^` and `$` lets trailing junk like `PT15Mxx` match.
- Writing a human duration `15 min` instead of the ISO form is the exact error this catches.

Skills gained re.compile | regex anchors | ISO-8601 duration | boolean guard

→ Where You'll Use This: cookTime, duration, and similar fields must be ISO durations; this regex validation catches a human writing 15 min or 1h30 instead of the machine-readable PT form.

⚡ Mental Model

Like a strict timecode format: the engine reads PT15M instantly but stares blankly at the human phrase fifteen minutes.

Project 335 Parse JSON-LD Back From a String

💡 The Idea Behind It

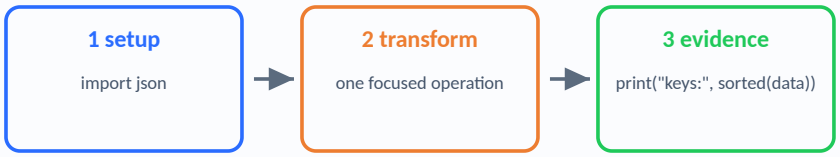
Auditing real pages means reading JSON-LD text back into Python. This code holds a raw JSON string, calls json.loads to turn it into a dict, then inspects the result by printing the @type, the headline, and the sorted keys. The round-trip from text to dict is what lets you examine markup pulled from a live page field by field.

What You'll Build & Learn

Parse a JSON-LD string into a dict and inspect its fields.

- json.loads parses text into a dict
- Inspect parsed fields by key
- sorted lists the keys

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 334: validate an iso 8601 duration. Project 336 changes the surface problem while preserving the underlying method. *progress check*

Reading target: parse json-ld back from a string is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("keys:", sorted(data))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`raw = '{"@context": "https://schema.org", "@type": "Article", "headline": "Hi"}'`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. slow line
3. Check the evidence	`print("keys:", sorted(data))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `raw = '{"@context": "https://schema.org", "@type": "Article", "headline": "Hi"}'`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Parse JSON-LD Back From a String: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, raw, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: raw = '{"@context": "https://schema.org", "@type": "Article", "headline... | Evidence: print("keys:", sorted(data))

🛠️ Reader to Writer Bridge

1. Read: explain parse json-ld back from a string in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 334.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 336 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("keys:", sorted(data))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse json-ld back from a string and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`json.loads` reverses `json.dumps`, parsing the block's text into a dict whose keys (sorted here for stable output) can then be audited.

```
import json
raw = '{"@context": "https://schema.org", "@type": "Article", "headline":
"Hi"}'
data = json.loads(raw)
print("type:", data["@type"])
```

```
print("headline:", data["headline"])
print("keys:", sorted(data))
```

```
output
type: Article
headline: Hi
keys: ['@context', '@type', 'headline']
```

How it works:

1. raw is a JSON string declaring an Article with a headline.
2. json.loads(raw) parses it into the data dict.
3. The prints read data['@type'] and data['headline'], and sorted(data) lists the three keys alphabetically.

Try it:

1. Catch a json.JSONDecodeError on malformed input
2. Parse a string holding an @graph array
3. Pretty-print the parsed dict with json.dumps and indent
4. Add a nested `author` object to the raw string and read it.

⚠ Common Mistakes

- Single-quoting the JSON inside the string makes it invalid JSON; JSON requires double quotes.
- A trailing comma in the source string raises `json.JSONDecodeError`.
- Assuming `data` is a list when a single block parses to a dict (or vice versa for an array).

Skills gained json.loads | parsing | dict inspection | sorted

→ Where You'll Use This: Every page-auditing pipeline starts by parsing the JSON-LD text from a crawl into Python objects so the rest of your validation logic can examine the structured data.

Mental Model

Like decoding a sealed message back into plain words: json.loads opens the envelope so you can read each line.

Project 336 Extract JSON-LD From a Script Tag

The Idea Behind It

On a live page the JSON-LD sits inside a script tag of type application/ld+json. This code holds an HTML string, uses a regex to capture the inner text between the opening and closing script tags, then feeds that captured

group to json.loads. The escaped plus sign in the pattern matches the literal ld+json, and the resulting dict is inspected by key.

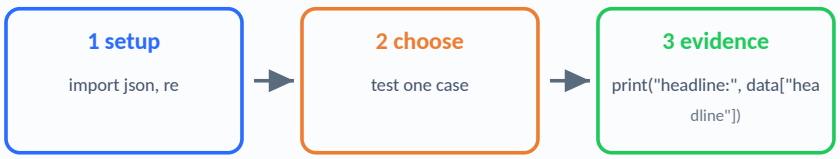
What You'll Build & Learn

Extract JSON-LD from an HTML script tag and parse it.

- JSON-LD lives in a typed script tag
- Regex captures the inner text
- Escape the plus in ld+json

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 335: parse json-ld back from a string. Project 337 changes the surface problem while preserving the underlying method.



progress check

Reading target: extract json-ld from a script tag is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json, re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("headline:", data["headline"])` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json, re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`'<head><title>Page</title>'`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print("headline:", data["headline"])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `'<head><title>Page</title>'`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Extract JSON-LD From a Script Tag: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, re, html, head, title. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json, re | Core: '<head><title>Page</title>' | Evidence: print("headline:", data["headline"])

Reader to Writer Bridge

1. Read: explain extract json-ld from a script tag in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 335.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 337 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("headline:", data["headline"])`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json, re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of extract json-ld from a script tag and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A non-greedy `(.*?)` capture grabs only the script tag's inner JSON, which `json.loads` parses; the `\+` escapes the literal plus in `ld+json`.

```
import json, re
html = (
    '<head><title>Page</title>'
    '<script type="application/ld+json">'
    '{"@type": "Article", "headline": "Found Me"}'
    '</script></head>'
)
m = re.search(r'<script type="application/ld\+json">(.*?)</script>', html)
data = json.loads(m.group(1))
print("extracted @type:", data["@type"])
print("headline:", data["headline"])
```

```
output
extracted @type: Article
headline: Found Me
```

How it works:

1. html is a string containing a head with a script of type application/ld+json holding an Article.
2. re.search captures the inner JSON with a pattern escaping the plus.
3. json.loads(m.group(1)) parses it, and the prints show the @type and headline.

Try it:

1. Use re.findall to extract multiple script blocks from one page
2. Add re.DOTALL so the pattern spans newlines
3. Fall back gracefully when no script tag matches
4. Add a second JSON-LD script and switch to `re.findall` to get both.

⚠ Common Mistakes

- Forgetting to escape the `+` in `ld+json` makes the regex match a repeated `d`, not the literal tag.
- A greedy `(.*)` would swallow everything up to the last `</script>` on a multi-block page.
- Regex-parsing HTML is brittle; a real auditor would use an HTML parser for nested or attribute-reordered tags.

Skills gained re.search | regex capture | json.loads | HTML extraction

→ Where You'll Use This: Scraping structured data from fetched pages means locating each ld+json script tag and parsing its contents, the core step in any large-scale structured-data audit crawler.

⚡ Mental Model

Like fishing a note out of a labeled drawer: the script tag is the drawer, the regex is the hand that pulls the note, json.loads reads it.

Project 337 Validate AggregateOffer Low and High

💡 The Idea Behind It

An AggregateOffer summarizes many sellers with a lowPrice and a highPrice, and the low must not exceed the high. This code reads both prices, floats them to compare numerically, and checks lo <= hi. A valid band prints valid range; an inverted pair would print low > high. It is a quick numeric sanity check on the price span.

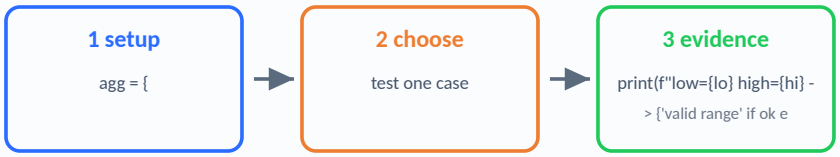
What You'll Build & Learn

Validate that an AggregateOffer's low price does not exceed its high.

- AggregateOffer spans many sellers
- lowPrice must not exceed highPrice
- float for numeric comparison

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 336: extract json-ld from a script tag. Project 338 changes the surface problem while preserving the underlying method. *progress check*



Reading target: validate aggregateoffer low and high is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `agg = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`agg = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Validate AggregateOffer Low and High: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: agg, type, AggregateOffer, lowPrice, highPrice. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: agg = { | Core: print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}") | Evidence: print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")

Reader to Writer Bridge

1. Read: explain validate aggregateoffer low and high in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 336.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 338 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `agg = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate aggregateoffer low and high and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Casting the price strings to floats lets a numeric comparison confirm the band is ordered; an AggregateOffer with low above high is incoherent.

```
agg = {
    "@type": "AggregateOffer",
    "lowPrice": "29.00",
    "highPrice": "59.00",
    "priceCurrency": "USD",
    "offerCount": 4,
}
lo = float(agg["lowPrice"])
hi = float(agg["highPrice"])
ok = lo <= hi
print(f"low={lo} high={hi} -> {'valid range' if ok else 'low > high'}")
```

```
output
low=29.0 high=59.0 -> valid range
```

How it works:

1. The agg dict declares AggregateOffer with lowPrice, highPrice, priceCurrency, and offerCount.
2. lo and hi float-parse the two price strings.
3. ok checks lo <= hi, and the f-string prints the numeric low and high plus a valid range or low > high verdict.

Try it:

1. Also confirm offerCount is a positive integer
2. Validate both prices parse as numbers before comparing
3. Check the currency code against an ISO set as well
4. Swap the two prices and watch the verdict flip.

⚠ Common Mistakes

- Comparing the price strings directly (`'29.00' <= '59.00'`) happens to work here but fails lexically once values differ in length, e.g. `'100' < '29'`.
- Forgetting `offerCount` leaves the aggregate without the seller tally it should report.
- Swapping `lowPrice` and `highPrice` produces a silently inverted, invalid band.

Skills gained float | AggregateOffer | range check | f-strings

→ Where You'll Use This: Comparison and marketplace pages emit an AggregateOffer for a product sold by many merchants; this guards against a feed bug that swaps the low and high price bounds.

Mental Model

Like a price range on a listing: the from price must sit below the to price, or the band reads backwards and makes no sense.

Project 338 Audit a Full Product JSON-LD Block

The Idea Behind It

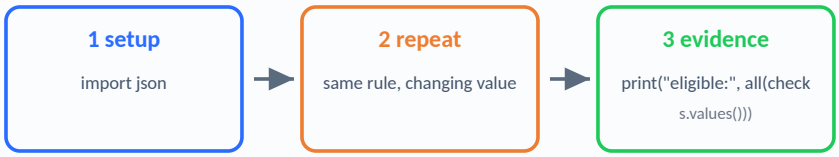
This capstone ties the chapter together with one audit over a Product block. It builds a checks dict whose values are boolean tests of the context, type, name, image, and the nested offer price, using get to read fields safely. Looping prints PASS or FAIL per check, and all over the values declares overall rich-result eligibility from the combined verdicts.

What You'll Build & Learn

Run a combined audit of a Product block and declare eligibility.

- A checks dict maps names to boolean tests
- dict.get reads fields safely
- all over the values gives the verdict

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 337: validate aggregateoffer low and high. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: audit a full product json-ld block is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
- Evidence: `print("eligible:", all(checks.values()))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
2. Apply the rule	`print(f"{k}: {'PASS' if ok else 'FAIL'}")`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print("eligible:", all(checks.values()))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Structured Data and Rich Results becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f"{k}: {'PASS' if ok else 'FAIL'}")`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Audit a Full Product JSON-LD Block: connect the surface task to the chapter skill, generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.
Names	Watch these names first: json, product, context, https, schema. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: print(f"{k}: {'PASS' if ok else 'FAIL'}") | Evidence: print("eligible:", all(checks.values()))

🛠️ Reader to Writer Bridge

1. Read: explain audit a full product json-ld block in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 337.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print("eligible:", all(checks.values()))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of audit a full product json-ld block and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each named check evaluates to a boolean, and `all(checks.values())` collapses them into a single eligibility verdict, the skeleton of a real structured-data linter.

```
import json
product = {
    "@context": "https://schema.org",
    "@type": "Product",
    "name": "Trail Runner Shoe",
    "image": "https://example.com/shoe.jpg",
    "offers": {
        "@type": "Offer",
        "price": "89.99",
        "priceCurrency": "USD",
        "availability": "https://schema.org/InStock",
    },
}
checks = {
    "@context": product.get("@context") == "https://schema.org",
    "@type": product.get("@type") == "Product",
    "name": bool(product.get("name")),
    "image": bool(product.get("image")),
    "offer price": "price" in product.get("offers", {}),
}
for k, ok in checks.items():
    print(f"{k}: {'PASS' if ok else 'FAIL'}")
print("eligible:", all(checks.values()))
```

```
output
@context: PASS
@type: PASS
name: PASS
image: PASS
offer price: PASS
eligible: True
```

How it works:

1. product is a full Product with name, image, and a nested Offer.
2. The checks dict tests @context, @type, name, image, and offer price using get and bool.
3. The loop prints PASS or FAIL per check, and all(checks.values()) prints eligible True.

Try it:

1. Add a check that priceCurrency is a valid ISO code
2. Report only the failing check names at the end
3. Generalize the audit to dispatch checks by the block's @type
4. Remove the `image` key and watch eligibility turn False.

⚠ Common Mistakes

- Using `product['offers']['price']` instead of `'price' in product.get('offers', {})` raises KeyError when `offers` is absent.
- Checking `product['name']` truthiness with `bool(...)` treats an empty string as a fail, which is the intent but surprises if names can legitimately be blank.
- Returning eligibility before printing the per-field results hides why a block failed.

Skills gained dict.get | all | boolean checks | Product audit

→ Where You'll Use This: This is the template for a real per-page structured-data linter: a named set of boolean assertions whose combined result is a single ship-or-fix verdict for each block.

⚡ Mental Model

Like a pre-flight checklist: each item gets a green or red light, and the plane only takes off when every light is green.

✅ Chapter Progress Checkpoint

What this chapter added: after 37 mini-projects, Structured Data and Rich Results should feel like a reusable Python move: generate and validate json-ld for article, product, faq, localbusiness and breadcrumb.

chapter checkpoint

1 Read
Open any project from Projects 302-338 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 10 (International SEO and hreflang) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall | 2 Meaning | 3 Structure | 1 Transfer

9.1.Q1 Recall MEDIUM Turn back to Project 307 (Count Question and Answer Pairs). Without running it, what exactly does it print?

9.1.Q2 Meaning MEDIUM Turn back to Project 309 (Validate Breadcrumb Position Ordering). Without running it, what exactly does it print?

9.1.Q3 Structure MEDIUM Turn back to Project 322 (Check Rich-Result Eligibility). Without running it, what exactly does it print?

9.1.Q4 Transfer MEDIUM Turn back to Project 336 (Extract JSON-LD From a Script Tag). Without running it, what exactly does it print?

9.1.Q5 Recall EASY In a JSON-LD block, what do the @context and @type keys do?

A @context sets the page URL; @type sets the title

B @context names the vocabulary (schema.org); @type names what the object is

C They are optional comments ignored by engines

D @context is the author; @type is the date

9.1.Q6 Meaning MEDIUM A Product block has a name and an image but no offers, while the required set for Product is name and offers. What is the result?

A It still gets a full shopping rich result

B It is not eligible for the rich result until offers is added

C The engine invents a default price

D It is rejected as spam

9.1.Q7 Structure EASY Why is a misspelled @type value like "Prodcut" especially dangerous?

A It crashes the page

B It raises a visible validation error you cannot miss

C The engine silently ignores the unknown type, so the block does nothing and you may not notice

D It changes the page URL

9.1.Q8 Structure MEDIUM A Product's offers value needs a price, currency and stock state. How is that expressed in JSON-LD, and why?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 9 – Structured Data and Rich Results

9.1.Q1. `questions=3 answered=3`

9.1.Q2. `positions=[1, 2, 3] -> ordered`

9.1.Q3. `A -> eligible` then `B -> needs ['image']`

9.1.Q4. `extracted @type: Article` then `headline: Found Me`

9.1.Q5. B @context says which vocabulary the field names come from (always "https://schema.org" for SEO), and @type says what kind of thing the object describes.

9.1.Q6. B a type is eligible only when every required property is present; missing the required offers means no rich result until it is added.

9.1.Q7. C unknown types are silently dropped rather than flagged, so the structured data quietly stops working.

9.1.Q8. As a nested Offer object (its own @type with price, priceCurrency and availability) — because a value with internal structure becomes a typed sub-dictionary rather than a plain string.

PART III

Advanced Mastery

Push into the professional toolkit: concurrency, design patterns, performance, data work and the algorithms behind real systems.

Chapter 10 – International SEO and hreflang · Chapter 11 – Off-Page, Links and Authority · Chapter 12 – Local and Map SEO · Chapter 13 – Log-File and Server Analysis · Chapter 14 – GEO, AEO and the End-to-End Technical Audit

Chapter 10 · International SEO and hreflang

Validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

Chapter Skill Map

What this chapter adds: In International SEO and hreflang, the focus is validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay. You practise it across 32 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples.

chapter arc

What it builds on: Chapter 10 assumes the reading habits from Chapter 9: Structured Data and Rich Results. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 11, Off-Page, Links and Authority, reuses this chapter's discipline with a new kind of problem.

1 **Projects 339-348**	2 **Projects 349-358**	3 **Projects 359-370**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

hreflang is a bidirectional map of locale → URL that says *"for this audience, serve this page."*

same content, different audience

When the same content exists in several languages or for several countries, a search engine faces a choice it cannot make from the words alone: which version should it show a French user in Canada, or an English user in Britain? The hreflang annotation answers that. On each page you list every alternate version as a *(code, URL)* pair — `hreflang="fr-CA"` points at the Canadian-French URL, `hreflang="en-GB"` at the British-English one. The engine then serves the version whose code best matches the user's language and region.

The code itself has a strict shape: a language subtag, optionally followed by a region subtag. Language comes from ISO 639-1 (`en`, `fr`, `de`) and is written lowercase; region comes from ISO 3166-1 alpha-2 (`US`, `GB`, `CA`) and is written uppercase. So `en` means "English anywhere" and `en-US` means "English, United States." A single regex captures the legal form before you trust any tag:

```
import re
codes = ['en', 'en-US', 'fr-CA', 'English', 'en_US', 'de-de']
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
for c in codes:
    print(f'{c}: {"valid" if pat.match(c) else "invalid"}')
```

```
output
```

```
en: valid
en-US: valid
fr-CA: valid
English: invalid
en_US: invalid
de-de: invalid
```

Notice what the regex rejects: `English` (not a two-letter code), `en_US` (underscore, not hyphen), and `de-de` (lowercase region). A crawler silently *skips* a malformed value, so the tag you carefully wrote simply does nothing — the most expensive kind of bug, because it looks like it is working.

The rule that catches most teams is `reciprocity`: hreflang is a two-way handshake. If page A says "fr is over there at B," then B must say "en is back here at A." A link without a return tag is ignored by Google. So an hreflang cluster is not a list you write once on the homepage — it is the *same block, repeated on every page in the set*, each page including itself.

a one-way hreflang is no hreflang

Finally, hreflang lives alongside the `canonical` tag, and the two must agree. hreflang says "these pages are equals for different audiences"; canonical says "this page is the indexable original." If your French page canonicalizes to the English one, you have told Google to *drop French from the index* — and your hreflang for French now points at a page that will never appear. The safe rule: every localized page canonicalizes to *itself*.

HREFLANG

An annotation (in the page `<head>`, an HTTP header, or the XML sitemap) listing each alternate language/region version of a page as a `(code, URL)` pair, so the engine can serve the right version per user.

LOCALE CODE

The value of an hreflang attribute: a language subtag, optionally a hyphen and a region subtag — `en`, `en-US`, `fr-CA`. Plus the special value `x-default`.

ISO 639-1

The standard for two-letter language codes — `en`, `fr`, `de`, `ja`. The language subtag of an hreflang code must be a real 639-1 code, written lowercase (`jp` is not the code for Japanese; `ja` is).

ISO 3166-1 ALPHA-2

The standard for two-letter country/region codes — US, GB, CA, BR. The optional region subtag must be one of these, written uppercase. Three-letter or numeric codes are not allowed in hreflang.

RETURN TAG (RECIPROCITY)

For hreflang to count, if page A links to page B as an alternate, B must link back to A. A missing return tag means the engine ignores the relationship entirely.

X-DEFAULT

The special hreflang value naming the page to serve users whose language/region matches none of your locales — typically a language selector or neutral root page.

SELF-REFERENCE

The rule that every page must list its *own* locale among its hreflang alternates. A page missing its self-reference invalidates the whole cluster for that page.

Read the code: language is not region

Every hreflang value decomposes into at most two parts split by a hyphen. The first is the `language` (ISO 639-1, lowercase); the second, if present, is the `region` (ISO 3166-1 alpha-2, uppercase). Two letters alone is not enough — the language must be a *real* 639-1 code. The classic trap is `jp` for Japanese; the correct code is `ja`. Validate the language subtag against a known set, not just its length:

```
known = {'en', 'fr', 'de', 'es', 'ja', 'zh'}
codes = ['en-US', 'fr', 'xx-GB', 'de-DE', 'jp-JP']
for c in codes:
    lang = c.split('-')[0]
    ok = lang in known
    print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')
```

```
output
en-US: lang=en known
fr: lang=fr known
xx-GB: lang=xx UNKNOWN
de-DE: lang=de known
jp-JP: lang=jp UNKNOWN
```

The region subtag is just as strict: exactly two letters, uppercase, and a real 3166-1 code. That rules out three-letter codes like `DEU`, lowercase `us`, and the numeric UN region codes such as `419` (Latin America) that some standards allow but hreflang does not. A casing swap — uppercase language, lowercase region, as in `EN-us` — is the single most common typo, and it is silently dropped:

```
codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR']
for c in codes:
    if '-' not in c:
        print(f'{c}: no region'); continue
    region = c.split('-', 1)[1]
    ok = len(region) == 2 and region.isalpha() and region.isupper()
    print(f'{c}: region={region} {"valid" if ok else "INVALID"}')
```

```
output
en-US: region=US valid
en-us: region=us INVALID
fr-CA: region=CA valid
de-DEU: region=DEU INVALID
es-419: region=419 INVALID
pt-BR: region=BR valid
```

The cluster and the reciprocity handshake

The set of all language alternates for one piece of content is its hreflang cluster. The defining property of a correct cluster: the hreflang block is identical on every page in it — each page lists all locales, including itself. That symmetry is what gives you reciprocity for free. Generate the block once from the cluster and stamp it on every URL, and you can never produce a one-way link:

```
cluster = {'en': 'https://s.com/en/', 'fr': 'https://s.com/fr/',
           'de': 'https://s.com/de/'}
for page_code in sorted(cluster):
    print(f'On {cluster[page_code]}:')
    for code in sorted(cluster):
        print(f'  hreflang="{code}" -> {cluster[code]}')
```

```
output
On https://s.com/de/:
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
On https://s.com/en/:
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
On https://s.com/fr/:
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
```

When clusters are edited by hand they drift, and a return tag goes missing. The audit is direct: for every alternate a page declares, look up the *target's* hreflang block and confirm the original page is named back. Report the exact

missing edge — the team needs the URL to fix, not a bare "broken":

```
pages = {
    'https://s.com/en/': {'en': 'https://s.com/en/', 'es': 'https://s.com/es/'},
    'https://s.com/es/': {'es': 'https://s.com/es/'},
}
missing = []
for page, alts in pages.items():
    for target in alts.values():
        if page not in pages.get(target, {}).values():
            missing.append((page, target))
for src, tgt in missing:
    print(f'missing return: {tgt} should link back to {src}')
print('broken links:', len(missing))
```

```
output
missing return: https://s.com/es/ should link back to https://s.com/en/
broken links: 1
```

x-default and the self-reference

Two values must appear that are easy to forget. The first is `x-default` — the page to serve a user whose language matches none of your locales (a German speaker landing on an English/French/Spanish store). It usually points at a neutral language selector or the root, *distinct* from any specific locale URL. The second is the `self-reference`: every page must list its own locale among its alternates, or Google invalidates the whole set for that page. A quick cluster audit checks both at once:

```
cluster_codes = {'en-US', 'en-GB', 'fr-FR'}
page_locale = 'en-US'
checks = {
    'self present': page_locale in cluster_codes,
    'x-default present': 'x-default' in cluster_codes,
    'at least 2 locales': len(cluster_codes) >= 2,
}
for name in sorted(checks):
    print(f'{name}: {"PASS" if checks[name] else "FAIL"}')
```

```
output
at least 2 locales: PASS
self present: PASS
x-default present: FAIL
```

The `x-default` is also where the locale fallback chain ends. When a requested locale is not served, the engine falls back to the bare language, then to `x-default`. Walking that chain is how a server (or browser) negotiates which version a visitor actually gets:

```
available = {'en', 'en-GB', 'fr'}
def resolve(req):
    chain = [req, req.split('-')[0], 'x-default']
    for cand in chain:
        if cand in available:
            return cand
    return 'none'
for req in ['en-GB', 'en-US', 'fr-CA', 'de-DE']:
    print(f'{req} -> {resolve(req)}')
```

```
output
en-GB -> en-GB
en-US -> en
fr-CA -> fr
de-DE -> none
```

How hreflang and canonical interact

hreflang and the `canonical` tag answer different questions, and they must not contradict each other. canonical says *"this is the indexable version of this page"*; hreflang says *"these are equal alternates for other audiences."* The safe configuration is that `every localized page is self-canonical` — it points its canonical at itself, keeping each language version eligible for the index. Verify it directly:

```
pages = {
    'https://s.com/en/': 'https://s.com/en/',
    'https://s.com/fr/': 'https://s.com/fr/',
    'https://s.com/de/': 'https://s.com/en/',
}
for page in sorted(pages):
    canon = pages[page]
    print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon}')
```

```
output
https://s.com/de/: POINTS AWAY -> https://s.com/en/
https://s.com/en/: self
https://s.com/fr/: self
```

The damage from a `cross-locale canonical` is subtle but total: if the French page canonicalizes to the English page, you have told Google the two are the *same* page and English is the keeper — so French is dropped from the index, and your `fr` hreflang now points at a page that will never rank. The audit compares the *locale of the page* with the *locale of its canonical* and flags any mismatch:

```
locale_of = {'https://s.com/en/': 'en', 'https://s.com/fr/': 'fr'}
canonicals = {
    'https://s.com/en/': 'https://s.com/en/',
```

```
    'https://s.com/fr/': 'https://s.com/en/',
}
for page in sorted(canonicals):
    canon = canonicals[page]
    if locale_of[page] != locale_of.get(canon):
        print(f'{page} ({locale_of[page]}) canonicalises to {locale_of.get(canon)}
- WRONG')
    else:
        print(f'{page}: same-locale canonical OK')
```

```
output
https://s.com/en/: same-locale canonical OK
https://s.com/fr/ (fr) canonicalises to en - WRONG
```

One pass: the full audit

Put the pieces together and you have the skeleton of an international-SEO audit. Across a real *page → alternates* map, in a single sweep: validate every code's shape, confirm each alternate has a return tag, and check that `x-default` appears everywhere. That trio catches the great majority of hreflang failures in production:

```
import re
pages = {
    'https://s.com/en/': {'en': 'https://s.com/en/', 'fr': 'https://s.com/fr/', 'x-
default': 'https://s.com/'},
    'https://s.com/fr/': {'en': 'https://s.com/en/', 'fr': 'https://s.com/fr/', 'x-
default': 'https://s.com/'},
}
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
bad_codes, no_return = [], []
for page, alts in pages.items():
    for code, target in alts.items():
        if code == 'x-default':
            continue
        if not pat.match(code):
            bad_codes.append(code)
        if page not in pages.get(target, {}).values():
            no_return.append((page, target))
xd_ok = all('x-default' in a for a in pages.values())
print('pages audited:', len(pages))
print('invalid codes:', sorted(set(bad_codes)))
print('broken return tags:', len(no_return))
print('x-default everywhere:', xd_ok)
```

```
output
pages audited: 2
invalid codes: []
```

```
broken return tags: 0
x-default everywhere: True
```

Example 1

Are these four hreflang values legal? `en-US`, `EN-us`, `de-DEU`, `pt-BR`. For each invalid one, say exactly what is wrong.

SOLUTION

1. `en-US`: language `en` is lowercase 639-1, region `US` is uppercase two-letter 3166-1 — valid.
2. `EN-us`: the casing is swapped — language should be lowercase, region should be uppercase. Invalid.
3. `de-DEU`: the region `DEU` is three letters; hreflang requires the two-letter alpha-2 form `DE`. Invalid.
4. `pt-BR`: `pt` is a real language code and `BR` a valid region — valid.

Valid: en-US, pt-BR. Invalid: EN-us (casing swapped), de-DEU (three-letter region).

shape is lowercase-lang, optional uppercase-2-letter-region

Example 2

A two-page set: the English page lists `en → /en/, es → /es/`; the Spanish page lists only `es → /es/`. Does reciprocity hold? What breaks?

SOLUTION

1. Check the English page: it names `/es/` as an alternate, so the Spanish page must name `/en/` back.
2. Look at the Spanish page's block: it lists only `es → /es/` (its self-reference is present), but there is no return tag pointing at `/en/`.
3. Because the link is one-way, Google ignores the English→Spanish relationship entirely; the missing edge is the Spanish page's `en → /en/`.

Reciprocity is broken: `/es/` must link back to `/en/`. Until the Spanish page adds `en → /en/`, the cluster is invalid.

hreflang is a two-way handshake

Example 3

You serve `en`, `en-GB`, and `fr`. A visitor requests `en-US`. Which version do they get, and why?

SOLUTION

1. Try the exact requested locale `en-US` against what is available — it is not served.
2. Fall back to the bare language: `en-US`.split → `en`, which is available. Match.
3. No need to reach `x-default`; the language-level fallback already resolved.

They get `en` (generic English), via the chain en-US → en. The fallback walks exact → language → x-default.

bare language is the safety net before x-default

⚡ Mental-Math Shortcut

Same block on every page, each naming itself, all self-canonical. A correct hreflang cluster is one *(code → URL)* table repeated identically on every page in the set: every page lists every locale including its own, an x-default is present, and each page canonicalizes to itself. If you generate the block from one source instead of editing per page, reciprocity, self-reference, and consistency all come for free.

⚠ Common Mistakes

- Swapping the case — `EN-us` instead of `en-US`. Language is lowercase (ISO 639-1), region is uppercase (ISO 3166-1 alpha-2); crawlers silently skip a wrongly-cased code.
- Using `jp` for Japanese (the code is `ja`), `gb` as a language, or a country code where a language belongs. Two valid-looking letters are not enough; the subtag must be the real standard code.
- Forgetting the return tag, so page A links to B but B never links back — the relationship is ignored. Edit clusters from one generated source rather than by hand to avoid this.
- Canonicalizing a localized page to a different locale (e.g. French → English). That tells Google to drop the French page from the index, and the `fr` hreflang then points at a page that will never appear. Keep every locale self-canonical.
- Omitting the self-reference or the `x-default`: a page that does not list its own locale invalidates the whole set for that page, and a cluster with no x-default leaves international fallback to chance.

This chapter contains 32 hands-on mini-projects (Projects 339–370). Type each one out, run it, and experiment.

Project 339 Validate an Hreflang Value

💡 The Idea Behind It

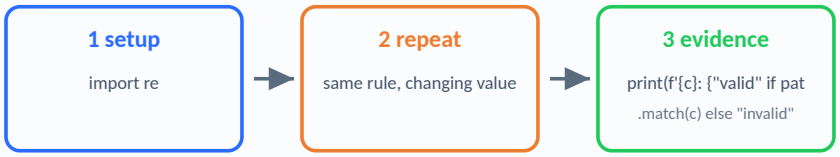
A valid hreflang value is either a bare two-letter language or a language-region pair joined by a hyphen. This project compiles one regular expression, anchored at both ends, that demands lowercase letters for the language and an optional uppercase two-letter region, then tests six sample codes so you can see exactly which shapes pass and which fail.

What You'll Build & Learn

Build a single regex that accepts legal hreflang shapes and rejects everything else, proving the pattern on mixed input.

- The canonical hreflang shape lang or lang-REGION
- Anchoring a regex with caret and dollar
- Why casing and separators matter to crawlers

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 340 changes the surface problem while preserving the underlying method. *progress check*

Reading target: validate an hreflang value is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{c}: {"valid" if pat.match(c) else "invalid"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`print(f'{c}: {"valid" if pat.match(c) else "invalid"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: {"valid" if pat.match(c) else "invalid"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{c}: {"valid" if pat.match(c) else "invalid"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate an Hreflang Value: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: re, codes, en, US, fr. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: print(f'{c}: {"valid" if pat.match(c) else "invalid"}') | Evidence: print(f'{c}: {"valid" if pat.match(c) else "invalid"}')

🛠️ Reader to Writer Bridge

1. Read: explain validate an hreflang value in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 340 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: {"valid" if pat.match(c) else "invalid"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate an hreflang value and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The pattern `^[a-z]{2}(-[A-Z]{2})?$` demands a two-letter lowercase language with an optional uppercase two-letter region, rejecting underscores, full words, and wrong casing.

```
import re
codes = ['en', 'en-US', 'fr-CA', 'English', 'en_US', 'de-de']
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
for c in codes:
    print(f'{c}: {"valid" if pat.match(c) else "invalid"}')
```

```
output
en: valid
en-US: valid
fr-CA: valid
English: invalid
en_US: invalid
de-de: invalid
```

How it works:

1. A list named codes holds six strings mixing valid and invalid forms like 'en', 'en-US', and 'English'.
2. re.compile builds the pattern '^[a-z]{2}(-[A-Z]{2})?$' once, with the region group made optional by the trailing question mark.
3. The loop calls pat.match on each code and prints 'valid' when it matches and 'invalid' otherwise, using an inline conditional inside an f-string.

Try it:

1. Extend the pattern to also accept the literal token 'x-default' as a special case.
2. Add codes with three-letter languages and confirm the regex rejects them.
3. Capture the language and region into named groups and print each part separately.
4. Add `'es-419'` and decide whether numeric UN M.49 regions should be allowed.

⚠ Common Mistakes

- Allowing `en_US` by matching `_` instead of `-` accepts a value Google ignores.
- Dropping the case anchors lets `EN-us` slip through even though hreflang is case-insensitive only on input, not on convention.
- Forgetting `^` and `$` lets the regex match a valid fragment inside a longer junk string.

Skills gained regex validation hreflang f-strings

→ **Where You'll Use This:** Every hreflang audit starts by separating well-formed codes from typos before any deeper checks; this regex is the gatekeeper you run first on scraped tag values.

Mental Model

The regex is a bouncer at the door: it does not care who you are, only that your ID has the right format before you get inside.

Project 340 Validate the ISO 639-1 Language Part

The Idea Behind It

Passing the shape test is not enough; the language subtag must also be a real ISO 639-1 code. Here a set of known languages is the source of truth, and each input is split on the hyphen to isolate its language part before membership is checked. Invented codes like 'xx' and the wrong code 'jp' for Japanese are caught even though they look structurally fine.

What You'll Build & Learn

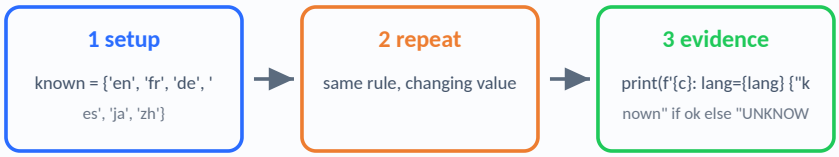
Confirm the language portion of each code is a genuine ISO 639-1 entry by testing it against a known set.

- Shape validity differs from semantic validity
- Set membership for fast lookups
- Common wrong code jp versus ja

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 339: validate an hreflang value. Project 341 changes the surface problem while preserving the underlying method.

progress check



Reading target: validate the iso 639-1 language part is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `known = {'en', 'fr', 'de', 'es', 'ja', 'zh'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`known = {'en', 'fr', 'de', 'es', 'ja', 'zh'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate the ISO 639-1 Language Part: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: known, en, fr, de, es. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: known = {'en', 'fr', 'de', 'es', 'ja', 'zh'} | Core: print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}') | Evidence: print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')

🛠️ Reader to Writer Bridge

1. Read: explain validate the iso 639-1 language part in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 339.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 341 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `known = {'en', 'fr', 'de', 'es', 'ja', 'zh'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of validate the iso 639-1 language part and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting on `-` isolates the language subtag, and membership in a curated ISO 639-1 set separates real languages from plausible-looking typos.

```
known = {'en', 'fr', 'de', 'es', 'ja', 'zh'}
codes = ['en-US', 'fr', 'xx-GB', 'de-DE', 'jp-JP']
for c in codes:
    lang = c.split('-')[0]
    ok = lang in known
    print(f'{c}: lang={lang} {"known" if ok else "UNKNOWN"}')
```

```
output
en-US: lang=en known
fr: lang=fr known
xx-GB: lang=xx UNKNOWN
de-DE: lang=de known
jp-JP: lang=jp UNKNOWN
```

How it works:

1. A set named known lists the real two-letter languages the site supports, such as 'en', 'fr', and 'ja'.
2. For each code in the list, split('-')[0] grabs the language part, dropping any region after the hyphen.
3. The boolean ok tests lang in known, and the f-string prints the extracted language plus 'known' or 'UNKNOWN'.

Try it:

1. Load the full ISO 639-1 list from a file instead of a small hard-coded set.
2. Print a suggestion when 'jp' is seen, pointing the editor to 'ja'.
3. Count how many codes fail and report the failure rate as a percentage.
4. Add `'pt'` to the known set and re-test a `pt-BR` code.

⚠ Common Mistakes

- Assuming any two lowercase letters is a valid language misses that `jp` is not the ISO code for Japanese (`ja` is).
- Splitting on `_` instead of `-` never isolates the language part of a hyphenated code.
- Treating the region (`US`) as the language by taking the second part inverts the check.

Skills gained sets iso-639-1 string split membership

→ Where You'll Use This: Auditors use a whitelist of supported languages so that a code which is the right shape but a fictional or mistyped language gets flagged before it reaches production tags.

Mental Model

The set is a guest list at a private club: the format of your name does not matter if it is not actually on the list.

Project 341 Validate the ISO 3166-1 Region Part

The Idea Behind It

When a region is present in an hreflang value it must be an ISO 3166-1 alpha-2 code: exactly two letters, all uppercase. This project splits each code once, then applies three conditions together so it can reject three-letter codes, lowercase regions, and the numeric UN regions that hreflang does not support, while quietly noting codes that carry no region at all.

What You'll Build & Learn

Validate the region subtag as a two-letter uppercase alpha-2 code, rejecting wrong lengths, casing, and numeric forms.

- ISO 3166-1 alpha-2 requires two uppercase letters
- Combining length, alpha, and upper checks
- Handling codes with no region gracefully

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 340: validate the iso 639-1 language part. Project 342 changes the surface problem while preserving the underlying method.

progress check

Reading target: validate the iso 3166-1 region part is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print(f'{c}: region={region} {"valid" if ok else "INVALID"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if '-' not in c:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: region={region} {"valid" if ok else "INVALID"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if '-' not in c:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate the ISO 3166-1 Region Part: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: codes, en, US, us, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR'] | Core: if '-' not in c: | Evidence: print(f'{c}: region={region} {"valid" if ok else "INVALID"}')

🛠️ Reader to Writer Bridge

1. Read: explain validate the iso 3166-1 region part in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 340.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 342 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: region={region} {"valid" if ok else "INVALID"}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate the iso 3166-1 region part and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

After splitting off the region, three string predicates (length 2, alphabetic, uppercase) together enforce the alpha-2 uppercase convention.

```
codes = ['en-US', 'en-us', 'fr-CA', 'de-DEU', 'es-419', 'pt-BR']
for c in codes:
    if '-' not in c:
        print(f'{c}: no region'); continue
    region = c.split('-', 1)[1]
    ok = len(region) == 2 and region.isalpha() and region.isupper()
    print(f'{c}: region={region} {"valid" if ok else "INVALID"}')
```

```
output
en-US: region=US valid
en-us: region=us INVALID
fr-CA: region=CA valid
de-DEU: region=DEU INVALID
es-419: region=419 INVALID
pt-BR: region=BR valid
```

How it works:

1. The loop first checks for a hyphen; codes without one print 'no region' and continue to the next item.
2. split('-', 1)[1] isolates everything after the first hyphen as the region string.
3. Three conditions joined with and confirm len is two, isalpha is true, and isupper is true, then the result prints as 'valid' or 'INVALID'.

Try it:

1. Check each region against a real set of ISO 3166-1 alpha-2 codes, not just the shape.
2. Allow the UN M49 region '419' as a valid Latin-America special case.
3. Report both the language and region validity for every code on one line.
4. Decide whether to allow `419` (Latin America) as a special numeric region.

⚠ Common Mistakes

- Accepting `DEU` because it is alphabetic ignores that hreflang uses two-letter alpha-2, not three-letter alpha-3.
- Using `.upper() == region` instead of `.isupper()` wrongly passes an already-lowercased value.
- Forgetting `.isalpha()` lets the numeric `419` pass the length-2 check if you only count characters.

Skills gained iso-3166-1 | string methods | validation | conditionals

→ Where You'll Use This: Region casing and length errors are among the most common hreflang mistakes; this trio of checks pinpoints them in bulk when you parse a site's alternate tags.

Project 342 Detect a Malformed Hreflang Code

The Idea Behind It

Because a search crawler silently skips any hreflang value it cannot parse, an audit must surface the broken ones rather than let them vanish. This project reuses the shape regex but inverts the logic with a list comprehension, collecting every code that fails to match and printing both the offending list and its count for a quick report.

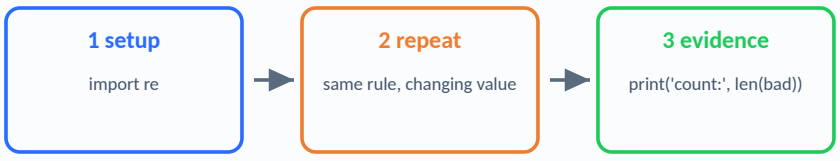
What You'll Build & Learn

Collect and count the malformed hreflang codes from a list so an audit can report them up front.

- Filtering with a negated regex match
- List comprehensions for collecting failures
- Why crawlers drop bad codes silently

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 341: validate the iso 3166-1 region part. Project 343 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a malformed hreflang code is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('count:', len(bad))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`bad = [c for c in codes if not pat.match(c)]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('count:', len(bad))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `bad = [c for c in codes if not pat.match(c)]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Malformed Hreflang Code: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: re, codes, en, US, EN. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: bad = [c for c in codes if not pat.match(c)] | Evidence: print('count:', len(bad))

🛠️ Reader to Writer Bridge

1. Read: explain detect a malformed hreflang code in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 341.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 343 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('count:', len(bad))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a malformed hreflang code and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the list by codes that fail the canonical pattern collects every malformed value, and the count gives a quick severity gauge.

```
import re
codes = ['en-US', 'EN-us', 'e-US', 'en-USA', 'en--US', 'en']
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
bad = [c for c in codes if not pat.match(c)]
print('malformed:', bad)
print('count:', len(bad))
```

```
output
malformed: ['EN-us', 'e-US', 'en-USA', 'en--US']
count: 4
```

How it works:

1. The same '^[a-z]{2}(-[A-Z]{2})?$' pattern is compiled to define the legal shape.
2. A list comprehension keeps each c where not pat.match(c) is true, building the bad list of malformed codes.
3. Two prints report the malformed list and len(bad), giving a headline number for the report.

Try it:

1. Also return the index of each malformed code so editors can find it in the source.

2. Split the failures into 'bad casing' versus 'bad structure' buckets.
3. Write the malformed list to a CSV file for the content team.
4. Print each malformed code with the reason it failed.

⚠ Common Mistakes

- Reporting `de-de` as fine because letters match while ignoring that the region must be uppercase.
- Counting `len(codes)` instead of `len(bad)` reports total codes, not the broken ones.
- A pattern without `$` would accept `en--US` by matching only its valid prefix.

Skills gained regex | list comprehension | auditing | len

→ Where You'll Use This: Surfacing the count of malformed codes is the first metric in an hreflang health report; a non-zero number tells stakeholders tags are being dropped invisibly.

Mental Model

Malformed tags are like envelopes with no address: the postal system tosses them without a word, so you must check the outbox yourself.

Project 343 Build an Hreflang Cluster from a Page

The Idea Behind It

An hreflang cluster is the full set of language alternates for one piece of content. This project models a page's alternates as a dict mapping locale to URL, then calls sorted on its items to produce a deterministic, alphabetized view. Stable ordering matters because an audit that prints clusters the same way every time is far easier to diff and reason about.

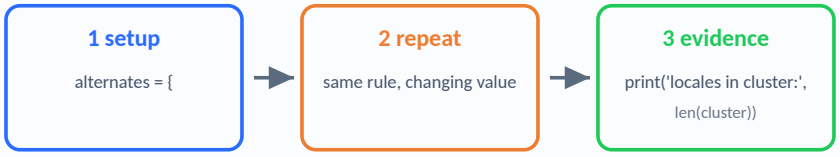
What You'll Build & Learn

Represent a page's language alternates as a dict and print them in a stable, sorted order with a count.

- A cluster is the alternates for one URL
- Sorting dict items for deterministic output
- Counting locales in a cluster

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 342: detect a malformed hreflang code. Project 344 changes the surface problem while preserving the underlying method.



progress check

Reading target: build an hreflang cluster from a page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `alternates = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('locales in cluster:', len(cluster))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`alternates = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`for code, url in cluster:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('locales in cluster:', len(cluster))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for code, url in cluster:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build an Hreflang Cluster from a Page: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: alternates, en, https, shop, com. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: alternates = { | Core: for code, url in cluster: | Evidence: print('locales in cluster:', len(cluster))

🛠️ Reader to Writer Bridge

1. Read: explain build an hreflang cluster from a page in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 342.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 344 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('locales in cluster:', len(cluster))`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `alternates = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build an hreflang cluster from a page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A dict of `code -> url` is the natural cluster model; sorting its items makes the printed cluster deterministic and counting the keys gives the locale count.

```
alternates = {
    'en': 'https://shop.com/en/',
    'fr': 'https://shop.com/fr/',
    'de': 'https://shop.com/de/',
}
cluster = sorted(alternates.items())
for code, url in cluster:
    print(f'{code} -> {url}')
print('locales in cluster:', len(cluster))
```

```
output
de -> https://shop.com/de/
en -> https://shop.com/en/
fr -> https://shop.com/fr/
locales in cluster: 3
```

How it works:

1. A dict named alternates maps three language codes to their absolute URLs on shop.com.
2. sorted(alternates.items()) returns a list of code-URL tuples ordered alphabetically by code.
3. The loop prints each 'code -> url' pair, then a final line reports len(cluster) as the number of locales.

Try it:

1. Add an 'x-default' entry and decide whether to count it as a locale.
2. Sort by URL instead of by code and observe the difference.
3. Wrap the logic in a function that takes any alternates dict and returns the sorted list.
4. Add an `x-default` entry and watch the cluster size grow.

⚠ Common Mistakes

- Printing the dict directly relies on insertion order and varies the output.
- Counting characters in the dict instead of `len(cluster)` mismeasures the locale count.

- Forgetting that the page itself must appear in its own cluster (the self-reference).

Skills gained dicts sorting clusters iteration

→ Where You'll Use This: Modeling clusters as dicts is the foundation for every reciprocity and completeness check; sorted output makes audit logs stable across runs and easy to compare.

Mental Model

The cluster is a family photo: everyone who belongs together appears in one frame, and sorting just lines them up in a predictable order.

Project 344 Check Return-Tag Reciprocity

The Idea Behind It

Hreflang must be bidirectional: if page A names page B as an alternate, B has to name A in return. This project stores each page's alternates as nested dicts, then walks every alternate target and checks whether the original page appears among that target's own alternate URLs, reporting a single OK or BROKEN verdict for the whole set.

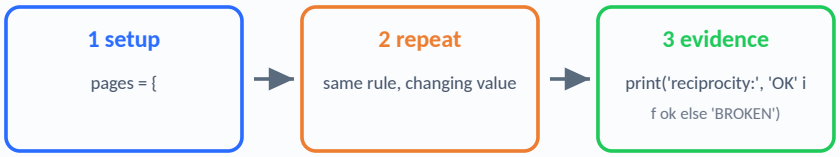
What You'll Build & Learn

Audit a small page-to-alternates map for full reciprocity and report a single pass or fail verdict.

- Hreflang reciprocity is mandatory
- Nested dicts model a cluster of pages
- A flag variable tracks overall validity

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 343: build an hreflang cluster from a page. Project 345 changes the surface problem while preserving the underlying method. *progress check*



Reading target: check return-tag reciprocity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('reciprocity:', 'OK' if ok else 'BROKEN')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if page not in back.values():`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('reciprocity:', 'OK' if ok else 'BROKEN')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if page not in back.values():`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

3. Transfer: change one small part of check return-tag reciprocity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each alternate target, looking up that target's own alternates and confirming the source URL appears among them proves the return tag exists.

```
pages = {
    'https://s.com/en/': {'en': 'https://s.com/en/', 'fr':
'https://s.com/fr/'},
    'https://s.com/fr/': {'en': 'https://s.com/en/', 'fr':
'https://s.com/fr/'},
}
ok = True
for page, alts in pages.items():
    for code, target in alts.items():
        back = pages.get(target, {})
        if page not in back.values():
            ok = False
            print(f'{page} -> {target} has NO return tag')
print('reciprocity:', 'OK' if ok else 'BROKEN')
```

```
output
reciprocity: OK
```

How it works:

1. The pages dict maps each page URL to its own alternates dict of code to target URL.
2. A boolean ok starts True, and nested loops visit every alternate target for every page.
3. pages.get(target, {}) fetches the target's alternates, and if the original page is not in back.values() the flag flips to False and the broken edge prints.

Try it:

1. Count the number of reciprocal edges versus total edges and print a ratio.
2. Return the list of broken pairs instead of just OK or BROKEN.
3. Add a third page and break one return tag to watch the verdict change.
4. Drop the `fr` page's `en` entry and watch reciprocity break.

⚠ Common Mistakes

- Comparing against the target's alternate keys (codes) instead of its values (URLs) never finds the return tag.
- Assuming reciprocity holds because A lists B, without checking B's tags at all.
- Using `target in back` checks dict keys, not the URL values, and gives a false negative.

Skills gained nested dicts reciprocity auditing boolean flags

→ Where You'll Use This: Reciprocity failures are the single most common reason Google ignores hreflang; this audit is the core check you run across an entire crawled cluster before launch.

Mental Model

Reciprocity is a handshake: if you extend your hand, the other person must extend theirs back, or the greeting does not count.

Project 345 Detect a Missing Reciprocal Tag

The Idea Behind It

A pass-or-fail verdict is not actionable; when reciprocity breaks, the team needs the exact missing edge. This project walks every alternate target and, for any target whose alternates do not link back to the source page, records the unreciprocated source-target pair so it can print each broken link and a total count of repairs needed.

What You'll Build & Learn

List every specific unreciprocated hreflang link so the team knows exactly which page must add a return tag.

- Reporting edges, not just a verdict
- Collecting tuples of failures
- Turning audits into fix lists

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 344: check return-tag reciprocity. Project 346 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a missing reciprocal tag is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print('broken links:', len(missing))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

3. Transfer: change one small part of detect a missing reciprocal tag and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Collecting `(source, target)` pairs whose target does not list the source pinpoints every one-way hreflang link that Google would discard.

```
pages = {
    'https://s.com/en/': {'en': 'https://s.com/en/', 'es':
'https://s.com/es/'},
    'https://s.com/es/': {'es': 'https://s.com/es/'},
}
missing = []
for page, alts in pages.items():
    for target in alts.values():
        if page not in pages.get(target, {}).values():
            missing.append((page, target))
for src, tgt in missing:
    print(f'missing return: {tgt} should link back to {src}')
print('broken links:', len(missing))
```

```
output
missing return: https://s.com/es/ should link back to https://s.com/en/
broken links: 1
```

How it works:

1. Two pages are defined where the English page links to Spanish, but the Spanish page only lists itself.
2. For each alternate target, the code checks page not in pages.get(target, {}).values() and appends a (page, target) tuple to missing when the back link is absent.
3. A loop prints 'missing return: target should link back to src' for each gap, then reports len(missing).

Try it:

1. Group missing returns by the page that needs fixing.
2. Include the language code of each missing link in the message.
3. Add a second broken pair and confirm both appear in the output.
4. Add the missing `en` entry to the `es` page and confirm zero broken links.

⚠ Common Mistakes

- Recording the target as the page to fix instead of the source that needs the return tag.
- Checking the target's alternate codes rather than its URLs misses the actual link.
- Skipping a page's self-reference can make a present return tag look absent.

Skills gained tuples reciprocity diagnostics iteration

→ Where You'll Use This: Turning a reciprocity failure into a precise list of which page must add which return tag is what makes an hreflang report something engineers can act on directly.

Project 346 Detect a Missing x-default Tag

The Idea Behind It

The x-default tag tells Google which page to serve visitors whose language matches none of your declared locales. This project stores each cluster's codes as a set and checks membership of the literal 'x-default' string, printing a clear has-or-missing line per cluster so you can spot any group that leaves international fallback to chance.

What You'll Build & Learn

Scan several clusters and flag any that lack the x-default fallback tag entirely.

- x-default handles unmatched languages
- Set membership for tag presence
- Why fallback should not be implicit

Skill Roadmap

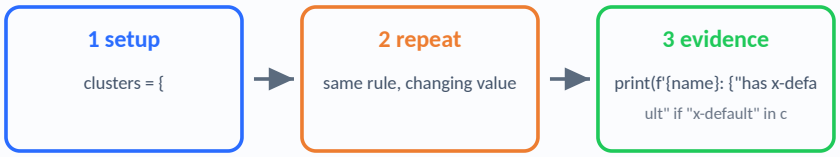
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 345: detect a missing reciprocal tag. Project 347 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a missing x-default tag is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `clusters = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{name}: {"has x-default" if "x-default" in codes else "MISSING x-default"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Code Reading Stack

Layer	What to read
Intent	Detect a Missing x-default Tag: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: clusters, product, en, US, GB. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: clusters = { | Core: print(f'{name}: {"has x-default" if "x-default" in codes else "MISSING... | Evidence: print(f'{name}: {"has x-default" if "x-default" in codes else "MISSING...

🛠️ Reader to Writer Bridge

1. Read: explain detect a missing x-default tag in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 345.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 347 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {"has x-default" if "x-default" in codes else "MISSING x-default"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `clusters = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a missing x-default tag and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Testing each cluster's code set for the literal `x-default` membership flags the clusters that omit the universal fallback.

```
clusters = {
    'product-A': {'en-US', 'en-GB', 'x-default'},
    'product-B': {'en-US', 'fr-FR'},
    'product-C': {'de-DE', 'x-default'},
}
for name in sorted(clusters):
```

```
    codes = clusters[name]
    print(f'{name}: {"has x-default" if "x-default" in codes else "MISSING x-default"}')
```

```
output
product-A: has x-default
product-B: MISSING x-default
product-C: has x-default
```

How it works:

1. A dict named clusters maps product names to sets of hreflang codes, one of which omits 'x-default'.
2. Iterating sorted(clusters) keeps the report alphabetical by product.
3. An inline conditional checks 'x-default' in codes and prints 'has x-default' or 'MISSING x-default' for each.

Try it:

1. Also verify that the x-default points to a real URL, not just that the tag exists.
2. Report the percentage of clusters that are missing x-default.
3. Allow a cluster to be exempt if it serves only one global language.
4. Add `x-default` to product-B and watch it pass.

⚠ Common Mistakes

- Treating any region-less code like `en` as the default instead of the explicit `x-default`.
- Iterating the dict in insertion order makes the report nondeterministic; sort the names.
- Assuming one site-wide x-default suffices when each cluster needs its own.

Skills gained sets | x-default | membership | auditing

→ Where You'll Use This: Missing x-default is a frequent gap on multinational sites; this check ensures every cluster declares a sensible landing page for users in unsupported regions.

Mental Model

x-default is the lobby of an international building: visitors who do not know which floor they need start there instead of getting lost.

Project 347 Detect Duplicate Hreflang Entries

The Idea Behind It

Listing the same hreflang code twice on a single page is a common copy-paste mistake that confuses crawlers. This project feeds a list of code-URL tuples into a Counter keyed only on the code, then keeps any code whose tally exceeds one, surfacing duplicate declarations regardless of whether the URLs they point to agree.

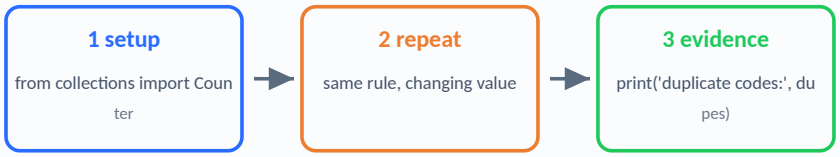
What You'll Build & Learn

Use a frequency count to detect any hreflang code that is declared more than once on a page.

- Counter tallies occurrences quickly
- Duplicate codes confuse crawlers
- Generator expressions feed Counter

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 346: detect a missing x-default tag. Project 348 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect duplicate hreflang entries is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('duplicate codes:', dupes)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`dupes = sorted(c for c, n in counts.items() if n > 1)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('duplicate codes:', dupes)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

1. Predict: before running, write the exact output you expect from `print('duplicate codes:', dupes)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect duplicate hreflang entries and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `Counter` over the codes tallies occurrences, and filtering for counts above one collects the duplicated codes deterministically once sorted.

```
from collections import Counter
entries = [
    ('en-US', 'https://s.com/en/'),
    ('fr-FR', 'https://s.com/fr/'),
    ('en-US', 'https://s.com/en2/'),
    ('de-DE', 'https://s.com/de/'),
]
counts = Counter(code for code, _ in entries)
dupes = sorted(c for c, n in counts.items() if n > 1)
print('duplicate codes:', dupes)
```

```
output
duplicate codes: ['en-US']
```

How it works:

1. A list named entries holds (code, url) tuples, with 'en-US' appearing twice pointing at different URLs.
2. Counter(code for code, _ in entries) counts how often each code appears, ignoring the URL via the throwaway underscore.
3. A comprehension keeps codes where n > 1, sorts them, and prints the duplicate list.

Try it:

1. Report how many times each duplicate code appears, not just that it repeats.
2. List the conflicting URLs alongside each duplicate code.
3. Ignore duplicates that point at the identical URL as harmless.
4. Add a second `de-DE` entry and watch it join the duplicate list.

⚠ Common Mistakes

- Counting `(code, url)` pairs treats two different URLs under one code as distinct and hides the duplicate code.
- Using a set to dedupe loses the information that a code repeated at all.
- Forgetting to sort the duplicate list makes the output order unstable.

Skills gained Counter duplicates generators collections

→ Where You'll Use This: Duplicate-code detection is a standard line item in tag QA; a content management system that injects alternates twice produces exactly this defect, and the count catches it.

⚡ Mental Model

A duplicate code is calling two people by the same name at a meeting: the room does not know which one you mean.

Project 348 Detect Conflicting Hreflang Targets

💡 The Idea Behind It

A harmless duplicate points to one URL twice, but a conflict is worse: one hreflang code mapped to two different URLs. This project builds a defaultdict of sets so each code accumulates its distinct targets, then any code whose set holds more than one URL is reported as a CONFLICT, the situation where Google cannot pick a winner and may drop the tag.

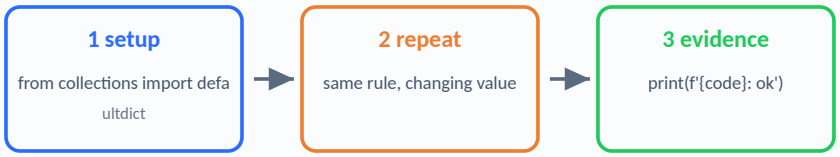
What You'll Build & Learn

Group alternate entries by code and flag any code that resolves to more than one distinct URL.

- Conflicts differ from plain duplicates
- defaultdict(set) collects unique targets
- Set size reveals ambiguity

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 347: detect duplicate hreflang entries. Project 349 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect conflicting hreflang targets is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{code}: ok')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if len(urls) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{code}: ok')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(urls) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Conflicting Hreflang Targets: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: collections, defaultdict, entries, en, US. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: if len(urls) > 1: | Evidence: print(f'{code}: ok')

🛠️ Reader to Writer Bridge

1. Read: explain detect conflicting hreflang targets in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 347.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 349 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: ok')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect conflicting hreflang targets and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Grouping URLs into a set per code reveals a conflict whenever a code's URL set has more than one member, while a single-member set is a clean mapping.

```
from collections import defaultdict
entries = [
    ('en-US', 'https://s.com/en/'),
    ('en-US', 'https://s.com/us/'),
    ('fr-FR', 'https://s.com/fr/'),
]
by_code = defaultdict(set)
for code, url in entries:
    by_code[code].add(url)
for code in sorted(by_code):
    urls = by_code[code]
    if len(urls) > 1:
        print(f'{code}: CONFLICT -> {sorted(urls)}')
    else:
        print(f'{code}: ok')
```

```
output
en-US: CONFLICT -> ['https://s.com/en/', 'https://s.com/us/']
fr-FR: ok
```

How it works:

1. A defaultdict(set) named by_code lets each new code start with an empty set automatically.
2. The loop adds each url to by_code[code], so duplicate URLs collapse but distinct ones accumulate.
3. For each code, len(urls) > 1 marks a CONFLICT and prints the sorted list of clashing URLs, else it prints 'ok'.

Try it:

1. Count the number of conflicting codes and exit non-zero if any exist.
2. Suggest the most frequently seen URL as the likely correct target.
3. Distinguish conflicts caused by trailing-slash differences only.
4. Point both `en-US` entries at the same URL and watch the conflict vanish.

⚠ Common Mistakes

- Using a list instead of a set reports a benign exact-duplicate URL as a conflict.
- Reporting the first URL and ignoring the rest hides that a conflict exists at all.
- Iterating `by_code` without sorting makes the conflict report nondeterministic.

Skills gained `defaultdict` `sets` `conflicts` `grouping`

→ **Where You'll Use This:** Conflicting targets often arise when a redirect or canonical change leaves stale alternates behind; spotting them prevents Google from discarding the entire hreflang block.

⚡ Mental Model

A conflict is two signposts at a fork both labeled 'this way': the traveller stops because neither can be trusted.

Project 349 Verify Self-Canonical Within a Locale

💡 The Idea Behind It

Each localized page should canonicalize to itself, not to another language version, so that every locale stays eligible for indexing. This project maps each page URL to its declared canonical and compares the two: when they match it prints 'self', and when a page points its canonical at a different locale it flags that the canonical points away.

What You'll Build & Learn

Check that each localized page declares itself as its own canonical rather than pointing at another locale.

- Localized pages need self-canonicals
- Cross-locale canonicals deindex versions
- Comparing a page to its canonical

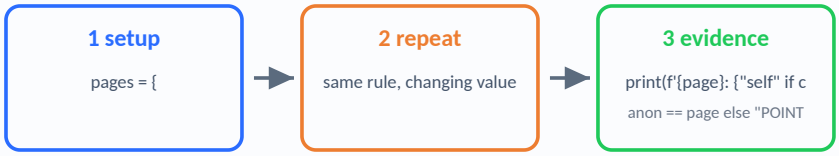
🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 348: detect conflicting hreflang targets. Project 350 changes the surface problem while preserving the underlying method.

progress check

Reading target: verify self-canonical within a locale is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



🔎 Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon}')` exposes the result; match it against the output before changing the program.

output proves the trace

Code Reading Stack

Layer	What to read
Intent	Verify Self-Canonical Within a Locale: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: pages, https, com, en, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon... | Evidence: print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon...

🛠️ Reader to Writer Bridge

1. Read: explain verify self-canonical within a locale in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 348.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 350 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of verify self-canonical within a locale and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing each page's canonical to its own URL flags any page that hands its indexing signal to a different locale.

```
pages = {
    'https://s.com/en/': 'https://s.com/en/',
    'https://s.com/fr/': 'https://s.com/fr/',
    'https://s.com/de/': 'https://s.com/en/',
}
for page in sorted(pages):
    canon = pages[page]
    print(f'{page}: {"self" if canon == page else "POINTS AWAY -> " + canon}')
```

```
output
https://s.com/de/: POINTS AWAY -> https://s.com/en/
https://s.com/en/: self
https://s.com/fr/: self
```

How it works:

1. A dict named pages maps each page URL to its declared canonical URL, with the German page wrongly pointing at English.
2. Iterating sorted(pages) gives a stable order over the page URLs.
3. The check canon == page prints 'self' when they agree, otherwise it prints 'POINTS AWAY ->' followed by the foreign canonical.

Try it:

1. Treat a canonical that differs only by trailing slash as self-referential.
2. Report the count of pages canonicalizing away from themselves.
3. Fetch the live canonical tag instead of reading from a static dict.
4. Fix the `de` page's canonical to point at itself and confirm all 'self'.

⚠ Common Mistakes

- Treating a canonical that points to the default locale as acceptable de-indexes the other languages.
- Comparing only the path, ignoring host, can mask a cross-domain canonical.
- Iterating the dict unsorted makes the per-page report order unstable.

Skills gained canonicals dicts comparison indexing

→ Where You'll Use This: A non-self canonical on a localized page is a silent indexing killer; this check is run alongside hreflang audits because the two signals must agree for international pages to rank.

Mental Model

A self-canonical is signing your own name on your own work; pointing it elsewhere is crediting someone else for what you made.

Project 350 Flag a Cross-Locale Canonical Error

The Idea Behind It

Beyond pointing to itself, a canonical must stay within its own locale. This project keeps a locale map and a canonical map, then compares the locale of each page against the locale of its canonical target. When the French page canonicalizes to English the locales differ, so it prints WRONG, capturing the precise error that tells Google to drop a language from the index.

What You'll Build & Learn

Detect a canonical that crosses locale boundaries by comparing the locale of the page and its canonical target.

- Canonicals must stay within a locale
- Mapping URLs to their locale
- Comparing two lookups to find errors

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 349: verify self-canonical within a locale. Project 351 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag a cross-locale canonical error is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `locale_of = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print(f'{page}: same-locale canonical OK')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

🛠️ Reader to Writer Bridge

1. Read: explain flag a cross-locale canonical error in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 349.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 351 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page}: same-locale canonical OK')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `locale_of = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag a cross-locale canonical error and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Looking up the locale of both the page and its canonical target and comparing them detects when a canonical crosses a language boundary.

```
locale_of = {
    'https://s.com/en/': 'en',
    'https://s.com/fr/': 'fr',
}
canonicals = {
    'https://s.com/en/': 'https://s.com/en/',
    'https://s.com/fr/': 'https://s.com/en/',
}
for page in sorted(canonicals):
    canon = canonicals[page]
    if locale_of[page] != locale_of.get(canon):
        print(f'{page} ({locale_of[page]}) canonicalises to
{locale_of.get(canon)} — WRONG')
    else:
        print(f'{page}: same-locale canonical OK')
```

```
output
https://s.com/en/: same-locale canonical OK
https://s.com/fr/ (fr) canonicalises to en — WRONG
```

How it works:

1. locale_of maps each page URL to its language, and canonicals maps each page to its declared canonical.
2. For each page, the code compares locale_of[page] against locale_of.get(canon), the locale of the canonical target.
3. When the two locales differ it prints a WRONG message naming both locales, otherwise it confirms a same-locale canonical.

Try it:

1. Handle a canonical target missing from locale_of without raising a KeyError.
2. Print the page's URL plus the offending canonical URL for both sides.
3. Aggregate which locale is most often the wrong canonical destination.
4. Repoint the `fr` page's canonical to itself and watch the error clear.

⚠ Common Mistakes

- Comparing the raw URLs instead of their locales misses that a same-locale alias is fine.
- Using `locale_of[canon]` (not `.get`) raises a KeyError when the canonical is an unknown URL.
- Assuming any self-pointing canonical is correct without checking the locale mapping behind it.

Skills gained canonicals | locales | dict lookups | diagnostics

→ Where You'll Use This: Cross-locale canonicalization quietly removes whole languages from search; pairing a locale map with a canonical map is how an audit proves each version canonicalizes inside its own language.

⚡ Mental Model

Each locale is a separate filing drawer; a cross-locale canonical files the French folder inside the English drawer, so French disappears.

Project 351 Count Distinct Locales in a Cluster

💡 The Idea Behind It

An audit summary needs two numbers: how many locale variants you serve and how many distinct languages sit behind them. This project filters out the 'x-default' entry because it is a fallback rather than a locale, counts the remaining variants, and derives the unique set of language subtags by splitting each code on its hyphen.

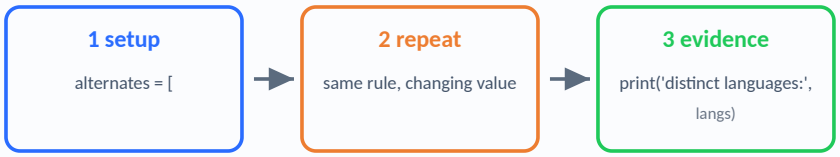
What You'll Build & Learn

Summarize a cluster by counting locale variants and the distinct languages behind them, excluding x-default.

- Locale variants versus distinct languages
- x-default is a fallback, not a locale
- Set comprehension for unique languages

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 350: flag a cross-locale canonical error. Project 352 changes the surface problem while preserving the underlying method.



progress check

Reading target: count distinct locales in a cluster is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `alternates = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('distinct languages:', langs)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`alternates = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`locales = [c for c in alternates if c != 'x-default']`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('distinct languages:', langs)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `locales = [c for c in alternates if c != 'x-default']`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Distinct Locales in a Cluster: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: alternates, en, US, GB, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: alternates = [| Core: locales = [c for c in alternates if c != 'x-default'] | Evidence: print('distinct languages:', langs)

🛠️ Reader to Writer Bridge

1. Read: explain count distinct locales in a cluster in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 350.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 352 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('distinct languages:', langs)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `alternates = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count distinct locales in a cluster and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering out `x-default` leaves true locale variants, and reducing each to its language subtag via a set counts the distinct languages served.

```
alternates = [
    'en-US', 'en-GB', 'fr-FR', 'fr-CA', 'de-DE', 'x-default',
]
locales = [c for c in alternates if c != 'x-default']
langs = sorted({c.split('-')[0] for c in locales})
print('locale variants:', len(locales))
print('distinct languages:', langs)
```

```
output
locale variants: 5
distinct languages: ['de', 'en', 'fr']
```

How it works:

1. A list named alternates holds five region variants plus the 'x-default' token.
2. A comprehension builds locales by keeping every code that is not 'x-default'.
3. A set comprehension over c.split('-')[0] collects the unique language parts, and the two prints report the variant count and the sorted languages.

Try it:

1. Also report how many regions each language serves.
2. Raise the count if 'x-default' is missing from the list.
3. Sort the language list by number of regions instead of alphabetically.
4. Add `es-ES` and watch both counts rise.

⚠ Common Mistakes

- Counting `x-default` as a locale inflates the variant total by one.
- Counting locale variants as if they were distinct languages double-counts `en-US` and `en-GB`.
- Forgetting to sort the language set makes the printed list nondeterministic.

Skills gained set comprehension | counting | string split | x-default

→ Where You'll Use This: Reporting both variant count and language count gives stakeholders an honest picture of international coverage, distinguishing many regions of one language from genuine multilingual reach.

⚡ Mental Model

It is the difference between counting cars and counting car brands: five variants might all be the same language wearing different plates.

Project 352 Check Hreflang Matrix Completeness

💡 The Idea Behind It

In a complete hreflang matrix every locale links to all locales in the set, including itself. This project holds an expected set of languages and a matrix mapping each locale to the set it actually links to, then uses set subtraction to find what each locale is missing, reporting the German page's omission of French.

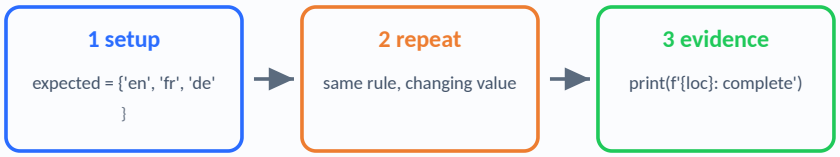
What You'll Build & Learn

Verify that every locale in a matrix links to the full expected set, reporting each locale's missing alternates.

- A complete matrix links every locale to all
- Set difference finds gaps
- One gap weakens the whole cluster

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 351: count distinct locales in a cluster. Project 353 changes the surface problem while preserving the underlying method.



progress check

Reading target: check hreflang matrix completeness is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `expected = {'en', 'fr', 'de'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{loc}: complete')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`expected = {'en', 'fr', 'de'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

Move	Code to inspect	Why it matters
2. Apply the rule	`if missing:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: complete')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if missing:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Hreflang Matrix Completeness: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: expected, en, fr, de, matrix. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: expected = {'en', 'fr', 'de'} | Core: if missing: | Evidence: print(f'{loc}: complete')

Reader to Writer Bridge

1. Read: explain check hreflang matrix completeness in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 351.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 353 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: complete')`. Then compare punctuation, spacing, and order.
2. Explain: point to `expected = {'en', 'fr', 'de'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check hreflang matrix completeness and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting each locale's declared set from the expected full set reveals exactly which alternates that page is missing.

```
expected = {'en', 'fr', 'de'}
matrix = {
    'en': {'en', 'fr', 'de'},
    'fr': {'en', 'fr', 'de'},
    'de': {'en', 'de'},
}
for loc in sorted(matrix):
    missing = expected - matrix[loc]
    if missing:
        print(f'{loc}: missing {sorted(missing)}')
    else:
        print(f'{loc}: complete')
```

```
output
de: missing ['fr']
en: complete
fr: complete
```

How it works:

1. An expected set lists the three languages that should appear, and matrix maps each locale to the set it actually links to.
2. For each locale, expected - matrix[loc] computes the set of languages it is missing.
3. If that difference is non-empty the code prints the sorted missing list, otherwise it prints 'complete'.

Try it:

1. Also detect extra locales a page links to that are not in expected.
2. Print a full grid showing every locale-to-locale link status.
3. Compute a completeness percentage across the whole matrix.
4. Add the missing `fr` to the `de` row and watch it report complete.

⚠ Common Mistakes

- Checking only that each page links to the others while forgetting the required self-reference.
- Comparing list lengths instead of set differences hides which specific locale is absent.
- Iterating the matrix unsorted makes the per-locale report order vary.

Skills gained set difference | matrix | completeness | auditing

→ Where You'll Use This: Matrix completeness checks catch the case where one page in a cluster forgot an alternate; that single gap breaks reciprocity for the missing pair and undermines the entire group.

Mental Model

The matrix is a round-robin tournament bracket: if one player skips a match, the whole schedule is incomplete.

Project 353 Detect an Orphan Alternate URL

The Idea Behind It

An hreflang tag can point at a URL that does not actually exist on the site, an orphan alternate that wastes crawl budget and breaks reciprocity. This project keeps a set of URLs that really exist, then filters the linked alternate URLs to find any that are absent from that set, surfacing the Italian page that was declared but never built.

What You'll Build & Learn

Find alternate URLs declared in hreflang that do not exist among the site's real pages.

- Orphan alternates point at nonexistent URLs
- Set membership detects missing pages
- Orphans break reciprocity and waste crawl

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 352: check hreflang matrix completeness. Project 354 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect an orphan alternate url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `existing = {'https://s.com/en/', 'https://s.com/fr/'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('orphan alternates:', orphans)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`existing = {'https://s.com/en/', 'https://s.com/fr/'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`orphans = sorted(u for u in linked.values() if u not in existing)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('orphan alternates:', orphans)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the

behaviour.

CORE LINE `orphans = sorted(u for u in linked.values() if u not in existing)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect an Orphan Alternate URL: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: existing, https, com, en, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: existing = {'https://s.com/en/', 'https://s.com/fr/'} | Core: orphans = sorted(u for u in linked.values() if u not in existing) | Evidence: print('orphan alternates:', orphans)

🛠️ Reader to Writer Bridge

1. Read: explain detect an orphan alternate url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 352.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 354 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('orphan alternates:', orphans)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `existing = {'https://s.com/en/', 'https://s.com/fr/'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect an orphan alternate url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing each linked alternate URL against the set of pages that truly exist isolates the alternates whose targets are absent.

```
existing = {'https://s.com/en/', 'https://s.com/fr/'}
linked = {
    'en': 'https://s.com/en/',
    'fr': 'https://s.com/fr/',
    'it': 'https://s.com/it/',
}
orphans = sorted(u for u in linked.values() if u not in existing)
print('orphan alternates:', orphans)
```

```
output
orphan alternates: ['https://s.com/it/']
```

How it works:

1. A set named existing lists the URLs that truly exist on the site.
2. A dict named linked maps locales to declared alternate URLs, including an Italian URL that is not in existing.
3. A comprehension keeps every linked URL not in existing, sorts the result, and prints the orphan alternates list.

Try it:

1. Report which locale code declared each orphan URL.
2. Cross-check orphans against a live status-code crawl for 404s.
3. Add several orphans and confirm all appear sorted.
4. Add `https://s.com/it/` to the existing set and confirm zero orphans.

⚠ Common Mistakes

- Comparing alternate codes against existing URLs instead of comparing the URLs themselves.
- Treating a relative alternate as missing when it merely needs resolving against the host first.
- Forgetting to sort the orphan list makes the output order unstable.

Skills gained sets orphans membership crawl budget

→ Where You'll Use This: Orphan alternates appear when a locale is deprecated but its hreflang tags linger; finding them stops crawlers chasing dead URLs and prevents reciprocity from silently failing.

Mental Model

An orphan alternate is a phone number on a business card for a line that was disconnected: dial it and you reach nothing.

Project 354 Catch a Lang and Region Case Swap

The Idea Behind It

A classic hreflang typo inverts the casing, writing an uppercase language and a lowercase region as in 'EN-us'. This project partitions each code on its first hyphen and checks the case of the language and region subtags independently, collecting a precise list of issues per code so the editor sees exactly which half is wrong.

What You'll Build & Learn

Detect case mistakes by checking the language and region subtags separately and reporting each specific issue.

- Language should be lowercase, region uppercase
- str.partition splits on first hyphen
- Reporting each issue separately

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 353: detect an orphan alternate url. Project 355 changes the surface problem while preserving the underlying method.

progress check

Reading target: catch a lang and region case swap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `codes = ['en-US', 'EN-us', 'fr-FR', 'DE-de', 'es-ES']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print(f'{c}: {"; ".join(issues) if issues else "ok"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`codes = ['en-US', 'EN-us', 'fr-FR', 'DE-de', 'es-ES']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if not lang.islower():`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: {"; ".join(issues) if issues else "ok"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not lang.islower():`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Catch a Lang and Region Case Swap: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: codes, en, US, EN, us. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: codes = ['en-US', 'EN-us', 'fr-FR', 'DE-de', 'es-ES'] | Core: if not lang.islower(): | Evidence: print(f'{c}: {"; ".join(issues) if issues else "ok"}')

🛠️ Reader to Writer Bridge

1. Read: explain catch a lang and region case swap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 353.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 355 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: {"; ".join(issues) if issues else "ok"}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `codes = ['en-US', 'EN-us', 'fr-FR', 'DE-de', 'es-ES']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of catch a lang and region case swap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Partitioning on `-` yields the language and region, and `islower()`/`isupper()` on each subtag reports precisely which half has the wrong case.

```
codes = ['en-US', 'EN-us', 'fr-FR', 'DE-de', 'es-ES']
for c in codes:
    lang, _, region = c.partition('-')
    issues = []
    if not lang.islower():
        issues.append('lang should be lowercase')
    if region and not region.isupper():
        issues.append('region should be uppercase')
    print(f'{c}: {"; ".join(issues) if issues else "ok"}')
```

```
output
en-US: ok
EN-us: lang should be lowercase; region should be uppercase
fr-FR: ok
DE-de: lang should be lowercase; region should be uppercase
es-ES: ok
```

How it works:

1. c.partition('-') splits each code into lang, the separator, and region in one call.
2. If lang.islower() is false an issue is appended, and if a region exists but is not isupper another issue is appended.
3. The issues list is joined with semicolons and printed, or 'ok' is shown when the list is empty.

Try it:

1. Auto-correct the casing and print the fixed code beside the issue.
2. Treat a code with no region but uppercase language as still wrong.
3. Count how many codes have at least one casing issue.
4. Add `en-Us` (only the region's second letter lowercased) and see it flagged.

⚠ Common Mistakes

- Lowercasing the whole code before checking erases the very casing error you are hunting.
- Using `partition('-')` is safe for a region-less code, but indexing `[1]` after `split` would raise.
- Reporting a single generic 'invalid' loses which subtag was miscased.

Skills gained partition | case checks | diagnostics | hreflang

→ Where You'll Use This: Case-swap typos slip past structural shape checks because the letters are right; checking each subtag's case separately is how a thorough audit catches the most embarrassing common mistake.

Mental Model

It is a typo in someone's title: 'mr SMITH' has both halves wrong, and you need to point at each separately to fix it.

Project 355 Resolve a Language Fallback Chain

The Idea Behind It

When a requested locale is not served, negotiation falls back: from a full locale like 'en-US' to the bare language 'en', then to 'x-default'. This project defines a resolve function that builds that ordered chain for any request and returns the first candidate present in the available set, modeling how a browser or server settles on a locale.

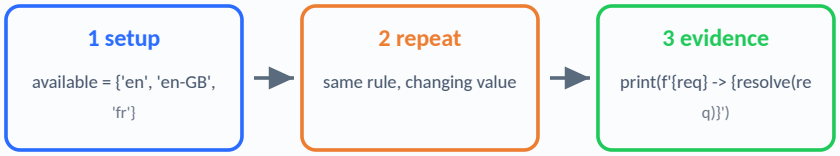
What You'll Build & Learn

Model locale negotiation by resolving a requested code down a fallback chain to whatever is actually available.

- Fallback chain locale, language, x-default
- First match wins in negotiation
- Returning none when nothing matches

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 354: catch a lang and region case swap. Project 356 changes the surface problem while preserving the underlying method.



progress check

Reading target: resolve a language fallback chain is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `available = {'en', 'en-GB', 'fr'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{req} -> {resolve(req)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`available = {'en', 'en-GB', 'fr'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if cand in available:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{req} -> {resolve(req)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if cand in available:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Resolve a Language Fallback Chain: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: available, en, GB, fr, resolve. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: available = {'en', 'en-GB', 'fr'} | Core: if cand in available: | Evidence: print(f'{req} -> {resolve(req)}')

🛠️ Reader to Writer Bridge

1. Read: explain resolve a language fallback chain in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 354.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 356 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{req} -> {resolve(req)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `available = {'en', 'en-GB', 'fr'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of resolve a language fallback chain and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Building the candidate chain `[exact, language, x-default]` and returning the first one present in the available set implements graceful locale degradation.

```
available = {'en', 'en-GB', 'fr'}
def resolve(req):
    chain = [req, req.split('-')[0], 'x-default']
    for cand in chain:
        if cand in available:
            return cand
    return 'none'
```

```
for req in ['en-GB', 'en-US', 'fr-CA', 'de-DE']:
    print(f'{req} -> {resolve(req)}')
```

```
output
en-GB -> en-GB
en-US -> en
fr-CA -> fr
de-DE -> none
```

How it works:

1. The available set names the locales actually served, such as 'en', 'en-GB', and 'fr'.
2. resolve builds chain as [req, req.split('-')[0], 'x-default'] and returns the first candidate found in available.
3. Calling resolve on several requests prints how each one degrades, with 'de-DE' resolving to 'none' since no German fallback exists.

Try it:

1. Add a region-to-language map so 'fr-CA' can prefer 'fr-FR' before bare 'fr'.
2. Log the full chain that was tried for each request.
3. Return the matched URL instead of just the matched code.
4. Add `de` to the available set and watch `de-DE` resolve.

⚠ Common Mistakes

- Returning the exact request without a fallback chain leaves unmatched users with nothing.
- Putting `x-default` before the bare language wrongly skips a perfectly good language match.
- Splitting on `_` instead of `-` never extracts the bare-language fallback.

Skills gained functions fallback locales negotiation

→ Where You'll Use This: Server-side locale routing relies on exactly this degradation logic; understanding it helps you predict which page a visitor lands on and why some requests fall through to a default.

Mental Model

Locale negotiation is asking for a specific coffee, then a generic one, then 'whatever you have' until the barista can actually pour something.

Project 356 Require Absolute Alternate URLs

The Idea Behind It

Hreflang alternates must be fully-qualified absolute URLs; search engines ignore relative paths entirely. This project keeps an alternates dict mixing absolute and relative values, then tests each URL with a simple

startswith('https://') check, labeling the absolute ones valid and printing the broken relative paths so they can be corrected.

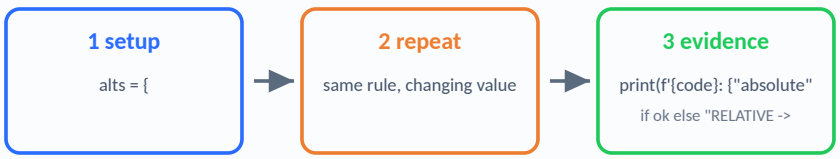
What You'll Build & Learn

Separate absolute alternate URLs from relative ones that search engines will ignore.

- Alternates must be absolute URLs
- Relative paths are silently ignored
- startswith is a cheap scheme check

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 355: resolve a language fallback chain. Project 357 changes the surface problem while preserving the underlying method.



progress check

Reading target: require absolute alternate urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `alts = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`alts = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Require Absolute Alternate URLs: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: alts, en, https, com, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: alts = { | Core: print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}') | Evidence: print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')

🛠️ Reader to Writer Bridge

1. Read: explain require absolute alternate urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 355.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 357 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `alts = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of require absolute alternate urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Testing each alternate for a `https://` prefix flags relative paths like `/fr/` and `es/index.html` that crawlers cannot resolve from an hreflang tag.

```
alts = {
    'en': 'https://s.com/en/',
    'fr': '/fr/',
    'de': 'https://s.com/de/',
    'es': 'es/index.html',
}
for code in sorted(alts):
    url = alts[code]
    ok = url.startswith('https://')
    print(f'{code}: {"absolute" if ok else "RELATIVE -> " + url}')
```

```
output
de: absolute
en: absolute
es: RELATIVE -> es/index.html
fr: RELATIVE -> /fr/
```

How it works:

1. A dict named alts maps locales to URLs, two of which are relative paths like '/fr/' and 'es/index.html'.

2. Iterating sorted(alts) keeps the output ordered by locale code.
3. url.startswith('https://') decides each case, printing 'absolute' or 'RELATIVE ->' with the offending value.

Try it:

1. Also accept http:// but warn that https is preferred.
2. Resolve relative paths against a base URL and print the absolute form.
3. Reject protocol-relative '//host/path' URLs as ambiguous.
4. Make every alternate absolute and confirm they all pass.

⚠ Common Mistakes

- Accepting a root-relative `/fr/` because it 'looks like a URL' though hreflang requires absolute form.
- Checking only for a leading `/` would still reject a valid absolute `https://` URL.
- Iterating the dict unsorted makes the per-code report order vary.

Skills gained startswith | absolute urls | validation | dicts

→ Where You'll Use This: Templating bugs frequently emit relative alternate URLs that search engines discard; a scheme check across every alternate is a fast guard before tags ship to production.

⚡ Mental Model

A relative URL is directions that say 'turn left at the shop' with no city named: useless to anyone who is not already standing where you are.

Project 357 Reconcile Head and Sitemap Hreflang

💡 The Idea Behind It

Hreflang can be declared in the page head or in the XML sitemap, but the two sources must agree. This project represents each source as a set of locale codes and uses set arithmetic to find which locales appear only in the head, which appear only in the sitemap, and whether the two sets are equal overall.

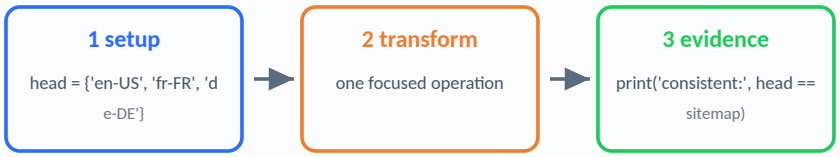
What You'll Build & Learn

Reconcile head-based and sitemap-based hreflang by finding the locales unique to each source.

- Hreflang lives in head or sitemap
- The two sources must match
- Set difference and equality compare them

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 356: require absolute alternate urls. Project 358 changes the surface problem while preserving the underlying method.



progress check

Reading target: reconcile head and sitemap hreflang is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `head = {'en-US', 'fr-FR', 'de-DE'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('consistent:', head == sitemap)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`head = {'en-US', 'fr-FR', 'de-DE'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`sitemap = {'en-US', 'fr-FR', 'es-ES'}`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print('consistent:', head == sitemap)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `sitemap = {'en-US', 'fr-FR', 'es-ES'}`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Reconcile Head and Sitemap Hreflang: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: head, en, US, fr, FR. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: head = {'en-US', 'fr-FR', 'de-DE'} | Core: sitemap = {'en-US', 'fr-FR', 'es-ES'} | Evidence: print('consistent:', head == sitemap)

🛠️ Reader to Writer Bridge

1. Read: explain reconcile head and sitemap hreflang in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 356.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 358 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('consistent:', head == sitemap)`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `head = {'en-US', 'fr-FR', 'de-DE'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of reconcile head and sitemap hreflang and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting the sitemap set from the head set (and vice versa) reveals locale declarations that exist in just one source, and equality confirms full consistency.

```
head = {'en-US', 'fr-FR', 'de-DE'}
sitemap = {'en-US', 'fr-FR', 'es-ES'}
print('in head only:', sorted(head - sitemap))
print('in sitemap only:', sorted(sitemap - head))
print('consistent:', head == sitemap)
```

```
output
in head only: ['de-DE']
in sitemap only: ['es-ES']
consistent: False
```

How it works:

1. Two sets, head and sitemap, hold the locale codes each source declares.
2. head - sitemap finds locales only in the head and sitemap - head finds those only in the sitemap.
3. head == sitemap prints whether the two declarations are fully consistent.

Try it:

1. Report the intersection as the locales both sources agree on.
2. Extend to compare URLs per locale, not just the code set.
3. Run the comparison across many pages and total the inconsistencies.
4. Add `es-ES` to the head and watch the 'sitemap only' list shrink.

⚠ Common Mistakes

- Comparing the two as lists lets ordering differences masquerade as content differences.
- Reporting only the union hides which source is missing a locale.
- Assuming the head is authoritative without flagging sitemap-only locales.

Skills gained sets | set difference | reconciliation | sitemaps

→ **Where You'll Use This:** Large sites often manage head tags and sitemap entries with different systems; a drift between them confuses crawlers, and this set comparison is how you prove the two stay in sync.

Mental Model

The head and the sitemap are two witnesses to the same event; if their stories differ, the investigator notes exactly where they diverge.

Project 358 Require an Hreflang Self-Reference

The Idea Behind It

Every page in a cluster must list its own locale among its hreflang alternates, or the whole set is invalidated for that page. This project pairs a pages dict of alternate sets with a locale map, then checks for each page whether its own locale appears in its alternate set, confirming the required self-reference.

What You'll Build & Learn

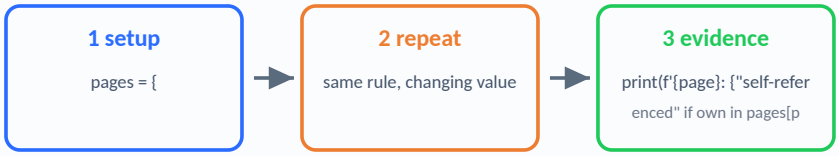
Confirm that each page includes its own locale in its hreflang alternates, the mandatory self-reference.

- Each page must self-reference
- A missing self-ref voids the set
- Pairing alternates with a locale map

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 357: reconcile head and sitemap hreflang. Project 359 changes the surface problem while preserving the underlying method.

progress check



Reading target: require an hreflang self-reference is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Require an Hreflang Self-Reference: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: pages, https, com, en, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING... | Evidence: print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING...

🛠️ Reader to Writer Bridge

1. Read: explain require an hreflang self-reference in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 357.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 359 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of require an hreflang self-reference and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Looking up each page's own locale and checking it is present in that page's declared code set enforces the self-reference rule.

```
pages = {
    'https://s.com/en/': {'en', 'fr'},
    'https://s.com/fr/': {'en', 'fr'},
}
locale = {'https://s.com/en/': 'en', 'https://s.com/fr/': 'fr'}
for page in sorted(pages):
    own = locale[page]
    print(f'{page}: {"self-referenced" if own in pages[page] else "MISSING self ref"}')
```

```
output
https://s.com/en/: self-referenced
https://s.com/fr/: self-referenced
```

How it works:

1. The pages dict maps each URL to the set of locale codes it declares as alternates.
2. A separate locale dict records which locale each page actually is.
3. For each page, own in pages[page] checks whether its own locale is listed, printing 'self-referenced' or 'MISSING self ref'.

Try it:

1. Report the count of pages missing their self-reference.
2. Verify the self-reference URL actually points at the page itself.
3. Combine this with the reciprocity check into one report.
4. Remove `en` from the `en` page's set and watch it fail.

⚠ Common Mistakes

- Assuming the self-reference is implicit and never declaring it in the tags.
- Checking for the page URL among codes instead of the page's locale subtag.
- Iterating the pages unsorted makes the per-page verdict order unstable.

Skills gained sets self-reference dicts validation

→ Where You'll Use This: Google requires the self-referential alternate; a page that lists its siblings but forgets itself has its entire hreflang block disregarded, so this check guards a non-obvious but critical rule.

⚡ Mental Model

Forgetting your self-reference is leaving yourself off the group roster you wrote: the team is told you are not on it.

Project 359 Normalize Hreflang Code Casing

The Idea Behind It

Crawlers tolerate any casing, but storing codes in one canonical form, lowercase language and uppercase region, makes deduplication and comparison reliable. This project defines a norm function that partitions each raw code, lowercases the language, and conditionally appends an uppercased region, turning messy input like 'EN-us' and 'Fr-fr' into a tidy standard shape.

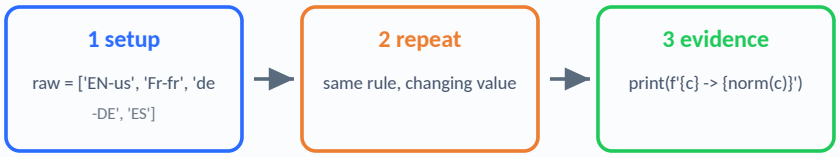
What You'll Build & Learn

Normalize mixed-case hreflang codes into a canonical lowercase-language, uppercase-region form.

- Canonical form aids deduplication
- Lowercase language, uppercase region
- Conditionally rebuilding the region part

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 358: require an hreflang self-reference. Project 360 changes the surface problem while preserving the underlying method.



progress check

Reading target: normalize hreflang code casing is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `raw = ['EN-us', 'Fr-fr', 'de-DE', 'ES']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{c} -> {norm(c)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`raw = ['EN-us', 'Fr-fr', 'de-DE', 'ES']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`return lang.lower() + ('-' + region.upper() if region else '')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{c} -> {norm(c)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return lang.lower() + ('-' + region.upper() if region else '')`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Normalize Hreflang Code Casing: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: raw, EN, us, Fr, fr. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: raw = ['EN-us', 'Fr-fr', 'de-DE', 'ES'] | Core: return lang.lower() + ('-' + region.upper() if region else '') | Evidence: print(f'{c} -> {norm(c)}')

🛠️ Reader to Writer Bridge

1. Read: explain normalize hreflang code casing in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 358.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 360 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c} -> {norm(c)}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `raw = ['EN-us', 'Fr-fr', 'de-DE', 'ES']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize hreflang code casing and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Partitioning on `-` and applying `lower()` to the language and `upper()` to the region rebuilds each code in its conventional canonical casing.

```
raw = ['EN-us', 'Fr-fr', 'de-DE', 'ES']
def norm(c):
    lang, _, region = c.partition('-')
    return lang.lower() + ('-' + region.upper() if region else '')
for c in raw:
    print(f'{c} -> {norm(c)}')
```

```
output
```

```
EN-us -> en-US
Fr-fr -> fr-FR
de-DE -> de-DE
ES -> es
```

How it works:

1. A list named raw holds codes in inconsistent casing, including the region-less 'ES'.
2. norm uses partition('-') to split, then returns lang.lower() plus, only if a region exists, '-' and region.upper().
3. The loop prints each original code mapped to its normalized form, so 'EN-us' becomes 'en-US'.

Try it:

1. Strip surrounding whitespace before normalizing each code.
2. Preserve the special 'x-default' token untouched through norm.
3. Return None for codes that cannot be parsed into a valid shape.
4. Add `ZH-hant` and decide how to canonicalize a script subtag.

⚠ Common Mistakes

- Lowercasing the entire code turns `de-DE` into `de-de` and loses the region convention.
- Forgetting the region-less case would append a stray `-` to a bare language like `es`.
- Title-casing the language (`En`) is neither convention nor valid for matching.

Skills gained partition normalization functions casing

→ **Where You'll Use This:** Before deduplicating or comparing hreflang codes scraped from many pages, normalizing casing prevents 'en-US' and 'EN-us' from being treated as different locales in your audit data.

Mental Model

Normalization is alphabetizing a contacts list by a fixed rule so that 'McLeod' and 'Mcleod' file together instead of drifting apart.

Project 360 Map a Locale to Its Currency

The Idea Behind It

A localized storefront should show prices in each region's own currency. This project keeps a lookup table mapping serviced locales to currency codes, then resolves several locales through it, using dict.get with a default so an unconfigured locale like 'en-CA' is flagged UNMAPPED rather than crashing or silently defaulting.

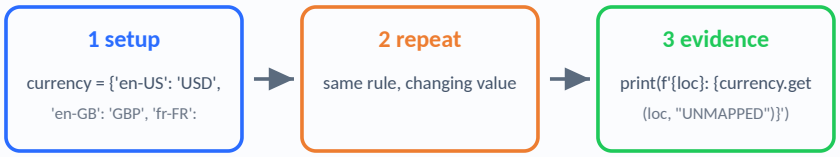
What You'll Build & Learn

Map each serviced locale to its currency and flag any locale that has not been configured.

- Locales drive storefront currency
- dict.get with a default avoids errors
- Flagging unconfigured locales

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 359: normalize hreflang code casing. Project 361 changes the surface problem while preserving the underlying method.



progress check

Reading target: map a locale to its currency is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `currency = {'en-US': 'USD', 'en-GB': 'GBP', 'fr-FR': 'EUR', 'ja-JP': 'JPY'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{loc}: {currency.get(loc, "UNMAPPED")}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`currency = {'en-US': 'USD', 'en-GB': 'GBP', 'fr-FR': 'EUR', 'ja-JP': 'JPY'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

Move	Code to inspect	Why it matters
2. Apply the rule	`for loc in ['en-US', 'fr-FR', 'en-CA']:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: {currency.get(loc, "UNMAPPED")}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for loc in ['en-US', 'fr-FR', 'en-CA']:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Map a Locale to Its Currency: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: currency, en, US, GB, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: currency = {'en-US': 'USD', 'en-GB': 'GBP', 'fr-FR': 'EUR', 'ja-JP': 'J... | Core: for loc in ['en-US', 'fr-FR', 'en-CA']: | Evidence: print(f'{loc}: {currency.get(loc, "UNMAPPED")}')

Reader to Writer Bridge

1. Read: explain map a locale to its currency in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 359.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 361 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {currency.get(loc, "UNMAPPED")}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `currency = {'en-US': 'USD', 'en-GB': 'GBP', 'fr-FR': 'EUR', 'ja-JP': 'JPY'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of map a locale to its currency and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A dict from locale to ISO 4217 currency code, queried with `.get` and a sentinel, reports the currency or surfaces an unmapped locale.

```
currency = {'en-US': 'USD', 'en-GB': 'GBP', 'fr-FR': 'EUR', 'ja-JP': 'JPY'}
for loc in ['en-US', 'fr-FR', 'en-CA']:
    print(f'{loc}: {currency.get(loc, "UNMAPPED")}')
```

```
output
en-US: USD
fr-FR: EUR
en-CA: UNMAPPED
```

How it works:

1. A dict named currency maps four locales such as 'en-US' to currency codes like 'USD'.
2. The loop iterates a list of locales to resolve, including 'en-CA' which is absent from the table.
3. currency.get(loc, 'UNMAPPED') returns the currency or the fallback string, which prints for the missing Canadian locale.

Try it:

1. Add tax rate and payment methods alongside currency per locale.
2. Raise an error instead of printing UNMAPPED to fail a build.
3. Group locales by shared currency such as several EUR markets.

4. Add `en-CA -> CAD` and watch it resolve.

⚠ Common Mistakes

- Mapping on language alone (`en`) ignores that `en-US` and `en-GB` use different currencies.
- Indexing with `currency[loc]` raises a KeyError for any locale you forgot to configure.
- Hard-coding one currency per language breaks every multi-region language.

Skills gained dicts | lookup tables | get default | localization

→ Where You'll Use This: International commerce sites tie locale to currency, tax, and payment options; this lookup pattern is the basis for catching a market you launched without setting up its currency.

⚡ Mental Model

The lookup table is a currency exchange board at the airport: if your country is not listed, the clerk shrugs instead of guessing.

Project 361 Route a Visitor to a Default Locale

💡 The Idea Behind It

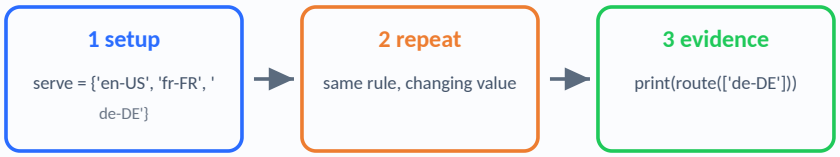
When none of a visitor's preferred locales are available you serve a default. This project keeps a set of served locales and a fixed default, then defines a route function that walks the visitor's ordered preferences and returns the first one that is served, falling back to the default when nothing matches, modeling server-side locale routing.

What You'll Build & Learn

Route a visitor to the first of their preferred locales that you serve, defaulting when none match.

- Honor ordered visitor preferences
- Fall back to a default locale
- First served preference wins

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 360: map a locale to its currency. Project 362 changes the surface problem while preserving the underlying method. *progress check*

Reading target: route a visitor to a default locale is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `serve = {'en-US', 'fr-FR', 'de-DE'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(route(['de-DE']))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`serve = {'en-US', 'fr-FR', 'de-DE'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if pref in serve:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(route(['de-DE']))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if pref in serve:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Route a Visitor to a Default Locale: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: serve, en, US, fr, FR. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: serve = {'en-US', 'fr-FR', 'de-DE'} | Core: if pref in serve: | Evidence: print(route(['de-DE']))

🛠️ Reader to Writer Bridge

1. Read: explain route a visitor to a default locale in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 360.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 362 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(route(['de-DE']))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `serve = {'en-US', 'fr-FR', 'de-DE'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of route a visitor to a default locale and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Returning the first preference present in the served set, or the default when none match, implements priority-ordered locale negotiation.

```
serve = {'en-US', 'fr-FR', 'de-DE'}
default = 'en-US'
def route(accept):
    for pref in accept:
        if pref in serve:
            return pref
    return default
print(route(['fr-FR', 'en-US']))
print(route(['it-IT', 'es-ES']))
print(route(['de-DE']))
```

```
output
fr-FR
en-US
de-DE
```

How it works:

1. A set named serve lists the three locales the site offers and default holds 'en-US'.
2. route loops over the visitor's accept list and returns the first pref found in serve.
3. Three calls show a served preference winning, an all-unavailable list dropping to the default, and a single served locale being chosen.

Try it:

1. Fall back to bare language before the global default.
2. Return the matched locale's URL rather than its code.
3. Log when the hard default was used so you can measure mismatches.
4. Add `es-ES` to the served set and re-run the Spanish-leaning request.

⚠ Common Mistakes

- Returning the default before exhausting the visitor's preference list ignores valid matches.
- Treating preferences as an unordered set loses the visitor's priority order.
- Using a default that is not in the served set can route users to a missing page.

Skills gained functions routing preferences defaults

→ Where You'll Use This: Geo and language routing at the edge or in middleware uses this priority-then-default logic; getting it right keeps visitors on a relevant page instead of a jarring wrong-language landing.

Mental Model

Routing is a host seating guests by request: first choice if free, second if not, and a standard table when nothing they asked for is open.

Project 362 Pick a Locale from Accept-Language

The Idea Behind It

Browsers send an Accept-Language header listing locales with quality weights like 'en-US;q=1.0'. This project parses that header by splitting on commas, partitioning each part on ';q=' to separate the code from its weight, then choosing the highest-weighted locale with max over (weight, code) tuples, showing how a server reads a visitor's true priority.

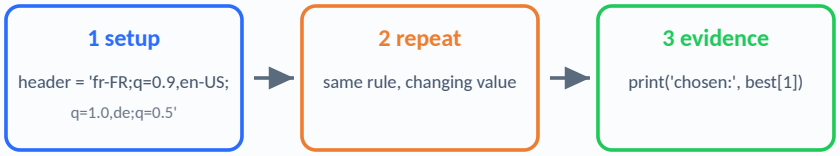
What You'll Build & Learn

Parse an Accept-Language header with quality weights and pick the visitor's highest-priority locale.

- Accept-Language carries q quality weights
- Partitioning a header field on ';q='
- max over tuples picks the top weight

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 361: route a visitor to a default locale. Project 363 changes the surface problem while preserving the underlying method.



progress check

Reading target: pick a locale from accept-language is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `header = 'fr-FR;q=0.9,en-US;q=1.0,de;q=0.5'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('chosen:', best[1])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`header = 'fr-FR;q=0.9,en-US;q=1.0,de;q=0.5'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`parsed.append((float(q) if q else 1.0, code))`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('chosen:', best[1])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `parsed.append((float(q) if q else 1.0, code))`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pick a Locale from Accept-Language: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: header, fr, FR, en, US. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: header = 'fr-FR;q=0.9,en-US;q=1.0,de;q=0.5' | Core: parsed.append *float(q) if q else 1.0, code* | Evidence: print('chosen:', best[1])

Reader to Writer Bridge

1. Read: explain pick a locale from accept-language in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 361.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 363 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('chosen:', best[1])`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `header = 'fr-FR;q=0.9,en-US;q=1.0,de;q=0.5'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pick a locale from accept-language and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

Splitting each part on `;q=` separates code from weight, defaulting to 1.0 when absent, and `max` over `(weight, code)` tuples selects the strongest preference.

```
header = 'fr-FR;q=0.9,en-US;q=1.0,de;q=0.5'
parsed = []
for part in header.split(','):
    code, _, q = part.partition(';q=')
    parsed.append((float(q) if q else 1.0, code))
best = max(parsed)
```

```
print('weights:', sorted(parsed, reverse=True))
print('chosen:', best[1])
```

```
output
weights: [(1.0, 'en-US'), (0.9, 'fr-FR'), (0.5, 'de')]
chosen: en-US
```

How it works:

1. The header string lists three locales each with a ;q= weight, comma separated.
2. Splitting on commas and partitioning each part on ';q=' yields the code and weight, stored as (float(q) if q else 1.0, code) tuples.
3. max(parsed) returns the tuple with the highest weight, and the prints show the sorted weights plus the chosen 'en-US'.

Try it:

1. Handle a malformed q-value gracefully instead of crashing.
2. Break ties by preferring a more specific locale over a bare language.
3. Filter to only locales the site actually serves before choosing.
4. Give `de` a weight of 1.0 and watch the tie-break behaviour.

⚠ Common Mistakes

- Treating a missing `;q=` as weight 0 instead of the spec's default of 1.0.
- Comparing weights as strings makes `0.9` outrank `1.0` lexically.
- Forgetting that whitespace can surround entries in a real header and break the split.

Skills gained parsing | accept-language | tuples | max

→ Where You'll Use This: Servers that personalize language without a stored preference rely on Accept-Language; parsing its q-values correctly is what decides the locale a first-time visitor sees.

Mental Model

The q-weights are a ranked-choice ballot: the visitor lists languages in order of preference and the server tallies the winner.

Project 363 Validate the x-default Target

The Idea Behind It

The x-default URL should usually be a neutral language selector or root page, distinct from any one locale's URL. This project pulls the x-default target out of a cluster, gathers the set of all the other locale URLs, and

checks that the x-default is not among them, catching a fallback misconfigured to duplicate a specific market's page.

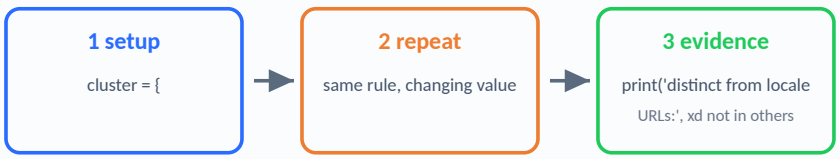
What You'll Build & Learn

Verify the x-default target is distinct from every specific locale URL in the cluster.

- x-default should be neutral
- It must differ from locale URLs
- Set membership tests distinctness

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 362: pick a locale from accept-language. Project 364 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate the x-default target is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `cluster = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('distinct from locale URLs:', xd not in others)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`cluster = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`others = {u for c, u in cluster.items() if c != 'x-default'}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('distinct from locale URLs:', xd not in others)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `others = {u for c, u in cluster.items() if c != 'x-default'}`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate the x-default Target: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: cluster, en, US, https, com. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: cluster = { | Core: others = {u for c, u in cluster.items() if c != 'x-default'} | Evidence: print('distinct from locale URLs:', xd not in others)

🛠️ Reader to Writer Bridge

1. Read: explain validate the x-default target in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 362.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 364 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('distinct from locale URLs:', xd not in others)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `cluster = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate the x-default target and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Collecting the non-default locale URLs into a set and testing that the `x-default` target is not among them confirms the fallback is its own neutral page.

```
cluster = {
    'en-US': 'https://s.com/us/',
    'en-GB': 'https://s.com/gb/',
    'x-default': 'https://s.com/',
}
xd = cluster.get('x-default')
others = {u for c, u in cluster.items() if c != 'x-default'}
print('x-default ->', xd)
print('distinct from locale URLs:', xd not in others)
```

```
output
x-default -> https://s.com/
distinct from locale URLs: True
```

How it works:

1. A cluster dict maps two English locales plus 'x-default' to their URLs, with x-default pointing at the bare root.

2. cluster.get('x-default') extracts the fallback URL, and a set comprehension gathers every other locale's URL.
3. xd not in others prints True, confirming the x-default does not collide with a specific locale page.

Try it:

1. Warn if x-default points at a locale-specific subpath like /us/.
2. Allow the x-default to equal the root only if a selector exists there.
3. Run the check across many clusters and total the violations.
4. Point `x-default` at the US URL and watch the distinctness check fail.

⚠ Common Mistakes

- Pointing `x-default` at a specific locale (e.g. the US page) defeats its neutral purpose.
- Comparing against locale codes rather than their URLs gives a meaningless check.
- Assuming any present `x-default` is correct without inspecting where it points.

Skills gained sets | x-default | membership | validation

→ Where You'll Use This: A misconfigured x-default that simply repeats the US page tells Google to send unmatched visitors into a market-specific experience; this distinctness check guards against that subtle fallback error.

⚡ Mental Model

x-default should be the neutral reception desk, not someone's private office; sending lost visitors into a single office is a misroute.

Project 364 Group Locale Pages by Language

💡 The Idea Behind It

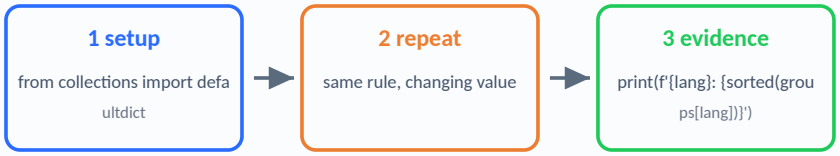
Reporting locales grouped by language shows regional coverage at a glance: which languages you serve and in how many regions each. This project uses a defaultdict of lists to bucket every code under its language subtag by splitting on the hyphen, then prints each language with its sorted regional variants, the inverse of flattening a matrix.

What You'll Build & Learn

Group locale codes by their language so you can read regional coverage per language at a glance.

- Grouping reveals regional coverage
- defaultdict(list) buckets by key
- Splitting code to find its language

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 363: validate the x-default target. Project 365 changes the surface problem while preserving the underlying method. *progress check*

Reading target: group locale pages by language is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f'{lang}: {sorted(groups[lang])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`for c in codes:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{lang}: {sorted(groups[lang])}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group locale pages by language and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A `defaultdict(list)` keyed by the language subtag collects each region under its language, and sorting both the keys and the grouped lists keeps the output deterministic.

```
from collections import defaultdict
codes = ['en-US', 'en-GB', 'fr-FR', 'fr-CA', 'de-DE']
groups = defaultdict(list)
for c in codes:
    groups[c.split('-')[0]].append(c)
for lang in sorted(groups):
    print(f'{lang}: {sorted(groups[lang])}')
```

```
output
de: ['de-DE']
en: ['en-GB', 'en-US']
fr: ['fr-CA', 'fr-FR']
```

How it works:

1. A list named codes holds five locale variants across English, French, and German.
2. A defaultdict(list) named groups appends each code under groups[c.split('-')[0]], its language part.
3. Iterating sorted(groups) prints each language followed by its sorted list of regional variants.

Try it:

1. Append the count of regions next to each language.
2. Sort languages by how many regions they cover.
3. Handle a bare language code with no region in the grouping.
4. Add `es-ES` and `es-MX` to see a new language group form.

⚠ Common Mistakes

- Grouping by the full code keeps `en-US` and `en-GB` apart and defeats the purpose.
- Using a plain dict and indexing a missing key raises instead of starting a new group.

- Forgetting to sort the per-language lists makes the regions print in arbitrary order.

Skills gained defaultdict | grouping | string split | reporting

→ Where You'll Use This: Coverage reports for stakeholders read better grouped by language than as a flat list; this grouping shows at once that English serves two regions while German serves only one.

Mental Model

Grouping by language is sorting a bookshelf by author, then seeing at a glance who wrote one book and who wrote ten.

Project 365 Flag a Duplicate Region per Language

The Idea Behind It

Declaring the same locale twice, such as two 'en-US' tags, is a duplication bug. This project tallies a list of locale codes with a Counter, then prints each code alongside its occurrence count, appending a DUPLICATE flag to any code that appears more than once so repeated region declarations stand out.

What You'll Build & Learn

Tally locale codes and flag any that appear more than once as duplicate region declarations.

- Repeating a locale is a bug
- Counter gives per-code tallies
- Flagging counts above one

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 364: group locale pages by language. Project 366 changes the surface problem while preserving the underlying method. *progress check*

Reading target: flag a duplicate region per language is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

- Evidence: `print(f'{c}: x{counts[c]}{flag}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`flag = ' DUPLICATE' if counts[c] > 1 else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: x{counts[c]}{flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = ' DUPLICATE' if counts[c] > 1 else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag a Duplicate Region per Language: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: collections, Counter, codes, en, US. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: flag = ' DUPLICATE' if counts[c] > 1 else '' | Evidence: print(f'{c}: x{counts[c]}{flag}')

🛠️ Reader to Writer Bridge

1. Read: explain flag a duplicate region per language in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 364.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 366 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: x{counts[c]} {flag}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag a duplicate region per language and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `Counter` over the codes gives each one's occurrence count, and printing a flag whenever the count exceeds one surfaces the duplicates in sorted order.

```
from collections import Counter
codes = ['en-US', 'en-GB', 'en-US', 'fr-FR']
counts = Counter(codes)
for c in sorted(counts):
```

```
    flag = ' DUPLICATE' if counts[c] > 1 else ''
    print(f'{c}: x{counts[c]}{flag}')
```

```
output
en-GB: x1
en-US: x2 DUPLICATE
fr-FR: x1
```

How it works:

1. A list named codes has 'en-US' twice among the four entries.
2. Counter(codes) builds a tally of how often each code appears.
3. Iterating sorted(counts) prints each code with 'x' and its count, adding ' DUPLICATE' when the count exceeds one.

Try it:

1. Exit with an error code if any duplicate is found.
2. Report only the duplicates instead of every code.
3. Show which language has the most duplicated regions.
4. Add a third `en-US` and watch the multiplier rise to x3.

⚠ Common Mistakes

- Deduping with a set first erases the very repetition you want to report.
- Flagging codes that merely share a language (`en-US`, `en-GB`) confuses regions with duplicates.
- Iterating the Counter unsorted makes the report order vary run to run.

Skills gained Counter duplicates collections auditing

→ Where You'll Use This: A page that injects the same region tag twice often comes from a looping template; the per-code tally turns that defect into a clear, sorted line item in your QA output.

⚡ Mental Model

The Counter is a turnstile clicker: it just counts each badge as it passes and lights up when the same one comes through twice.

Project 366 Generate a Reciprocal Hreflang Set

💡 The Idea Behind It

Given one cluster, the correct hreflang block is identical on every page: each lists all locales including itself. This project iterates the cluster once per page and, for each, prints the full set of hreflang declarations, generating a reciprocal block programmatically so every page ends up with the same complete, mutually-linking tags.

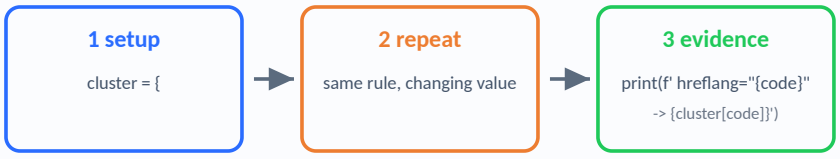
What You'll Build & Learn

Generate the identical, fully reciprocal hreflang block that every page in a cluster should carry.

- Every page shares one identical block
- Generation guarantees reciprocity
- Nested iteration over a cluster

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 365: flag a duplicate region per language. Project 367 changes the surface problem while preserving the underlying method.



progress check

Reading target: generate a reciprocal hreflang set is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `cluster = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print(f' hreflang="{code}" -> {cluster[code]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`cluster = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`for page_code in sorted(cluster):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f' hreflang="{code}" -> {cluster[code]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for page_code in sorted(cluster):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Generate a Reciprocal Hreflang Set: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: cluster, en, https, com, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: cluster = { | Core: for page_code in sorted(cluster): | Evidence: print(f' hreflang="{code}" -> {cluster[code]}')

🛠️ Reader to Writer Bridge

1. Read: explain generate a reciprocal hreflang set in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 365.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 367 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f' hreflang="{code}" -> {cluster[code]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `cluster = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of generate a reciprocal hreflang set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each page in the cluster, emitting a tag for every locale (sorted) produces the same complete, self-including block everywhere, which is exactly what reciprocity requires.

```
cluster = {
    'en': 'https://s.com/en/',
    'fr': 'https://s.com/fr/',
    'de': 'https://s.com/de/',
}
for page_code in sorted(cluster):
    print(f'On {cluster[page_code]}:')
    for code in sorted(cluster):
        print(f'  hreflang="{code}" -> {cluster[code]}')
```

```
output
On https://s.com/de/:
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
On https://s.com/en/:
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
On https://s.com/fr/:
```

```
  hreflang="de" -> https://s.com/de/
  hreflang="en" -> https://s.com/en/
  hreflang="fr" -> https://s.com/fr/
```

How it works:

1. A cluster dict maps three language codes to their absolute URLs.
2. The outer loop over sorted(cluster) prints an 'On URL:' header for each page.
3. The inner loop over sorted(cluster) prints every hreflang code and its URL, so each page emits the same complete reciprocal block.

Try it:

1. Append an x-default line to every generated block.
2. Output real link rel='alternate' HTML tags instead of arrows.
3. Emit the equivalent XML sitemap hreflang entries instead.
4. Add an `x-default` entry and watch every block gain it.

⚠ Common Mistakes

- Omitting a page's own locale from its block breaks the self-reference rule.
- Generating a different subset per page reintroduces the reciprocity bugs you meant to avoid.
- Iterating the cluster unsorted makes the generated tags print in unstable order.

Skills gained nested loops | generation | reciprocity | dicts

→ Where You'll Use This: Generating hreflang from a single source of truth, rather than hand-editing per page, is the practical way to guarantee reciprocity and self-references stay perfect as locales are added.

⚡ Mental Model

It is photocopying one master page for everyone: because the original is correct, every copy is automatically correct and consistent.

Project 367 Audit a Cluster for Required Tags

💡 The Idea Behind It

A cluster passes only if it self-references, declares an x-default, and lists at least two locales. This project bundles those three conditions into a checks dict of named booleans, evaluating each against the cluster's codes, then prints a PASS or FAIL line per rule to deliver a quick compliance verdict in one place.

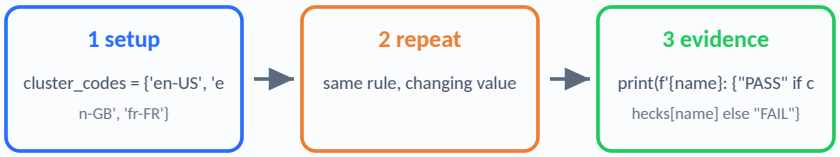
What You'll Build & Learn

Run three required-tag checks on a cluster at once and report a pass or fail for each.

- Three rules define a passing cluster
- A dict of named boolean checks
- Reporting each rule's verdict

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 366: generate a reciprocal hreflang set. Project 368 changes the surface problem while preserving the underlying method.



progress check

Reading target: audit a cluster for required tags is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `cluster_codes = {'en-US', 'en-GB', 'fr-FR'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {"PASS" if checks[name] else "FAIL"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `cluster_codes = {'en-US', 'en-GB', 'fr-FR'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of audit a cluster for required tags and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Encoding each requirement as a boolean in a dict lets you print a labelled PASS/FAIL line per rule, making a partial failure (here, the missing x-default) obvious.

```
cluster_codes = {'en-US', 'en-GB', 'fr-FR'}
page_locale = 'en-US'
checks = {
    'self present': page_locale in cluster_codes,
    'x-default present': 'x-default' in cluster_codes,
    'at least 2 locales': len(cluster_codes) >= 2,
}
for name in sorted(checks):
    print(f'{name}: {"PASS" if checks[name] else "FAIL"}')
```

```
output
at least 2 locales: PASS
self present: PASS
x-default present: FAIL
```

How it works:

1. cluster_codes is a set and page_locale names the page's own locale, here 'en-US'.
2. A checks dict maps three rule names to booleans: self present, x-default present, and at least two locales.
3. Iterating sorted(checks) prints each rule with PASS or FAIL, exposing that x-default is missing.

Try it:

1. Add a rule requiring all codes to be well-formed.

2. Compute an overall PASS only when every check passes.
3. Raise the locale minimum to three and observe the change.
4. Add `x-default` to the code set and watch that line flip to PASS.

⚠ Common Mistakes

- Combining the checks into one boolean hides which specific rule failed.
- Counting `x-default` toward the 'at least two locales' rule inflates the locale count.
- Iterating the checks dict unsorted makes the report order vary.

Skills gained dicts | boolean checks | compliance | sets

→ Where You'll Use This: A compact pass/fail panel per cluster is what a dashboard surfaces to non-technical stakeholders; bundling the named rules keeps the report readable and easy to extend with new criteria.

Mental Model

The checks dict is a pre-flight checklist: each item gets its own tick, and the plane only leaves when they all read green.

Project 368 Check Alternates Share a Scheme

The Idea Behind It

Alternates may live on subdomains or ccTLDs, but they should at least share a single scheme such as all https. This project extracts the scheme and host from each alternate URL by splitting on '://' and the first slash, then reports the distinct schemes and hosts and confirms whether exactly one scheme is in use, revealing the cluster's URL topology.

What You'll Build & Learn

Extract schemes and hosts from alternate URLs and confirm the whole cluster shares one scheme.

- Alternates can span subdomains or ccTLDs
- They should share a single scheme
- Splitting URLs into scheme and host

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 367: audit a cluster for required tags. Project 369 changes the surface problem while preserving the underlying method.

progress check

Reading target: check alternates share a scheme is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `alts = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('single scheme:', len(schemes) == 1)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`alts = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`schemes = {u.split('://', 1)[0] for u in alts.values()}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('single scheme:', len(schemes) == 1)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `schemes = {u.split('://', 1)[0] for u in alts.values()}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Alternates Share a Scheme: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: alts, en, https, com, fr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: alts = { | Core: schemes = {u.split('://', 1)[0] for u in alts.values()} | Evidence: print('single scheme:', len(schemes) == 1)

🛠️ Reader to Writer Bridge

1. Read: explain check alternates share a scheme in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 367.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 369 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('single scheme:', len(schemes) == 1)`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `alts = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check alternates share a scheme and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Splitting each URL on `://` isolates the scheme, and splitting the remainder on the first `/` isolates the host, so set sizes reveal whether the cluster mixes schemes or hosts.

```
alts = {
    'en': 'https://s.com/en/',
    'fr': 'https://s.com/fr/',
    'de': 'https://de.s.com/',
}
schemes = {u.split('://', 1)[0] for u in alts.values()}
hosts = {u.split('://', 1)[1].split('/', 1)[0] for u in alts.values()}
print('schemes:', sorted(schemes))
print('hosts:', sorted(hosts))
print('single scheme:', len(schemes) == 1)
```

```
output
schemes: ['https']
hosts: ['de.s.com', 's.com']
single scheme: True
```

How it works:

1. An alts dict maps locales to URLs, one on the de.s.com subdomain.
2. A set comprehension splits each URL on '://' to collect schemes, and another splits the remainder on the first slash to collect hosts.
3. The prints show the sorted schemes and hosts, and len(schemes) == 1 confirms a single shared scheme.

Try it:

1. Flag any http URL as a downgrade from https.
2. Report whether all hosts share a common registrable domain.
3. Use urllib.parse for robust scheme and host extraction.
4. Change one alternate to a relative path and watch the scheme split fail to find https.

⚠ Common Mistakes

- Assuming differing hosts is an error when subdomain or ccTLD strategies legitimately differ.
- Splitting on `/` without first removing the scheme captures the wrong host segment.

- Forgetting to sort the scheme and host sets makes the output nondeterministic.

Skills gained `string split` `sets` `url parsing` `schemes`

→ **Where You'll Use This:** International sites legitimately mix subdomains and country domains; checking that they at least share https avoids the mixed-scheme inconsistency that erodes trust and complicates canonical handling.

Mental Model

The scheme is the language everyone speaks at a multinational meeting: the offices differ, but the conversation should stay in one tongue.

Project 369 Score an Hreflang Cluster's Health

The Idea Behind It

Rolling several checks into a single 0-to-100 score gives stakeholders a one-glance health metric. This project weights three rules, valid code shapes worth forty points, x-default presence worth thirty, and all-https alternates worth thirty, multiplying each all-pass boolean by its weight and summing them into a composite hreflang health score.

What You'll Build & Learn

Combine validity, x-default, and https checks into a weighted 0-100 hreflang health score.

- Weighted rules form a composite score
- Booleans multiply by point values
- A single metric for stakeholders

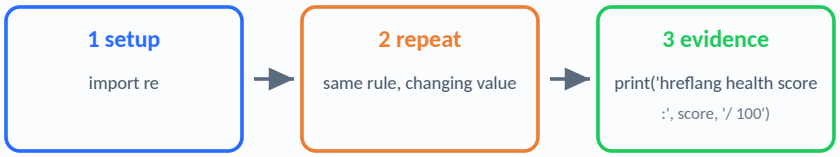
Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 368: check alternates share a scheme. Project 370 changes the surface problem while preserving the underlying method.

progress check

Reading target: score an hreflang cluster's health is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('hreflang health score:', score, '/ 100')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`score += all(c == 'x-default' or pat.match(c) for c in cluster) * 40`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('hreflang health score:', score, '/ 100')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `score += all(c == 'x-default' or pat.match(c) for c in cluster) * 40`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score an Hreflang Cluster's Health: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: re, cluster, en, US, https. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: score += all(c == 'x-default' or pat.match(c) for c in cluster) * 40 | Evidence: print('hreflang health score:', score, '/ 100')

🛠️ Reader to Writer Bridge

1. Read: explain score an hreflang cluster's health in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 368.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 370 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('hreflang health score:', score, '/ 100')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of score an hreflang cluster's health and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Multiplying each boolean check by its point weight and summing yields a deterministic score; valid codes, an x-default, and absolute URLs here total a perfect 100.

```
import re
cluster = {'en-US': 'https://s.com/en/', 'fr-FR': 'https://s.com/fr/', 'x-
default': 'https://s.com/'}
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
score = 0
score += all(c == 'x-default' or pat.match(c) for c in cluster) * 40
score += ('x-default' in cluster) * 30
score += all(u.startswith('https://') for u in cluster.values()) * 30
print('hreflang health score:', score, '/ 100')
```

```
output
hreflang health score: 100 / 100
```

How it works:

1. A cluster dict and the shape regex pat are defined, and score starts at zero.
2. Each rule's all(...) boolean is multiplied by its weight: 40 for valid codes (treating 'x-default' as exempt), 30 for x-default present, and 30 for all-https.
3. Summing the three weighted terms yields the final score, printed here as 100 out of 100.

Try it:

1. Add a reciprocity check worth its own slice of the score.
2. Return a breakdown of which rules earned which points.
3. Make the weights configurable so teams can re-prioritize.
4. Drop the `x-default` entry and watch the score fall to 70.

⚠ Common Mistakes

- Forgetting to exempt `x-default` from the code regex zeroes the validity slice.
- Letting the weights sum to something other than 100 makes the score hard to read.
- Using `and` results without multiplying by weights collapses the score to a bare boolean.

Skills gained scoring | weighting | regex | boolean arithmetic

→ Where You'll Use This: A single health score lets you trend hreflang quality over time and across templates in a dashboard, turning a pile of individual checks into one number leadership can track.

Mental Model

The score is a credit rating: many underlying factors collapse into one number that everyone can compare at a glance.

Project 370 Run a Full Hreflang Audit Report

The Idea Behind It

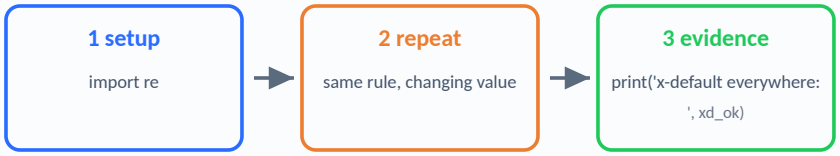
This capstone ties the chapter together across a real page-to-alternates map. In one pass it validates each code against the shape regex while skipping x-default, checks every alternate target for a return tag, and confirms x-default appears on every page, then prints the count of pages, invalid codes, broken return tags, and overall x-default coverage as the skeleton of an international SEO audit.

What You'll Build & Learn

Run validity, reciprocity, and x-default coverage checks together over a page map as one combined audit.

- Combining several audits in one pass
- Skipping x-default during code validation
- Reporting a multi-metric summary

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 369: score an hreflang cluster's health. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full hreflang audit report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
- Evidence: `print('x-default everywhere:', xd_ok)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
2. Apply the rule	`if code == 'x-default':`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('x-default everywhere:', xd_ok)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: International SEO and hreflang becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if code == 'x-default':`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Run a Full Hreflang Audit Report: connect the surface task to the chapter skill, validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay.
Names	Watch these names first: re, pages, https, com, en. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if code == 'x-default': | Evidence: print('x-default everywhere:', xd_ok)

🛠️ Reader to Writer Bridge

1. Read: explain run a full hreflang audit report in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 369.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('x-default everywhere:', xd_ok)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full hreflang audit report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One walk over every page's alternates accumulates invalid codes and broken return tags while a separate check confirms x-default everywhere, summarising cluster health in four lines.

```
import re
pages = {
    'https://s.com/en/': {'en': 'https://s.com/en/', 'fr': 'https://s.com/fr/',
'x-default': 'https://s.com/'},
    'https://s.com/fr/': {'en': 'https://s.com/en/', 'fr': 'https://s.com/fr/',
'x-default': 'https://s.com/'},
}
pat = re.compile(r'^[a-z]{2}(-[A-Z]{2})?$')
```

```
bad_codes, no_return = [], []
for page, alts in pages.items():
    for code, target in alts.items():
        if code == 'x-default':
            continue
        if not pat.match(code):
            bad_codes.append(code)
        if page not in pages.get(target, {}).values():
            no_return.append((page, target))
xd_ok = all('x-default' in a for a in pages.values())
print('pages audited:', len(pages))
print('invalid codes:', sorted(set(bad_codes)))
print('broken return tags:', len(no_return))
print('x-default everywhere:', xd_ok)
```

```
output
pages audited: 2
invalid codes: []
broken return tags: 0
x-default everywhere: True
```

How it works:

1. A pages dict maps two page URLs to their alternate dicts including an 'x-default' entry each.
2. Nested loops skip the x-default code, append any code that fails pat.match to bad_codes, and append a pair to no_return when the target does not link back.
3. xd_ok checks 'x-default' appears in every page's alternates, and four prints summarize pages audited, invalid codes, broken return tags, and x-default coverage.

Try it:

1. Add duplicate and conflict detection per page to the same pass.
2. Emit the report as JSON for a monitoring pipeline to ingest.
3. Include orphan-alternate detection against a set of real URLs.
4. Break one return tag and watch the broken count rise.

⚠ Common Mistakes

- Running the code regex on `x-default` flags the fallback as an invalid locale.
- Counting return tags against the x-default URL (which need not reciprocate) inflates the broken count.
- Reporting raw lists without `set` dedupe repeats the same invalid code many times.

Skills gained regex | reciprocity | x-default | auditing

→ Where You'll Use This: This is the shape of a production hreflang auditor: feed it a crawl's page-to-alternates map and it returns the headline numbers an SEO team needs to triage international tagging issues.

Mental Model

The capstone is a full health screening: one appointment runs every test and hands back a single chart covering all the vital signs.

Chapter Progress Checkpoint

What this chapter added: after 32 mini-projects, International SEO and hreflang should feel like a reusable Python move: validate hreflang matrices and return-tag reciprocity, locale/region codes and canonical interplay. *chapter checkpoint*

1 Read
Open any project from Projects 339-370 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.
transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 11 (Off-Page, Links and Authority) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall | 3 Meaning | 1 Structure | 2 Transfer

10.1.Q1 Recall MEDIUM — Turn back to Project 363 (Validate the x-default Target). Without running it, what exactly does it print?

10.1.Q2 Meaning MEDIUM — Turn back to Project 351 (Count Distinct Locales in a Cluster). Without running it, what exactly does it print?

10.1.Q3 Structure MEDIUM — Turn back to Project 342 (Detect a Malformed Hreflang Code). Without running it, what exactly does it print?

10.1.Q4 Transfer MEDIUM — Turn back to Project 362 (Pick a Locale from Accept-Language). Without running it, what exactly does it print?

10.1.Q5 Recall MEDIUM In the hreflang code **`fr-CA`**, which part is the language and which is the region, and how is each cased?

- A `fr` region uppercase, CA language lowercase
- B `fr` language lowercase (ISO 639-1), CA region uppercase (ISO 3166-1 alpha-2)
- C Both are languages
- D CA is the language because it comes first in importance

10.1.Q6 Meaning MEDIUM Page A declares page B as an **`fr`** alternate, but page B does not list page A anywhere in its hreflang block. What happens?

- A Google still honours the A→B link
- B The relationship is ignored because the return tag is missing (reciprocity is broken)
- C Page B is deleted from the index
- D Nothing — return tags are optional

10.1.Q7 Meaning MEDIUM Your French page (**`/fr/`**) sets its canonical to the English page (**`/en/`**). What is the likely effect on the French page and its hreflang?

- A French ranks better in France
- B French is treated as a duplicate of English and dropped from the index, so the `fr` hreflang points at a page that will not appear
- C Both pages merge into one URL
- D The canonical is ignored when hreflang is present

10.1.Q8 Transfer MEDIUM What is the purpose of the **`x-default`** hreflang value, and how does it relate to the locale fallback chain?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 10 – International SEO and hreflang

10.1.Q1. `x-default -> https://s.com/` then `distinct from locale URLs: True`

10.1.Q2. `locale variants: 5` then `distinct languages: ['de', 'en', 'fr']`

10.1.Q3. `malformed: ['EN-us', 'e-US', 'en-USA', 'en--US']` then `count: 4`

10.1.Q4. `weights: [(1.0, 'en-US'), (0.9, 'fr-FR'), (0.5, 'de')]` then `chosen:` en-US

10.1.Q5. B language subtag `fr` is lowercase 639-1; region subtag `CA` is uppercase 3166-1 alpha-2.

10.1.Q6. B hreflang must be bidirectional; without B's return tag to A the engine ignores the pairing.

10.1.Q7. B a cross-locale canonical tells Google to drop the French version; keep each locale self-canonical.

10.1.Q8. It names the page to serve users whose language/region matches none of your locales (usually a neutral selector or root). It is the final step of the fallback chain: exact locale → bare language → x-default.

Chapter 11 · Off-Page, Links and Authority

Model internal link equity with a toy PageRank, anchor-text distribution and backlink-profile metrics.

Chapter Skill Map

What this chapter adds: In Off-Page, Links and Authority, the focus is model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics. You practise it across 32 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 11 assumes the reading habits from Chapter 10: International SEO and hreflang. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 12, Local and Map SEO, reuses this chapter's discipline with a new kind of problem.

1 **Projects 371-380**	2 **Projects 381-390**	3 **Projects 391-402**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

A link is a vote, and authority is what flows along the edges of that vote graph.

on-page is what you say; off-page is who vouches for you

On-page SEO is everything you control on your own pages. Off-page SEO is everything other pages say *about* you — and the loudest thing they can say is a link. Treat each link as a vote: a page that links to you is spending a little of its own credibility to say "this is worth seeing." The more credible the voter, and the more independent voters there are, the more authority pools on the target.

The same idea runs *inside* your own site. Every internal link is a vote you cast for one of your own pages, so the link graph quietly decides which of your URLs collects the most equity. The first off-page measurement is therefore pure graph bookkeeping: for each page, how many links point *at* it (in-degree) versus how many it sends *out* (out-degree). The gap tells you where equity gathers.

```
links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['home', 'post1'],
    'post1': ['blog'],
}
out = {p: len(t) for p, t in links.items()}
inc = {p: 0 for p in links}
for targets in links.values():
    for t in targets:
        inc[t] += 1
```

```
for p in sorted(links):
    print(f'{p}: in={inc[p]} out={out[p]}')
```

```
output
about: in=1 out=1
blog: in=2 out=2
home: in=2 out=2
post1: in=1 out=1
```

Read the counts and the homepage already stands out — it collects the most inbound links, so it is the page your own site is implicitly voting most important. That is no accident: a sensible site funnels equity toward its hub.

the page with the highest in-degree is your implicit "most important" URL

Counting edges is only the start. Authority does not just *land* on a page — it flows through it, because a page hands its votes onward to whatever it links to. Following that flow until it settles is exactly what PageRank does, and it is the spine of this chapter. The off-page craft is then: get more independent, high-quality votes pointing in, route your own internal votes toward the pages that matter, and keep the profile looking natural so it reads as earned rather than bought.

IN-DEGREE / OUT-DEGREE

In-degree is the number of links pointing *at* a page; out-degree is the number it sends *out*. High in-degree means equity collects there; high out-degree means it leaks away.

LINK EQUITY ("LINK JUICE")

The ranking value a link passes from source to target. A page splits its equity across its out-links, so each extra out-link dilutes the share every link carries.

PAGERANK

A score for each page equal to the long-run share of a random surfer's visits. Computed by repeatedly spreading rank along out-links (the *power method*) with a damping factor for teleportation, until the values converge.

DAMPING FACTOR (D)

The probability (classically 0.85) that the random surfer follows a link rather than teleporting to a random page. The `(1 − d)` slice is shared out as a baseline so every page keeps some rank and the totals stay conserved.

ANCHOR TEXT

The visible, clickable words of a link. Search engines read it as a description of the target, so a profile of anchors should be a natural *spread* (branded, generic, naked-URL, partial) rather than a pile of one exact-match phrase.

DOFOLLOW VS NOFOLLOW

A `dofollow` link passes equity and is a real vote; a `rel="nofollow"` link is a hint that signals interest but does not vote. Only dofollow links move PageRank.

REFERRING DOMAIN

A distinct site that links to you. A hundred links from one domain count for far less than one link each from a hundred domains, so referring-domain count is the headline backlink metric.

Links are votes; in-degree finds the hub

If a link is a vote, the most-voted-for page is wherever inbound links pile up. Counting in-degree across the internal graph surfaces that hub in one pass — usually the homepage, because everything links back to it. Knowing the hub tells you which URL your own structure is promoting, whether or not that is the page you *want* promoted.

```
from collections import Counter

links = {
    'home': ['about', 'blog', 'shop'],
    'about': ['home'],
    'blog': ['home', 'shop'],
    'shop': ['home'],
    'post1': ['shop'],
}
indeg = Counter()
for targets in links.values():
    for t in targets:
        indeg[t] += 1
top = max(sorted(indeg), key=lambda p: indeg[p])
print(f'most-linked: {top} ({indeg[top]} inbound)')
```

```
output
most-linked: home (3 inbound)
```

Sorting *all* pages by in-degree gives the same idea as a ranked list — the top of it should be your most important pages. If a money page sits near the bottom, your internal linking is voting for the wrong URLs and you fix it by

adding edges, not content.

Equity dilutes: a page splits its vote across out-links

A page does not give each out-link a full vote — it splits its equity *evenly* across them. Two out-links each get half; ten out-links each get a tenth. That is why stuffing a page with links weakens every one of them, and why a `dangling node` (a page with zero out-links) is special: it has nowhere to send its share.

```
rank = {'home': 0.4, 'a': 0.3, 'b': 0.3}
links = {
    'home': ['a', 'b', 'shop'],
    'a': ['home'],
    'b': [],
}
for p, outs in links.items():
    if not outs:
        print(f'{p}: dangling, equity stays put')
        continue
    each = round(rank[p] / len(outs), 3)
    for t in outs:
        print(f'{p} -> {t}: {each}')
```

```
output
home -> a: 0.133
home -> b: 0.133
home -> shop: 0.133
a -> home: 0.3
b: dangling, equity stays put
```

`home` had 0.4 of equity and three out-links, so each link carries 0.133 — add a fourth out-link and that drops again. This even-split rule is the single most important mechanic in the chapter: it is what makes the iteration below converge. *more out-links = thinner equity per link*

One power-method step, then iterate to convergence

PageRank starts every page with equal rank (`1/N`) and repeats one move: each page hands its rank, split evenly, to the pages it links to. A single pass already shows equity starting to pool. Watch `c` — both `a` and `b` point at it, so after one step it holds 0.5:

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
rank = {p: round(1.0 / N, 3) for p in links}
nxt = {p: 0.0 for p in links}
```

```
for p, outs in links.items():
    share = rank[p] / len(outs)
    for t in outs:
        nxt[t] += share
for p in sorted(nxt):
    print(f'{p}: {round(nxt[p], 3)}')
```

```
output
a: 0.125
b: 0.125
c: 0.5
home: 0.25
```

One step is not the answer — the values are still moving. Real PageRank repeats the step with a damping factor `d = 0.85`: with 85% probability the surfer follows a link, and with 15% they teleport, so each round seeds every page with a baseline `(1 - d)/N` before the link flow is added. On a tiny graph a fixed 50 iterations is far more than enough to settle, and because the process is deterministic the numbers are reproducible every run:

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
d = 0.85
rank = {p: 1.0 / N for p in links}
for _ in range(50):
    nxt = {p: (1 - d) / N for p in links}
    for p, outs in links.items():
        share = rank[p] / len(outs)
        for t in outs:
            nxt[t] += d * share
    rank = nxt
for p in sorted(rank):
    print(f'{p}: {round(rank[p], 4)}')
print('sum:', round(sum(rank.values()), 4))
```

```
output
a: 0.1736
b: 0.1736
c: 0.3326
home: 0.3203
sum: 1.0
```

Two things to notice. First, the ranks sum to 1.0 — equity is conserved, it only moves around. Second, `c` and `home` end up strongest because the link flow loops through them, while `a` and `b` are mere pass-throughs. There is no

randomness in the loop: same graph, same iterations, same answer.

fixed d, fixed iterations → deterministic, reproducible ranks

A dangling node would break conservation — its rank vanishes each round since it has no out-links. The standard fix collects the dangling rank and redistributes it evenly across all pages, so the total stays at 1.0:

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': [],
    'c': ['home'],
}
N = len(links)
d = 0.85
rank = {p: 1.0 / N for p in links}
for _ in range(50):
    leaked = sum(rank[p] for p, o in links.items() if not o)
    nxt = {p: (1 - d) / N + d * leaked / N for p in links}
    for p, outs in links.items():
        if outs:
            share = rank[p] / len(outs)
            for t in outs:
                nxt[t] += d * share
    rank = nxt
for p in sorted(rank):
    print(f'{p}: {round(rank[p], 4)}')
print('sum:', round(sum(rank.values()), 4))
```

```
output
a: 0.2138
b: 0.2138
c: 0.2646
home: 0.3079
sum: 1.0
```

Anchor text: a healthy profile is a spread, not a pile

Search engines read a link's anchor text as a description of the target. Natural backlinks come with varied anchors — your brand, the bare URL, generic "click here", and the occasional keyword. So you bucket anchors into types and look at the *distribution*: exact-match, partial, branded, generic, naked-url.

```
from collections import Counter

anchors = [
    'buy running shoes', 'click here', 'example.com',
    'running shoes', 'Acme Store', 'best running shoes',
    'read more', 'Acme', 'shoes', 'https://example.com/shop',
]
```

```
target_kw = 'running shoes'
brand = {'acme', 'acme store'}
def classify(a):
    low = a.lower()
    if low == target_kw:
        return 'exact'
    if low in brand:
        return 'branded'
    if low.startswith('https://') or '.com' in low:
        return 'naked-url'
    if low in {'click here', 'read more'}:
        return 'generic'
    if target_kw in low or any(w in low for w in target_kw.split()):
        return 'partial'
    return 'generic'
tally = Counter(classify(a) for a in anchors)
for kind in sorted(tally):
    print(f'{kind}: {tally[kind]}')
```

```
output
branded: 2
exact: 1
generic: 2
naked-url: 2
partial: 3
```

That spread looks earned. The danger is over-optimization: when too many backlinks use the exact-match keyword, the profile looks bought and risks a penalty. A simple share threshold flags it — here 70% exact-match is far past a 30% line:

```
from collections import Counter

anchors = ['running shoes'] * 7 + ['Acme', 'click here', 'shop now']
target_kw = 'running shoes'
total = len(anchors)
exact = Counter(a.lower() for a in anchors)[target_kw]
pct = round(100 * exact / total, 1)
limit = 30.0
verdict = 'OVER-OPTIMIZED' if pct > limit else 'natural'
print(f'exact-match {exact}/{total} = {pct}% (limit {limit}%) -> {verdict}')
```

```
output
exact-match 7/10 = 70.0% (limit 30.0%) -> OVER-OPTIMIZED
```

Counting votes: dofollow, and domains over links

Not every link is a vote. A `rel="nofollow"` link signals interest but does not pass equity, so the `dofollow-to-nofollow ratio` tells you how much of a profile actually counts:

```
from collections import Counter

backlinks = [
    {'from': 'https://a.com', 'rel': 'dofollow'},
    {'from': 'https://b.com', 'rel': 'nofollow'},
    {'from': 'https://c.com', 'rel': 'dofollow'},
    {'from': 'https://d.com', 'rel': 'dofollow'},
    {'from': 'https://e.com', 'rel': 'nofollow'},
]
c = Counter(b['rel'] for b in backlinks)
df, nf = c['dofollow'], c['nofollow']
ratio = round(df / nf, 2)
print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')
```

```
output
dofollow=3 nofollow=2 ratio=1.5:1
```

The single most important headline metric, though, is `referring domains`, not raw link count. Twenty links from one blog are one vote repeated; one link each from twenty sites is twenty independent votes. Collapse the link list to its distinct hosts and count those:

```
backlinks = [
    {'from': 'https://blogA.com/post1', 'to': '/shoes'},
    {'from': 'https://blogA.com/post2', 'to': '/shoes'},
    {'from': 'https://news.org/review', 'to': '/shoes'},
    {'from': 'https://forum.net/t/9', 'to': '/home'},
    {'from': 'https://blogA.com/post3', 'to': '/home'},
]
def domain(url):
    return url.split('://', 1)[1].split('/', 1)[0]
domains = {domain(b['from']) for b in backlinks}
print('total backlinks:', len(backlinks))
print('referring domains:', len(domains))
for d in sorted(domains):
    print(' ', d)
```

```
output
total backlinks: 5
referring domains: 3
  blogA.com
  forum.net
  news.org
```

Five links collapse to three voters. A profile-health verdict combines these signals: too high an exact-match anchor share *and* too few distinct anchors together mean an unnatural profile — the reverse means an earned one.

domains, dofollow share, anchor spread → one health read

Example 1

A four-page site has links home→[a, b], a→[c], b→[c], c→[home]. Using the even-split rule, run ONE power-method step (no damping) from equal starting rank 0.25 each. What rank does page c hold after the step?

SOLUTION

1. Start equal: every page has rank `1/4 = 0.25`.
2. Each page splits its rank evenly over its out-links. a has one out-link (→c), so it sends all 0.25 to c; b likewise sends its 0.25 to c.
3. Page c receives 0.25 from a + 0.25 from b = 0.5. Meanwhile home gets c's 0.25 (rounded), and a, b each get half of home's 0.25 = 0.125.

c holds 0.5 after one step — two pages funnel their whole vote into it. Equity is already pooling on the well-linked page.

one step shows the trend; iterate to get the final value

Example 2

A backlink profile has these anchors: "running shoes" ×4, "Acme", "click here", "shop now", "best shoes" (8 total). The target keyword is "running shoes". Is this profile healthy on the two anchor signals (exact-match ≤30%, unique-ratio ≥0.5)?

SOLUTION

1. Exact-match share: "running shoes" appears 4 times in 8 anchors → 4/8 = 50%, which is over the 30% limit.
2. Anchor diversity: the distinct anchors are {running shoes, acme, click here, shop now, best shoes} = 5 unique out of 8 → 5/8 = 0.625, which clears the 0.5 floor.
3. One signal fails (exact-match over-optimised) and one passes, so any failing flag makes the verdict RISKY.

RISKY — exact-match over-optimised at 50%. Diversity is fine, but one bad signal is enough; the fix is to earn more branded/generic/naked-url anchors.

a single tripped flag overrides a passing one

Example 3

Site X has backlinks from blogA.com (3 links), blogB.com (2 links), and news.org (1 link) — 6 links total. Competitor Y also has a link from forbes.com. By the headline metric, how many independent votes does X have, and what is the one actionable gap?

SOLUTION

1. Collapse X's 6 links to distinct hosts: {blogA.com, blogB.com, news.org} → 3 referring domains, not 6.
2. Referring domains, not raw links, is the headline metric, so X has 3 independent votes.
3. Set-subtract X's domains from Y's: forbes.com links to Y but not X, so it is the link gap.

3 referring domains; the actionable gap is forbes.com (links to the competitor but not to you).

domains over links; gap = competitor's domains minus yours

Mental-Math Shortcut

Count the voters, not the votes — then watch where the votes flow. One link each from ten sites beats ten links from one site, because authority rewards *independent* endorsement. And inside your own site, every internal link is a vote you control: route them toward the pages that matter (high in-degree), keep out-links lean so each carries more equity, and let PageRank's even-split flow do the rest. Natural beats optimised — a varied anchor profile from many domains always outranks a stack of exact-match links bought in bulk.

⚠ Common Mistakes

- Bragging about raw backlink count when the referring-domain count is tiny — 500 links from 3 sites is 3 votes, not 500.
- Chasing exact-match keyword anchors. Push the exact-match share past ~30% and the profile reads as manipulated, inviting a penalty instead of a boost.
- Treating nofollow links as ranking votes. They can drive traffic and signal interest, but they pass no equity, so they do not move PageRank.
- Adding internal links indiscriminately. Because a page splits its equity evenly across out-links, every extra out-link thins the share each one carries — link with intent, not abundance.
- Leaving important pages orphaned (zero in-degree). With no internal link pointing at them they receive almost no equity and may never be indexed.

This chapter contains 32 hands-on mini-projects (Projects 371–402). Type each one out, run it, and experiment.

Project 371 Tally In-Degree and Out-Degree per Page

The Idea Behind It

A link graph is a dictionary mapping each page to the list of pages it points at. This project measures two opposite quantities: out-degree is just the length of each target list, while in-degree is built by walking every

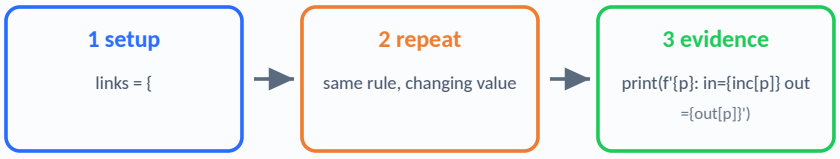
target list and incrementing a counter for the page it lands on. The gap between the two numbers tells you which pages collect equity versus which spend it.

What You'll Build & Learn

Compute inbound and outbound link counts for every page in a small internal link graph and print them side by side.

- In-degree versus out-degree on a link graph
- Counting inbound links by reversing the edges
- Dictionary comprehensions for per-page tallies

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 372 changes the surface problem while preserving the underlying method. *progress check*

Reading target: tally in-degree and out-degree per page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{p}: in={inc[p]} out={out[p]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`out = {p: len(t) for p, t in links.items()}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{p}: in={inc[p]} out={out[p]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `out = {p: len(t) for p, t in links.items()}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Tally In-Degree and Out-Degree per Page: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, home, about, blog, post1. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: out = {p: len(t) for p, t in links.items()} | Evidence: print(f'{p}: in={inc[p]} out={out[p]}')

Reader to Writer Bridge

1. Read: explain tally in-degree and out-degree per page in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 372 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p}: in={inc[p]} out={out[p]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of tally in-degree and out-degree per page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

From Concept to Code (Python)

Out-degree is just the length of each adjacency list, while in-degree needs a second pass that counts every page as it appears as a link target.

```
links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['home', 'post1'],
    'post1': ['blog'],
}
out = {p: len(t) for p, t in links.items()}
inc = {p: 0 for p in links}
for targets in links.values():
    for t in targets:
        inc[t] += 1
for p in sorted(links):
    print(f'{p}: in={inc[p]} out={out[p]}')
```

```
output
about: in=1 out=1
blog: in=2 out=2
```

```
home: in=2 out=2
post1: in=1 out=1
```

How it works:

1. The links dict gives each page a list of outbound targets, like home pointing at about and blog.
2. A comprehension sets out[p] to len(t), the number of outbound links each page emits.
3. inc starts every page at zero, then nested loops walk each target list and bump inc[t] by one.
4. Iterating over sorted(links) prints each page with its in and out counts aligned.

Try it:

1. Add a third metric that computes the ratio of in-degree to out-degree per page
2. Extend the links dict with a deeper blog structure and rerun the tallies
3. Print only pages whose in-degree exceeds their out-degree by two or more
4. Add a link from `post1` to `home` and watch `home`'s in-degree climb.

⚠ Common Mistakes

- Reading `len(links[p])` as in-degree actually gives out-degree.
- Initialising `inc` only from targets drops pages that have zero inbound links.
- Iterating `links.keys()` instead of the value lists never sees the link targets.

Skills gained link graphs | in-degree | dict comprehension

→ Where You'll Use This: Internal link audits in tools like Screaming Frog report exactly these numbers, helping you spot pages that hoard equity or leak it without earning links back.

⚡ Mental Model

Think of each page as a town: out-degree is roads leaving it, in-degree is roads arriving. Towns with many arriving roads become hubs.

Project 372 Find the Site's Internal Link Hub

💡 The Idea Behind It

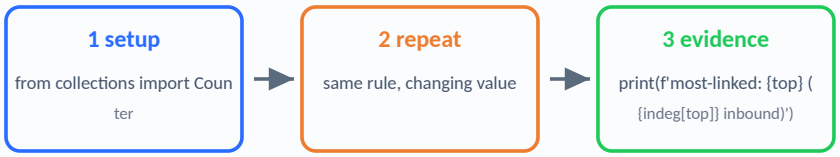
Building on raw in-degree counts, this project finds the single page that the rest of the site links to most. It accumulates inbound counts with a Counter, then uses max over a sorted key list so ties resolve deterministically by name. The winner is the URL your own internal linking is implicitly nominating as most important, almost always the homepage.

What You'll Build & Learn

Identify the most internally linked page so you know which URL your site treats as its authority hub.

- Using Counter to accumulate inbound link totals
- max with a key function over sorted keys
- Deterministic tie-breaking by sorting first

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 371: tally in-degree and out-degree per page. Project 373 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find the site's internal link hub is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'most-linked: {top} ({indeg[top]} inbound)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.

Move	Code to inspect	Why it matters
2. Apply the rule	`for targets in links.values():`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'most-linked: {top} ({indeg[top]} inbound)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for targets in links.values():`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Reader to Writer Bridge

1. Read: explain find the site's internal link hub in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 371.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 373 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'most-linked: {top} ({indeg[top]} inbound)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find the site's internal link hub and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

After tallying in-degree, `max` over the sorted keys with an in-degree key returns the hub, with sorting making any tie break alphabetically and deterministically.

```
from collections import Counter

links = {
    'home': ['about', 'blog', 'shop'],
    'about': ['home'],
    'blog': ['home', 'shop'],
    'shop': ['home'],
    'post1': ['shop'],
}
indeg = Counter()
for targets in links.values():
    for t in targets:
        indeg[t] += 1
top = max(sorted(indeg), key=lambda p: indeg[p])
print(f'most-linked: {top} ({indeg[top]} inbound)')
```

```
output
most-linked: home (3 inbound)
```

How it works:

1. A Counter named indeg starts empty and is filled by looping over every target list in the links dict.
2. Each appearance of a page as a link target increments its inbound count by one.

3. max scans sorted(indeg) using a lambda that returns indeg[p], picking the page with the highest count.
4. The print reports the winning page and its inbound link total, here home with three.

Try it:

1. Return the top three most-linked pages instead of only the single winner
2. Break ties by preferring the page with the shortest name
3. Flag a warning when the most-linked page is not named home
4. Add two more links to `shop` to flip the winner away from `home`.

⚠ Common Mistakes

- Calling `max` over the unsorted Counter makes ties resolve unpredictably.
- Passing `indeg.values()` to `max` loses which page the count belongs to.
- A page that is never a link target is absent from the Counter, not zero.

Skills gained Counter argmax internal linking

→ Where You'll Use This: When auditing a site, confirming the most-linked page matches your intended priority page catches accidental cases where a thin page outranks your money page internally.

⚡ Mental Model

It is like counting how many roads in a town lead to one building. The busiest intersection is what locals treat as the center.

Project 373 Spread Rank Once with the Power Method

💡 The Idea Behind It

This introduces the core PageRank move without the bells and whistles. Every page begins with equal rank, one over the page count. A single pass then has each page divide its rank evenly among its outbound links and hand each share to the target. After one iteration you can already see equity starting to pool on the well-linked page c, which two pages feed.

What You'll Build & Learn

Run one power-method step of PageRank so you can watch equity begin to redistribute across a link graph.

- Initialising equal rank as one over N
- Dividing a page's rank across its out-links
- One iteration of the power method

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 372: find the site's internal link hub. Project 374 changes the surface problem while preserving the underlying method.

progress check

Reading target: spread rank once with the power method is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

Code Reading Stack

Layer	What to read
Intent	Spread Rank Once with the Power Method: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, home, len, rank, round. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: rank = {p: round(1.0 / N, 3) for p in links} | Evidence: print(f'{p}: {round(nxt[p], 3)}')

Reader to Writer Bridge

1. Read: explain spread rank once with the power method in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 372.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 374 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p}: {round(nxt[p], 3)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spread rank once with the power method and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each page divides its current rank by its out-degree and adds that share to every target; one iteration is the building block the full algorithm repeats.

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
rank = {p: round(1.0 / N, 3) for p in links}
nxt = {p: 0.0 for p in links}
for p, outs in links.items():
    share = rank[p] / len(outs)
    for t in outs:
        nxt[t] += share
for p in sorted(nxt):
    print(f'{p}: {round(nxt[p], 3)}')
```

```
output
a: 0.125
b: 0.125
c: 0.5
home: 0.25
```

How it works:

1. rank gives each of the four pages a starting value of 0.25, rounded for display.
2. nxt is a fresh dict of zeros that will receive the redistributed equity.
3. For each page, share is its rank divided by the number of out-links, added to every target in nxt.
4. Printing sorted(nxt) shows c at 0.5 because both a and b funnel their share into it.

Try it:

1. Run the redistribution step three times in a loop and print after each pass

2. Add a new page that links only to home and observe the change
3. Print the total of all ranks after the pass to confirm it stays near one
4. Run a second iteration by copying `nxt` back into `rank` and repeating.

⚠ Common Mistakes

- Updating `rank` in place instead of writing to a fresh `nxt` mixes old and new values.
- Dividing by `len(links)` rather than the page's own out-degree spreads rank wrongly.
- A page with zero out-links would divide by zero, so this fixture gives every page an out-link.

Skills gained PageRank | power method | rank distribution

→ Where You'll Use This: Understanding this single step demystifies why link-equity flow tools show certain pages ballooning, and it underpins every internal-linking recommendation an SEO makes.

Mental Model

Each page pours a full cup of water evenly into the cups it points at. After one pour, cups fed by many start filling up.

Project 374 Iterate PageRank to Convergence with Damping

The Idea Behind It

The full algorithm adds two refinements to the single pass. A damping factor of 0.85 models the chance a surfer keeps clicking, while the remaining fifteen percent teleports uniformly to every page as the baseline term. Repeating the step fifty times lets the values settle, and summing them confirms the ranks still total one, the signature of a correct PageRank implementation.

What You'll Build & Learn

Iterate PageRank with damping until the ranks converge, and verify the total equity stays conserved at one.

- The 0.85 damping factor and teleport term
- Iterating the power method to convergence
- Checking ranks sum to one

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 373: spread rank once with the power method. Project 375 changes the surface problem while preserving the underlying method. *progress check*

Reading target: iterate pagerank to convergence with damping is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print('sum:', round(sum(rank.values()), 4))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`rank = {p: 1.0 / N for p in links}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('sum:', round(sum(rank.values()), 4))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `rank = {p: 1.0 / N for p in links}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Iterate PageRank to Convergence with Damping: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, home, len, rank, range. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: rank = {p: 1.0 / N for p in links} | Evidence: print('sum:', round(sum(rank.values()), 4))

🛠️ Reader to Writer Bridge

1. Read: explain iterate pagerank to convergence with damping in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 373.

   read with a pencil

3. Transfer: change one small part of iterate pagerank to convergence with damping and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each round gives every page a `(1-d)/N` teleport baseline then adds `d` times the rank flowing in along links; repeating drives the vector to its stationary distribution that sums to 1.

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
d = 0.85
rank = {p: 1.0 / N for p in links}
for _ in range(50):
    nxt = {p: (1 - d) / N for p in links}
    for p, outs in links.items():
        share = rank[p] / len(outs)
        for t in outs:
            nxt[t] += d * share
    rank = nxt
for p in sorted(rank):
    print(f'{p}: {round(rank[p], 4)}')
print('sum:', round(sum(rank.values()), 4))
```

```
output
a: 0.1736
b: 0.1736
c: 0.3326
home: 0.3203
sum: 1.0
```

How it works:

1. d is set to 0.85 and rank starts uniform at one over N for the four pages.
2. Each of fifty iterations seeds nxt with the teleport baseline (1-d)/N for every page.
3. Inner loops add d times each page's per-link share to its targets, then rank becomes nxt.
4. After the loop, sorted ranks print and sum(rank.values()) confirms a total of 1.0.

Try it:

1. Lower the damping factor to 0.5 and compare how the converged ranks shift

2. Stop the loop early once ranks change by less than a tiny threshold
3. Add a fifth page and watch how it dilutes everyone else's share
4. Drop the damping factor to 0.5 and watch the ranks flatten toward uniform.

⚠ Common Mistakes

- Forgetting the `(1-d)/N` teleport term lets rank drain into sinks and stop summing to 1.
- Mutating `rank` mid-round uses half-updated values and breaks convergence.
- Too few iterations on a larger graph stops before the ranks settle.

Skills gained damping factor | convergence | PageRank

→ Where You'll Use This: This is the actual model search engines descend from, so running it on your own crawl reveals which internal pages would accumulate the most algorithmic authority.

Mental Model

Picture a wanderer clicking links 85 percent of the time and randomly jumping the rest. Where they spend most time is a page's PageRank.

Project 375 Split Link Equity Evenly Across Out-Links

The Idea Behind It

Here the focus narrows to one rule of equity flow: a page splits its rank into equal slices, one per outbound link, so more links mean thinner slices. The code prints the per-link share and handles the special case of a dangling page with no out-links, which keeps its equity rather than passing anything on. It makes the dilution cost of stuffing a page with links visible.

What You'll Build & Learn

Show the exact equity slice each outbound link receives, and demonstrate what happens at a dangling page.

- Equity splits equally across out-links
- More links means a thinner share each
- Recognising a dangling page with no out-links

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 374: iterate pagerank to convergence with damping. Project 376 changes the surface problem while preserving the underlying method. *progress check*

Reading target: split link equity evenly across out-links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `rank = {'home': 0.4, 'a': 0.3, 'b': 0.3}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{p} -> {t}: {each}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`rank = {'home': 0.4, 'a': 0.3, 'b': 0.3}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if not outs:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{p} -> {t}: {each}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not outs:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Split Link Equity Evenly Across Out-Links: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: rank, home, links, shop, outs. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: rank = {'home': 0.4, 'a': 0.3, 'b': 0.3} | Core: if not outs: | Evidence: print(f'{p} -> {t}: {each}')

🛠️ Reader to Writer Bridge

1. Read: explain split link equity evenly across out-links in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 374.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 376 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p} -> {t}: {each}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `rank = {'home': 0.4, 'a': 0.3, 'b': 0.3}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split link equity evenly across out-links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Dividing a page's equity by its out-degree gives each link an equal share, while a page with no out-links is a dangling node whose equity has nowhere to go.

```
rank = {'home': 0.4, 'a': 0.3, 'b': 0.3}
links = {
    'home': ['a', 'b', 'shop'],
    'a': ['home'],
    'b': [],
}
for p, outs in links.items():
    if not outs:
        print(f'{p}: dangling, equity stays put')
        continue
    each = round(rank[p] / len(outs), 3)
    for t in outs:
        print(f'{p} -> {t}: {each}')
```

```
output
home -> a: 0.133
home -> b: 0.133
home -> shop: 0.133
a -> home: 0.3
b: dangling, equity stays put
```

How it works:

1. rank holds preset equity values for home, a, and b, while links lists each page's targets.
2. The loop checks if outs is empty and, if so, prints that the page is dangling and skips it.
3. Otherwise each is computed as rank[p] divided by the out-link count, rounded to three places.
4. home with three links gives each target 0.133, while a with one link passes its full 0.3.

Try it:

1. Add a fourth target to home and watch every share shrink accordingly
2. Give the dangling page b a single out-link and rerun
3. Sort the printed shares from largest to smallest before display
4. Give `b` an out-link and watch its equity start to flow instead of stalling.

⚠ Common Mistakes

- Dividing by the total page count instead of the out-degree under-shares the equity.
- Skipping the empty-list guard divides by zero on the dangling page `b`.
- Rounding before summing the shares can make them not quite add back to the source rank.

Skills gained equity sculpting | link dilution | dangling node

→ Where You'll Use This: When deciding how many links to place on a page, this shows why a cluttered navigation dilutes the equity reaching each linked page, a real consideration in template design.

⚡ Mental Model

A page slices a pizza equally for everyone it links to. Invite more guests and each slice gets smaller. A dangling page eats alone.

Project 376 Handle a Dangling Node in PageRank

💡 The Idea Behind It

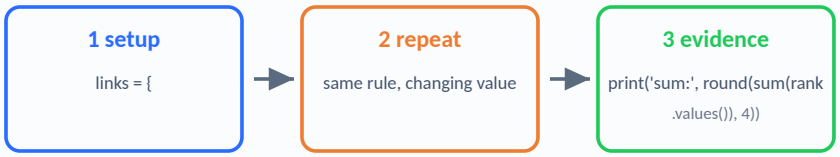
A dangling node breaks naive PageRank because its rank would evaporate each round. This version fixes the leak: before redistributing, it sums the rank held by all dead-end pages and sprinkles that pooled equity uniformly across every page through the d*leaked/N term. The sum check printing 1.0 proves the conservation that the leak would otherwise destroy.

What You'll Build & Learn

Patch PageRank so a dangling node's equity is redistributed instead of lost, keeping the total conserved.

- Why dangling nodes leak PageRank
- Summing and redistributing dangling rank
- Equity conservation across iterations

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 375: split link equity evenly across out-links. Project 377 changes the surface problem while preserving the underlying method. *progress check*

Reading target: handle a dangling node in pagerank is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.

Evidence	Entry: links = { | Core: leaked = sum(rank[p] for p, o in links.items() if not o) | Evidence: print('sum:', round(sum(rank.values()), 4))

🛠️ Reader to Writer Bridge

1. Read: explain handle a dangling node in pagerank in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 375.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 377 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('sum:', round(sum(rank.values()), 4))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of handle a dangling node in pagerank and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Summing the rank sitting on dangling pages and sprinkling `d * leaked / N` onto every page each round patches the leak so the rank vector keeps summing to 1.

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': [],
    'c': ['home'],
}
N = len(links)
d = 0.85
rank = {p: 1.0 / N for p in links}
for _ in range(50):
    leaked = sum(rank[p] for p, o in links.items() if not o)
    nxt = {p: (1 - d) / N + d * leaked / N for p in links}
    for p, outs in links.items():
        if outs:
            share = rank[p] / len(outs)
            for t in outs:
                nxt[t] += d * share
    rank = nxt
for p in sorted(rank):
    print(f'{p}: {round(rank[p], 4)}')
print('sum:', round(sum(rank.values()), 4))
```

```
output
a: 0.2138
b: 0.2138
c: 0.2646
home: 0.3079
sum: 1.0
```

How it works:

1. Page b has an empty out-list, marking it as the dangling node in this graph.
2. Each iteration computes leaked, the sum of rank over pages with no out-links.
3. nxt seeds every page with the teleport term plus d times leaked spread over N.
4. Pages with out-links still add their normal share, and the final sum prints exactly 1.0.

Try it:

1. Add a second dangling page and confirm the sum still equals one
2. Print the leaked value each iteration to watch it stabilise
3. Give b one out-link and verify the leaked term drops to zero
4. Remove the leak redistribution and watch the rank sum drift below 1.

⚠ Common Mistakes

- Ignoring the leak lets total rank fall below 1 every iteration.
- Computing `leaked` from the new ranks instead of the previous round's double-counts.
- Treating the dangling page as if it linked to itself changes the result subtly.

Skills gained dangling node | rank conservation | PageRank

→ Where You'll Use This: Real sites are full of dead-end pages like terminal PDFs or contact forms, so handling them correctly is essential before trusting any internal PageRank estimate.

Mental Model

A dead-end page is a bucket with no spout. Instead of letting its water sit useless, you ladle it back evenly into every bucket on the site.

Project 377 Tally the Anchor-Text Distribution

The Idea Behind It

Backlink anchor text is not one thing but a mix of categories, and this classifier sorts a list of anchors into exact-match, partial, branded, generic, and naked-url buckets. The classify function applies ordered rules, lowercasing first, and a Counter tallies the distribution. The spread it produces is the signal: a natural profile shows variety rather than a tower of exact-match phrases.

What You'll Build & Learn

Classify a list of backlink anchors into type buckets and tally how the profile is distributed.

- Anchor types: exact, partial, branded, generic, naked-url
- Ordered if-rules for classification
- Tallying categories with Counter

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 376: handle a dangling node in pagerank. Project 378 changes the surface problem while preserving the underlying method.

progress check

Reading target: tally the anchor-text distribution is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{kind}: {tally[kind]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if low == target_kw:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if low == target_kw:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Tally the Anchor-Text Distribution: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, anchors, buy, running. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: if low == target_kw: | Evidence: print(f'{kind}: {tally[kind]}')

🛠️ Reader to Writer Bridge

1. Read: explain tally the anchor-text distribution in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 376.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 378 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{kind}: {tally[kind]}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of tally the anchor-text distribution and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A small classifier maps each anchor to one bucket by checking it against the target keyword, brand names, generic phrases, and URL markers, then a Counter tallies the spread.

```
from collections import Counter

anchors = [
    'buy running shoes', 'click here', 'example.com',
    'running shoes', 'Acme Store', 'best running shoes',
    'read more', 'Acme', 'shoes', 'https://example.com/shop',
]
target_kw = 'running shoes'
brand = {'acme', 'acme store'}
def classify(a):
    low = a.lower()
    if low == target_kw:
        return 'exact'
    if low in brand:
        return 'branded'
    if low.startswith('https://') or '.com' in low:
        return 'naked-url'
    if low in {'click here', 'read more'}:
        return 'generic'
    if target_kw in low or any(w in low for w in target_kw.split()):
        return 'partial'
    return 'generic'
tally = Counter(classify(a) for a in anchors)
for kind in sorted(tally):
    print(f'{kind}: {tally[kind]}')
```

```
output
branded: 2
exact: 1
generic: 2
naked-url: 2
partial: 3
```

How it works:

1. A list of ten anchors and a target_kw of running shoes feed the classifier.

2. classify lowercases each anchor, then checks exact match, brand set membership, and URL markers in order.
3. Partial matches are caught when the target phrase or any of its words appears in the anchor.
4. Counter tallies the returned labels, printing each kind sorted with its count.

Try it:

1. Add an image-link category for anchors that are empty strings
2. Make the brand set case-insensitive by normalising it once up front
3. Print each category as a percentage of total anchors
4. Add the anchor `running` and confirm it lands in `partial`, not `exact`.

⚠ Common Mistakes

- Checking `partial` before `exact` would mislabel the exact-match anchor as partial.
- Forgetting to lowercase makes `Acme` miss the branded set keyed in lower case.
- Listing the naked-URL test after the partial test catches `.com` anchors as partial.

Skills gained anchor text | classification | Counter

→ Where You'll Use This: Backlink tools report anchor distributions exactly like this, and recognising an unhealthy skew toward exact-match anchors is a routine part of a backlink audit.

Mental Model

Sorting anchors is like sorting mail into pigeonholes by type. A healthy mailbox has a balanced spread, not a hundred identical flyers.

Project 378 Detect an Over-Optimized Anchor Profile

The Idea Behind It

This zooms in on a single danger signal from the anchor mix: an oversized share of exact-match anchors. It counts how many backlinks use the target keyword verbatim, turns that into a percentage of the total, and compares it against a thirty-percent threshold to label the profile over-optimised or natural. The arithmetic is trivial but the judgment it encodes prevents penalties.

What You'll Build & Learn

Flag a backlink profile as over-optimised when its exact-match anchor share crosses a safe threshold.

- Exact-match anchor share as a risk signal
- Turning a count into a percentage

- Threshold comparison for a verdict

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 377: tally the anchor-text distribution. Project 379 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect an over-optimized anchor profile is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'exact-match {exact}/{total} = {pct}% (limit {limit}%) -> {verdict}')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`verdict = 'OVER-OPTIMIZED' if pct > limit else 'natural'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f'exact-match {exact}/{total} = {pct}% (limit {limit}%) -> {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'OVER-OPTIMIZED' if pct > limit else 'natural'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect an Over-Optimized Anchor Profile: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.

1. Predict: before running, write the exact output you expect from `print(f'exact-match {exact}/{total} = {pct}% (limit {limit}%) -> {verdict}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect an over-optimized anchor profile and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Counting how many anchors equal the target keyword and dividing by the total gives the exact-match share, which over a 30% threshold trips the over-optimized flag.

```
from collections import Counter

anchors = ['running shoes'] * 7 + ['Acme', 'click here', 'shop now']
target_kw = 'running shoes'
total = len(anchors)
exact = Counter(a.lower() for a in anchors)[target_kw]
pct = round(100 * exact / total, 1)
limit = 30.0
verdict = 'OVER-OPTIMIZED' if pct > limit else 'natural'
print(f'exact-match {exact}/{total} = {pct}% (limit {limit}%) -> {verdict}')
```

```
output
exact-match 7/10 = 70.0% (limit 30.0%) -> OVER-OPTIMIZED
```

How it works:

1. The anchors list is built as seven exact-match phrases plus three varied ones, total ten.
2. A Counter on lowercased anchors gives exact, the count of the target keyword.
3. pct is 100 times exact over total, rounded, and limit is fixed at 30.0.
4. A conditional sets verdict to OVER-OPTIMIZED because 70 percent exceeds the limit, then prints it.

Try it:

1. Lower the limit to 20 percent and see whether the verdict changes
2. Report which specific anchor is over-represented, not just the percentage
3. Add a second branded-anchor floor that warns when branded share is too low
4. Add three branded anchors and watch the percentage fall below the limit.

⚠ Common Mistakes

- Comparing the raw exact count to the limit instead of the percentage ignores profile size.
- Counting anchors that merely contain the keyword inflates the exact-match share.
- Using `>=` rather than `>` flags a profile sitting exactly on the limit.

Skills gained over-optimisation | threshold | anchor risk

→ Where You'll Use This: Before launching a link-building campaign you set anchor-text guardrails, and a check like this stops a writer or vendor from overusing the money keyword and triggering a filter.

⚡ Mental Model

It is a smoke alarm for anchors: when too many links shout the same keyword, the alarm trips before the algorithm decides the smoke is arson.

Project 379 Count Referring Domains From a Backlink List

💡 The Idea Behind It

Raw backlink counts mislead because one site can link a thousand times. This project parses the host out of each backlink URL with simple string splitting and collapses the list into a set of unique referring domains. Comparing the five raw links against three distinct domains makes the headline backlink metric concrete: who links to you matters more than how often.

What You'll Build & Learn

Count distinct referring domains from a backlink list and contrast that with the raw link total.

- Referring domains versus raw link count
- Extracting a host with string splitting
- Deduplicating with a set

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 378: detect an over-optimized anchor profile. Project 380 changes the surface problem while preserving the underlying method. *progress check*

Reading target: count referring domains from a backlink list is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(' ', d)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`domains = {domain(b['from']) for b in backlinks}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' ', d)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `domains = {domain(b['from']) for b in backlinks}`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Count Referring Domains From a Backlink List: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, https, blogA, com, post1. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: backlinks = [| Core: domains = {domain(b['from']) for b in backlinks} | Evidence: print(' ', d)

🛠️ Reader to Writer Bridge

1. Read: explain count referring domains from a backlink list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 378.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 380 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ', d)`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count referring domains from a backlink list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Slicing the host out of each linking URL and collecting them in a set collapses many links from one site into a single referring domain.

```
backlinks = [
    {'from': 'https://blogA.com/post1', 'to': '/shoes'},
    {'from': 'https://blogA.com/post2', 'to': '/shoes'},
    {'from': 'https://news.org/review', 'to': '/shoes'},
    {'from': 'https://forum.net/t/9', 'to': '/home'},
    {'from': 'https://blogA.com/post3', 'to': '/home'},
]
def domain(url):
    return url.split('://', 1)[1].split('/', 1)[0]
domains = {domain(b['from']) for b in backlinks}
print('total backlinks:', len(backlinks))
print('referring domains:', len(domains))
for d in sorted(domains):
    print(' ', d)
```

```
output
total backlinks: 5
referring domains: 3
  blogA.com
  forum.net
  news.org
```

How it works:

1. backlinks is a list of dicts each holding a from URL and a to path.
2. domain splits a URL after the scheme, then before the first slash, returning the host.
3. A set comprehension over every from URL yields the unique referring domains.
4. It prints the total link count, the domain count, and each sorted domain.

Try it:

1. Also count how many backlinks each domain contributed
2. Handle URLs that lack a scheme without raising an error
3. Report the average number of links per referring domain
4. Add a fourth `blogA.com` link and confirm the domain count does not move.

⚠ Common Mistakes

- Counting `len(backlinks)` reports links, not the distinct domains that matter.
- Splitting on `.com` instead of the path breaks on other TLDs and subpaths.
- Forgetting to sort the domain set makes the printed list nondeterministic.

Skills gained referring domains | URL parsing | sets

→ Where You'll Use This: Referring-domain count is the first number on any backlink dashboard, and explaining why it beats raw link count is a constant conversation with clients chasing vanity totals.

Mental Model

A hundred votes from one person is one opinion. A hundred votes from a hundred people is consensus. Domains are the people.

Project 380 Measure the Dofollow-to-Nofollow Ratio

The Idea Behind It

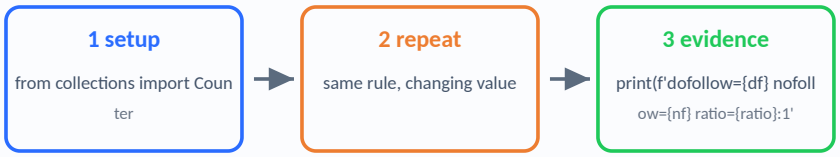
Not every backlink passes ranking power, so this project measures the split between dofollow links that vote and nofollow links that only hint. A Counter tallies the rel value of each backlink, then the dofollow count is divided by the nofollow count to express the balance as a ratio. The single figure summarises how much of a profile is actually working for rankings.

What You'll Build & Learn

Tally dofollow versus nofollow backlinks and express their balance as a single ratio.

- Dofollow links pass equity, nofollow do not
- Tallying a field with Counter
- Expressing a balance as a ratio

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 379: count referring domains from a backlink list. Project 381 changes the surface problem while preserving the underlying method. *progress check*

Reading target: measure the dofollow-to-nofollow ratio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`c = Counter(b['rel'] for b in backlinks)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `c = Counter(b['rel'] for b in backlinks)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Layer	What to read
Intent	Measure the Dofollow-to-Nofollow Ratio: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, backlinks, https, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: c = Counter(b['rel'] for b in backlinks) | Evidence: print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')

🛠️ Reader to Writer Bridge

1. Read: explain measure the dofollow-to-nofollow ratio in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 379.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 381 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure the dofollow-to-nofollow ratio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A Counter over the `rel` field splits the links into dofollow and nofollow, and dividing the two gives the equity-passing ratio.

```
from collections import Counter

backlinks = [
    {'from': 'https://a.com', 'rel': 'dofollow'},
    {'from': 'https://b.com', 'rel': 'nofollow'},
    {'from': 'https://c.com', 'rel': 'dofollow'},
    {'from': 'https://d.com', 'rel': 'dofollow'},
    {'from': 'https://e.com', 'rel': 'nofollow'},
]
c = Counter(b['rel'] for b in backlinks)
df, nf = c['dofollow'], c['nofollow']
ratio = round(df / nf, 2)
print(f'dofollow={df} nofollow={nf} ratio={ratio}:1')
```

```
output
dofollow=3 nofollow=2 ratio=1.5:1
```

How it works:

1. backlinks is a list of dicts each carrying a from URL and a rel attribute.
2. Counter over the rel of every backlink produces counts for dofollow and nofollow.
3. df and nf unpack those two counts from the Counter.
4. ratio is df divided by nf, rounded, and printed as a colon-one figure of 1.5.

Try it:

1. Guard against a zero nofollow count to avoid a division error
2. Add ugc and sponsored as their own rel categories
3. Express the dofollow links as a percentage of all backlinks
4. Add two more dofollow links and watch the ratio climb.

⚠ Common Mistakes

- Dividing nofollow by dofollow inverts the ratio you meant to report.

- A profile with zero nofollow links would divide by zero, so the fixture has both.
- Treating `ugc` and `sponsored` rels as dofollow overstates passed equity.

Skills gained dofollow nofollow ratio Counter

→ **Where You'll Use This:** A profile that is almost entirely nofollow earns trust but little ranking lift, so this ratio frames whether a site needs more equity-passing links in its strategy.

Mental Model

Dofollow links are signed votes that count toward the tally; nofollow links are unsigned notes the judges read but cannot count.

Project 381 Score Linking-Domain Diversity

The Idea Behind It

Diversity here is a ratio rather than a category breakdown. The project extracts the host from each link, collects the unique ones in a set, and divides that count by the total number of links to produce a single diversity score. A result of 0.5 means half the links are essentially repeats from the same handful of sites, a sign the profile lacks breadth.

What You'll Build & Learn

Score how spread out a backlink profile is by dividing unique domains by total links.

- Domain diversity as a ratio
- Set length over list length
- Low diversity signals repeated sources

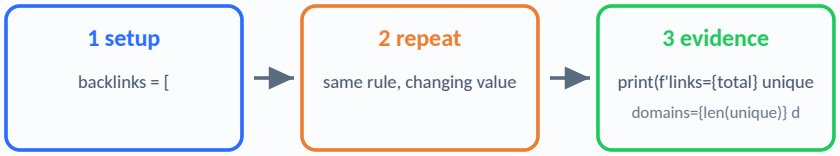
Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 380: measure the dofollow-to-nofollow ratio. Project 382 changes the surface problem while preserving the underlying method.

progress check

Reading target: score linking-domain diversity is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'links={total} unique domains={len(unique)} diversity={diversity}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

CORE LINE `unique = {domain(u) for u in backlinks}`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Score Linking-Domain Diversity: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, https, com, domain, split. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: backlinks = [| Core: unique = {domain(u) for u in backlinks} | Evidence: print(f'links={total} unique domains={len(unique)} diversity={diversity...

🛠️ Reader to Writer Bridge

1. Read: explain score linking-domain diversity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 380.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 382 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'links={total} unique domains={len(unique)} diversity={diversity}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score linking-domain diversity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The size of the domain set over the total link count is a diversity ratio: 1.0 means every link is from a different site, lower means concentration.

```
backlinks = [
    'https://a.com/1', 'https://a.com/2', 'https://a.com/3',
    'https://b.com/x', 'https://b.com/y',
    'https://c.com/z',
]
def domain(u):
    return u.split('://', 1)[1].split('/', 1)[0]
unique = {domain(u) for u in backlinks}
total = len(backlinks)
diversity = round(len(unique) / total, 2)
print(f'links={total} unique domains={len(unique)} diversity={diversity}')
```

```
output
links=6 unique domains=3 diversity=0.5
```

How it works:

1. backlinks is a flat list of six full URLs, several sharing the same host.
2. domain splits off the scheme and path to leave the host string.
3. unique is the set of those hosts, here three, while total is six.
4. diversity is len(unique) over total, rounded to 0.5, printed beside the raw counts.

Try it:

1. Print the most over-represented domain alongside the score
2. Weight the score so brand-new domains count extra
3. Compare the diversity scores of two separate backlink lists
4. Add three more domains and watch diversity rise toward 1.0.

⚠ Common Mistakes

- Dividing total links by unique domains inverts the ratio into links-per-domain.
- Building the set from full URLs not hosts treats every page as its own domain.
- Rounding to zero decimals hides meaningful differences between profiles.

Skills gained `diversity score` `sets` `ratio`

→ **Where You'll Use This:** Diversity scores let you compare two backlink profiles at a glance and justify why a campaign chasing many new domains beats one squeezing more links from existing partners.

Mental Model

A garden with one species repeated is monoculture; many species is biodiversity. The diversity ratio tells you which kind of backlink garden you grew.

Project 382 Track Link Velocity Month by Month

The Idea Behind It

Link velocity is the pace at which new backlinks arrive, and a sudden burst can read as a paid-link blast to a search engine. This project walks a month-keyed dict in sorted order, prints each month's new links with the signed delta from the prior month, and finishes with the monthly average. The deltas turn a flat table into a trend you can read.

What You'll Build & Learn

Chart new backlinks month over month with signed deltas, and report the average monthly rate.

- Link velocity as backlink arrival rate
- Computing month-over-month deltas
- Carrying a previous value through a loop

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 381: score linking-domain diversity. Project 383 changes the surface problem while preserving the underlying method.

progress check

Reading target: track link velocity month by month is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `monthly = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.

- Evidence: `print('avg/month:', avg)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`monthly = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if prev is None:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('avg/month:', avg)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if prev is None:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Track Link Velocity Month by Month: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: monthly, months, sorted, prev, is. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: monthly = { | Core: if prev is None: | Evidence: print('avg/month:', avg)

🛠️ Reader to Writer Bridge

1. Read: explain track link velocity month by month in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 381.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 383 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('avg/month:', avg)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `monthly = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of track link velocity month by month and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Sorting the month keys and subtracting each month's count from the previous one yields the velocity delta, with the first month seeded as a baseline.

```
monthly = {
    '2026-01': 12,
    '2026-02': 18,
    '2026-03': 25,
    '2026-04': 22,
    '2026-05': 40,
}
months = sorted(monthly)
prev = None
for m in months:
    n = monthly[m]
    if prev is None:
        print(f'{m}: {n} new (--)')
    else:
        delta = n - monthly[prev]
        sign = '+' if delta >= 0 else ''
        print(f'{m}: {n} new ({sign}{delta})')
    prev = m
avg = round(sum(monthly.values()) / len(monthly), 1)
print('avg/month:', avg)
```

```
output
2026-01: 12 new (--)
2026-02: 18 new (+6)
2026-03: 25 new (+7)
2026-04: 22 new (-3)
2026-05: 40 new (+18)
avg/month: 23.4
```

How it works:

1. monthly maps each year-month string to a count of new backlinks.
2. Iterating sorted months, the first prints with a placeholder delta of double dashes.
3. For later months, delta is the difference from the prior month with a plus sign when non-negative.
4. After the loop, avg is the mean of all monthly counts, here 23.4, printed last.

Try it:

1. Flag any month whose delta exceeds twice the running average
2. Compute a three-month rolling average instead of a single mean
3. Print the percentage change each month rather than the absolute delta
4. Add a month with a huge jump and flag it as a suspicious spike.

⚠ Common Mistakes

- Iterating an unsorted dict computes deltas against the wrong previous month.

- Forgetting the `prev is None` guard crashes on the first month with no predecessor.
- Reporting the cumulative total as velocity hides the per-month rate of change.

Skills gained link velocity | deltas | time series

→ Where You'll Use This: Tracking velocity spikes helps you distinguish organic growth from a manipulated burst, and explains sudden ranking changes when a competitor buys links en masse.

Mental Model

It is a speedometer for backlinks. Steady acceleration looks earned; a sudden floor-the-pedal jump makes the algorithm suspect a shortcut.

Project 383 Flag Toxic Links by Spammy TLD

The Idea Behind It

Some top-level domains are so cheap and abuse-prone that links from them are a toxicity signal. This project extracts the TLD from each backlink host with a right-split and checks it against a blocklist of known-spammy extensions like xyz, tk, and gq. Each link prints as TOXIC or ok, giving a fast first-pass filter before deeper manual review.

What You'll Build & Learn

Flag backlinks from spammy top-level domains using a blocklist as a quick toxicity filter.

- Spammy TLDs as a toxicity signal
- Extracting a TLD with rsplit
- Set membership for blocklist checks

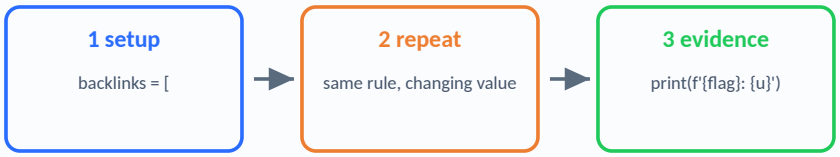
Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 382: track link velocity month by month. Project 384 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag toxic links by spammy tld is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{flag}: {u}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`flag = 'TOXIC' if t in spammy else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{flag}: {u}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = 'TOXIC' if t in spammy else 'ok'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Flag Toxic Links by Spammy TLD: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, https, shop, example, com. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: backlinks = [| Core: flag = 'TOXIC' if t in spammy else 'ok' | Evidence: print(f'{flag}: {u}')

🛠️ Reader to Writer Bridge

1. Read: explain flag toxic links by spammy tld in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 382.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 384 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{flag}: {u}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag toxic links by spammy tld and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Pulling the last dot-segment of each host yields the TLD, and membership in a spammy-TLD set flags the link as toxic.

```
backlinks = [
    'https://shop.example.com/a',
    'https://news.org/b',
    'https://spam.xyz/c',
    'https://casino.tk/d',
    'https://blog.com/e',
    'https://pills.gq/f',
]
spammy = {'xyz', 'tk', 'gq', 'ml', 'cf'}
def tld(u):
    host = u.split('://', 1)[1].split('/', 1)[0]
    return host.rsplit('.', 1)[-1]
for u in backlinks:
    t = tld(u)
    flag = 'TOXIC' if t in spammy else 'ok'
    print(f'{flag}: {u}')
```

```
output
ok: https://shop.example.com/a
ok: https://news.org/b
TOXIC: https://spam.xyz/c
TOXIC: https://casino.tk/d
ok: https://blog.com/e
TOXIC: https://pills.gq/f
```

How it works:

1. backlinks is a list of six URLs, some on suspicious extensions like xyz, tk, and gq.
2. spammy holds the blocklisted TLDs as a set for fast lookup.
3. tld splits off the scheme and path, then rsplits the host on the dot to grab the last label.
4. Each link prints TOXIC when its TLD is in the blocklist, otherwise ok.

Try it:

1. Add a few more abuse-prone TLDs you have seen in spam
2. Treat a link as toxic only if its TLD is spammy and its DR is low
3. Count how many toxic links each spammy TLD contributed
4. Add `.work` to the spammy set and re-run.

⚠ Common Mistakes

- Splitting on the first dot grabs a subdomain instead of the TLD.
- Comparing the whole host to the blocklist never matches a real domain.
- Treating a legitimate site that merely sits on a .xyz domain as automatically toxic.

Skills gained toxic links | TLD parsing | blocklist

→ Where You'll Use This: Before building a disavow file you triage thousands of backlinks, and a TLD blocklist quickly surfaces the obvious junk so manual review focuses on borderline cases.

⚡ Mental Model

Certain neighbourhoods of the web rent space to anyone for pennies. A link from one is like a reference written on the back of a betting slip.

Project 384 Compute the Deep-Link Ratio

💡 The Idea Behind It

A natural backlink profile points at inner pages, not just the homepage. This project counts how many backlink targets are the root path versus deeper URLs, then divides the deep count by the total to produce a deep-link ratio. A balanced result suggests organic interest in specific content, while an all-homepage profile can look artificially built.

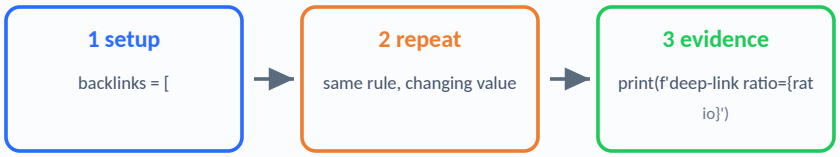
What You'll Build & Learn

Compute the share of backlinks that point at inner pages rather than the homepage.

- Deep links versus homepage links
- Deep-link ratio as a naturalness gauge
- Counting by comparing each path to root

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 383: flag toxic links by spammy tld. Project 385 changes the surface problem while preserving the underlying method.



progress check

Reading target: compute the deep-link ratio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'deep-link ratio={ratio}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`home = sum(1 for p in backlinks if p == '/')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'deep-link ratio={ratio}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `home = sum(1 for p in backlinks if p == '/')`

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute the Deep-Link Ratio: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, blog, post, products, shoes. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: backlinks = [| Core: home = sum(1 for p in backlinks if p == '/') | Evidence: print(f'deep-link ratio= {ratio}')

🛠️ Reader to Writer Bridge

1. Read: explain compute the deep-link ratio in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 383.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 385 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'deep-link ratio= {ratio}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of compute the deep-link ratio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting links whose target is exactly `/` gives the homepage share, and the rest are deep links into inner pages, whose ratio reflects topical link spread.

```
backlinks = [
    '/',
    '/blog/post-1',
    '/',
    '/products/shoes',
    '/about',
    '/',
]
home = sum(1 for p in backlinks if p == '/')
deep = len(backlinks) - home
ratio = round(deep / len(backlinks), 2)
print(f'homepage links={home} deep links={deep}')
print(f'deep-link ratio={ratio}')
```

```
output
homepage links=3 deep links=3
deep-link ratio=0.5
```

How it works:

1. backlinks is a list of target paths, three of which are the bare root slash.
2. home counts how many entries equal the root path using a generator sum.
3. deep is simply the total minus the homepage count.
4. ratio is deep over the total, rounded to 0.5, printed beneath the two raw counts.

Try it:

1. Group deep links by their top-level path segment like blog or products
2. Flag the profile when the homepage share exceeds sixty percent
3. Handle target paths that include query strings or fragments
4. Add two more inner-page links and watch the ratio rise.

⚠ Common Mistakes

- Treating `/` and an empty path differently miscounts the homepage links.
- Counting `/index.html` as deep when it is really the homepage.
- Dividing by the homepage count instead of the total skews the ratio.

Skills gained deep-link ratio path matching naturalness

→ **Where You'll Use This:** A skewed deep-link ratio prompts content-led link building that earns references to specific articles, which both diversifies the profile and pushes equity to pages that convert.

⚡ Mental Model

If everyone only ever recommends the front door of a building, no one knows what is inside. Deep links are recommendations for individual rooms.

Project 385 Detect Reciprocal Links Between Sites

💡 The Idea Behind It

Two sites linking to each other carry less editorial weight than a one-way link, so spotting reciprocal pairs matters. This project walks the link graph and, for each edge, checks whether the target links back to the source. Matches are stored as sorted tuples in a set so each pair counts once regardless of direction, revealing possible link-exchange schemes.

What You'll Build & Learn

Detect mutual link pairs in a link graph and count them, surfacing possible exchange schemes.

- Reciprocal links carry less weight
- Checking if a target links back
- Sorted tuples in a set to dedupe pairs

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 384: compute the deep-link ratio. Project 386 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect reciprocal links between sites is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.

- Evidence: `print('count:', len(recip))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if src in links.get(t, []):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('count:', len(recip))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Code Reading Stack

Layer	What to read
Intent	Detect Reciprocal Links Between Sites: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, siteA, siteB, siteC, siteD. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: links = { | Core: if src in links.get(t, []): | Evidence: print('count:', len(recip))

🛠️ Reader to Writer Bridge

1. Read: explain detect reciprocal links between sites in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 384.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 386 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('count:', len(recip))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect reciprocal links between sites and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

For each edge A to B, checking whether B also links back to A finds the reciprocal pair, stored as a sorted tuple so each pair is reported once.

```
links = {
    'siteA': ['siteB', 'siteC'],
    'siteB': ['siteA'],
    'siteC': ['siteD'],
    'siteD': ['siteC'],
}
recip = set()
for src, outs in links.items():
    for t in outs:
        if src in links.get(t, []):
            recip.add(tuple(sorted((src, t))))
for pair in sorted(recip):
    print(f'reciprocal: {pair[0]} <-> {pair[1]}')
print('count:', len(recip))
```

```
output
reciprocal: siteA <-> siteB
reciprocal: siteC <-> siteD
count: 2
```

How it works:

1. links maps four sites to their outbound targets, with two mutual pairs hidden inside.
2. For each source and target, the code checks whether src appears in links.get(t, []).
3. A match is added as tuple(sorted src, t) so direction never duplicates the pair.
4. Sorted pairs print with an arrow, and the final count reports two reciprocal links.

Try it:

1. Report what fraction of all edges are reciprocal
2. Allow a site to link itself without falsely flagging a pair
3. Extend detection to three-site link rings, not just two-way pairs
4. Break one back-link and confirm that pair drops out.

⚠ Common Mistakes

- Storing pairs unsorted records `(A,B)` and `(B,A)` as two distinct reciprocals.
- Using `links[t]` instead of `links.get(t, [])` raises if a target has no entry.
- Counting both directions doubles the reciprocal-pair total.

Skills gained reciprocal links | graph traversal | sets

→ Where You'll Use This: Auditing a profile for excessive reciprocity catches link-exchange patterns that search engines discount, and steers outreach toward earning unreciprocated editorial links instead.

Mental Model

Two people praising each other on cue sounds rehearsed. A reciprocal link is that mutual back-pat, worth less than an unsolicited compliment.

Project 386 Apply Google's First-Link-Counts Rule

The Idea Behind It

When a page links to the same target twice, classic PageRank credits only the anchor text of the first link. This project models that first-link-counts rule by walking links in order and recording each target only the first time it appears. The result changes which anchor a target page is associated with, a subtlety that affects internal-link planning.

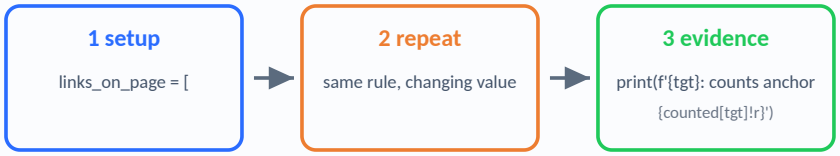
What You'll Build & Learn

Model the first-link-counts rule so each target keeps only its first anchor on a page.

- First link counts for anchor credit
- Recording a target only on first sight
- Order matters when iterating links

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 385: detect reciprocal links between sites. Project 387 changes the surface problem while preserving the underlying method.



progress check

Reading target: apply google's first-link-counts rule is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `links_on_page = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{tgt}: counts anchor {counted[tgt]!r}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links_on_page = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if link['to'] not in counted:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{tgt}: counts anchor {counted[tgt]!r}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if link['to'] not in counted:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Apply Google's First-Link-Counts Rule: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links_on_page, to, shoes, anchor, running. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links_on_page = [| Core: if link['to'] not in counted: | Evidence: print(f'{tgt}: counts anchor {counted[tgt]!r}')

🛠️ Reader to Writer Bridge

1. Read: explain apply google's first-link-counts rule in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 385.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 387 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

2. Explain: point to `links_on_page = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of apply google's first-link-counts rule and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Walking the page's links in order and keeping only the first anchor seen per target mirrors the first-link-counts behaviour: later links to the same URL are ignored for anchor purposes.

```
links_on_page = [
    {'to': '/shoes', 'anchor': 'running shoes'},
    {'to': '/shoes', 'anchor': 'click here'},
    {'to': '/boots', 'anchor': 'boots'},
    {'to': '/boots', 'anchor': 'winter boots'},
]
counted = {}
```

```
for link in links_on_page:
    if link['to'] not in counted:
        counted[link['to']] = link['anchor']
for tgt in sorted(counted):
    print(f'{tgt}: counts anchor {counted[tgt]!r}')
```

```
output
/boots: counts anchor 'boots'
/shoes: counts anchor 'running shoes'
```

How it works:

1. links_on_page lists four links in order, with shoes and boots each appearing twice.
2. counted is a dict that records a target's anchor only if the target is not already a key.
3. Because iteration is ordered, the first link to each target wins its anchor slot.
4. Sorted output shows shoes credited to running shoes and boots to boots, the first anchors.

Try it:

1. Switch the order of the duplicate links and see the credited anchor change
2. Record all anchors per target but mark which one is credited
3. Count how many links were ignored because the target was already seen
4. Reorder the two `/shoes` links and watch the counted anchor change.

⚠ Common Mistakes

- Overwriting the stored anchor on every link keeps the last, not the first.
- Using a plain dict assignment without the `not in` guard loses the first-link rule.
- Assuming both links to a target pass anchor equity when only the first does here.

Skills gained first link counts | ordered dict | anchor credit

→ Where You'll Use This: When a navigation and an in-body link both point to the same page, knowing which anchor counts shapes how you place keyword-rich links so the right phrase is credited.

⚡ Mental Model

If you introduce a friend twice at a party, only the first introduction sticks. The first-link rule remembers the first name you gave them.

Project 387 Split Outbound Links Into Internal and External

💡 The Idea Behind It

A page's outbound links split into internal ones that recycle equity and external ones that leak it off-site. This project parses the host from each URL and partitions the link list by comparing that host to the site's own. Subdomains count as external here, which matters because the split is the foundation of both equity sculpting and outbound-link audits.

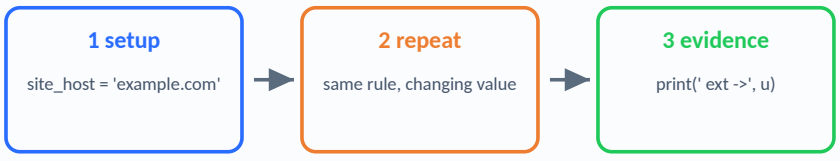
What You'll Build & Learn

Partition a page's outbound links into internal and external sets by comparing hosts.

- Internal links recycle equity, external leak it
- Comparing each link's host to the site
- Subdomains treated as external here

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 386: apply google's first-link-counts rule. Project 388 changes the surface problem while preserving the underlying method.



progress check

Reading target: split outbound links into internal and external is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `site_host = 'example.com'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(' ext ->', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`site_host = 'example.com'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`internal = [u for u in links if host(u) == site_host]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(' ext ->', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `internal = [u for u in links if host(u) == site_host]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Split Outbound Links Into Internal and External: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: site_host, example, com, links, https. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: site_host = 'example.com' | Core: internal = [u for u in links if host(u) == site_host] | Evidence: print(' ext ->', u)

🛠️ Reader to Writer Bridge

1. Read: explain split outbound links into internal and external in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 386.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 388 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ext ->', u)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `site_host = 'example.com'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split outbound links into internal and external and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Comparing each link's host against the site's own host partitions the links into internal and external sets, the first step of any link-flow analysis.

```
site_host = 'example.com'
links = [
    'https://example.com/about',
    'https://blog.example.com/x',
    'https://other.com/ref',
    'https://example.com/shop',
    'https://partner.org/y',
]
def host(u):
    return u.split('://', 1)[1].split('/', 1)[0]
internal = [u for u in links if host(u) == site_host]
external = [u for u in links if host(u) != site_host]
print('internal:', len(internal))
print('external:', len(external))
for u in sorted(external):
    print('  ext ->', u)
```

```
output
```

```
internal: 2
external: 3
  ext -> https://blog.example.com/x
  ext -> https://other.com/ref
  ext -> https://partner.org/y
```

How it works:

1. site_host is example.com and links is a list of five outbound URLs.
2. host splits off the scheme then the path to isolate each URL's host.
3. internal keeps links whose host equals site_host; external keeps the rest.
4. Counts print, and each external link is listed sorted, including the blog subdomain.

Try it:

1. Treat subdomains of the site as internal rather than external
2. Count the equity each external link would receive given a page rank
3. Report the external domains, deduplicated, instead of full URLs
4. Decide subdomains are internal and adjust the host comparison.

⚠ Common Mistakes

- Treating a subdomain like `blog.example.com` as internal when it is a separate host here.
- Matching on substring rather than exact host counts `notexample.com` as internal.
- Forgetting to sort the external list makes the output nondeterministic.

Skills gained internal external | host parsing | equity sculpting

→ Where You'll Use This: Outbound-link audits use this split to find pages leaking equity to low-value external sites, and to confirm internal links keep authority circulating within the domain.

Mental Model

Internal links are money spent inside your own shop; external links are money handed to neighbours. The split tells you where your equity goes.

Project 388 Compute an Authority Score From a Profile

The Idea Behind It

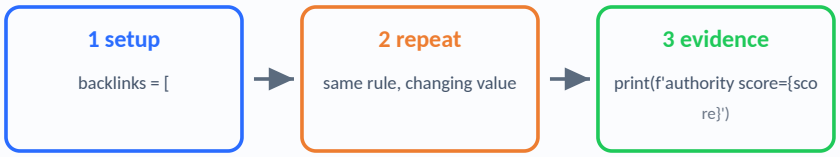
A profile is many numbers, but a single comparable score helps prioritise. This toy authority score weights the two things that matter most: distinct referring domains and dofollow links that pass equity. It multiplies the domain count by five and the dofollow count by two, then sums them, collapsing a whole profile into one figure you can track over time.

What You'll Build & Learn

Blend referring domains and dofollow links into one weighted authority score for a profile.

- Weighting domains above raw links
- Counting dofollow links in a profile
- Collapsing metrics into one score

🧭 Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 387: split outbound links into internal and external. Project 389 changes the surface problem while preserving the underlying method. *progress check*

Reading target: compute an authority score from a profile is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'authority score={score}')` exposes the result; match it against the output before changing the program. *output proves the trace*

prediction before proof

2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute an authority score from a profile and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Weighting unique referring domains more heavily than individual dofollow links and summing gives a single authority figure you can track over time.

```
backlinks = [
    {'domain': 'a.com', 'rel': 'dofollow'},
    {'domain': 'b.com', 'rel': 'dofollow'},
    {'domain': 'c.com', 'rel': 'nofollow'},
    {'domain': 'd.com', 'rel': 'dofollow'},
    {'domain': 'a.com', 'rel': 'nofollow'},
]
ref_domains = {b['domain'] for b in backlinks}
dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')
score = round(len(ref_domains) * 5 + dofollow * 2, 1)
print(f'ref domains={len(ref_domains)} dofollow links={dofollow}')
print(f'authority score={score}')
```

```
output
ref domains=4 dofollow links=3
authority score=26
```

How it works:

1. backlinks is a list of dicts each with a domain and a rel value.
2. ref_domains is the set of distinct domains, here four despite five links.

3. dofollow sums the links whose rel is dofollow, giving three.
4. score is four times five plus three times two, equal to 26, printed with its components.

Try it:

1. Subtract points for any toxic-TLD domains in the profile
2. Weight each domain by its DR before summing
3. Normalise the score to a zero-to-hundred scale
4. Add a link from a brand-new domain and watch the score jump.

⚠ Common Mistakes

- Counting total links instead of unique domains lets one spammy site inflate the score.
- Weighting dofollow and domains equally undervalues domain diversity.
- Including nofollow links in the dofollow term overstates passed equity.

Skills gained authority score | weighting | sets

→ Where You'll Use This: A blended score lets you rank prospect sites or track your own profile's growth month to month without staring at a dozen separate metrics each time.

Mental Model

Like a credit score, it boils many signals into one number. The weights decide which behaviours move the needle most.

Project 389 Apply a Disavow List to a Backlink Profile

The Idea Behind It

A disavow file tells Google to ignore specific toxic domains. This project applies that file locally by extracting each backlink's host and partitioning the list into kept and removed based on a disavow set. Recomputing your reported profile against only the kept links shows what your backlinks actually count for once the junk is stripped out.

What You'll Build & Learn

Apply a disavow set to a backlink list, separating kept links from disavowed ones.

- Disavow files ignore named domains
- Partitioning links by host membership
- Re-scoring the surviving profile

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 388: compute an authority score from a profile. Project 390 changes the surface problem while preserving the underlying method. *progress check*

Reading target: apply a disavow list to a backlink profile is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Filtering the backlinks by whether each host appears in the disavow set partitions the profile into kept and disavowed links.

```
backlinks = [
    'https://good.com/a',
    'https://spam.xyz/b',
    'https://news.org/c',
    'https://badnet.tk/d',
    'https://blog.com/e',
]
disavow = {'spam.xyz', 'badnet.tk'}
def host(u):
    return u.split('://', 1)[1].split('/', 1)[0]
kept = [u for u in backlinks if host(u) not in disavow]
removed = [u for u in backlinks if host(u) in disavow]
print('kept:', len(kept))
print('disavowed:', len(removed))
for u in sorted(removed):
    print('  removed', u)
```

```
output
kept: 3
disavowed: 2
  removed https://badnet.tk/d
  removed https://spam.xyz/b
```

How it works:

1. backlinks is five full URLs and disavow is a set of two toxic hosts.
2. host strips the scheme and path to return each URL's domain.
3. kept keeps links whose host is not in disavow; removed keeps the rest.
4. Counts print and each removed link is listed sorted, confirming three kept and two dropped.

Try it:

1. Support disavowing an entire TLD, not just exact domains
2. Report the percentage of links removed by the disavow
3. Recompute the authority score on the kept links only
4. Add `blog.com` to the disavow set and watch a clean link get removed.

⚠ Common Mistakes

- Matching the full URL against the disavow set, which lists domains, never removes anything.
- Disavowing a domain but leaving its subdomains linked lets equity leak through.
- Forgetting to sort the removed list makes the audit output nondeterministic.

Skills gained disavow | filtering | host parsing

→ Where You'll Use This: After identifying toxic backlinks you build a disavow file for Search Console, and modelling its effect locally previews how much of your reported authority will remain.

⚡ Mental Model

A disavow file is a do-not-count list you hand the referee. These witnesses still spoke, but you have asked the judge to disregard them.

Project 390 Sculpt Equity by Nofollowing a Link

💡 The Idea Behind It

PageRank sculpting once meant adding nofollow to low-value links so more equity reached the rest. This project models that by storing each link as a target-and-rel tuple, then computing shares only over the followed links. With one of home's three links nofollowed, the remaining two each get half the equity instead of a third, demonstrating the redistribution.

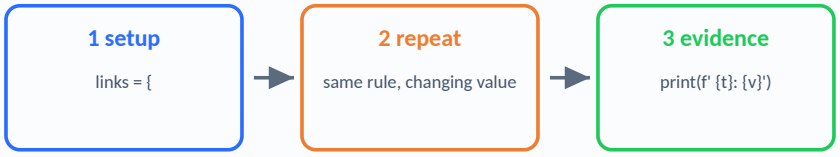
What You'll Build & Learn

Show how nofollowing one link reshapes the equity share each followed link receives.

- Nofollow excludes a link from equity flow
- Sculpting concentrates equity on followed links
- Counting only followed links for shares

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 389: apply a disavow list to a backlink profile. Project 391 changes the surface problem while preserving the underlying method.



progress check

Reading target: sculpt equity by nofollowing a link is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f' {t}: {v}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`followed = [t for t, rel in outs if rel == 'follow']`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f' {t}: {v}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `followed = [t for t, rel in outs if rel == 'follow']`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Sculpt Equity by Nofollowing a Link: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, home, follow, promo, nofollow. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: followed = [t for t, rel in outs if rel == 'follow'] | Evidence: print(f' {t}: {v}')

🛠️ Reader to Writer Bridge

1. Read: explain sculpt equity by nofollowing a link in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 389.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 391 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f' {t}: {v}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of sculpt equity by nofollowing a link and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting only followed out-links as the divisor means a nofollowed link no longer dilutes the share handed to the followed ones.

```
links = {
    'home': [('a', 'follow'), ('b', 'follow'), ('promo', 'nofollow')],
    'a': [('home', 'follow')],
    'b': [('home', 'follow')],
    'promo': [('home', 'follow')],
}
equity = {}
for src, outs in links.items():
    followed = [t for t, rel in outs if rel == 'follow']
    n = len(followed)
    share = round(1.0 / n, 3) if n else 0.0
    for t in followed:
        equity[(src, t)] = share
print('home passes equity to:')
for (src, t), v in sorted(equity.items()):
    if src == 'home':
        print(f'  {t}: {v}')
```

```
output
home passes equity to:
  a: 0.5
  b: 0.5
```

How it works:

1. links maps each page to a list of target-and-rel tuples, with home's promo link nofollowed.
2. For each source, followed filters to targets whose rel is follow.
3. share is one over the number of followed links, so home divides among two not three.
4. Equity entries print for home, showing a and b each receiving 0.5.

Try it:

1. Nofollow a second link and watch the remaining shares rise again
2. Treat nofollow as still consuming a share, the post-2009 behaviour
3. Report the equity each page sends across all sources, not just home
4. Remove the nofollow on `promo` and watch every share shrink.

⚠ Common Mistakes

- Dividing by all out-links including nofollow undoes the sculpting effect.
- A page whose every link is nofollow has no followed divisor and must be guarded.
- Believing modern Google still hoards the nofollowed link's share, which it no longer does.

Skills gained PageRank sculpting | nofollow | tuples

→ Where You'll Use This: Although modern engines treat nofollow as a hint, understanding sculpting clarifies historical advice and informs how you handle low-value links like login or cart pages today.

⚡ Mental Model

Sculpting is like sealing some of a watering can's spouts so the open ones gush harder. Each remaining flower drinks more.

Project 391 Find Pages With No Inbound Internal Links

💡 The Idea Behind It

An orphan page has no internal link pointing at it, so it receives almost no equity and may never get indexed. This project starts every page at zero inbound, walks the internal link graph to tally arrivals, then lists pages that stayed at zero. Surfacing these orphans is a routine step toward a fully crawlable site.

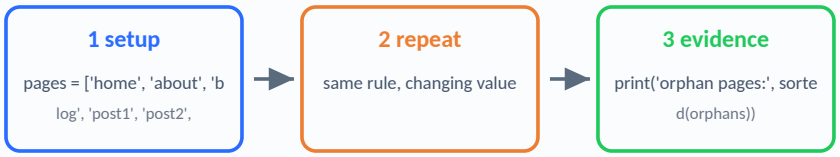
What You'll Build & Learn

Find orphan pages that receive no inbound internal links by listing those with zero in-degree.

- Orphan pages get no internal equity
- Initialising every page at zero inbound
- Listing pages with zero in-degree

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 390: sculpt equity by nofollowing a link. Project 392 changes the surface problem while preserving the underlying method.



progress check

Reading target: find pages with no inbound internal links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = ['home', 'about', 'blog', 'post1', 'post2', 'contact']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print('orphan pages:', sorted(orphans))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = ['home', 'about', 'blog', 'post1', 'post2', 'contact']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`orphans = [p for p in pages if inbound[p] == 0]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('orphan pages:', sorted(orphans))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `orphans = [p for p in pages if inbound[p] == 0]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Pages With No Inbound Internal Links: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: pages, home, about, blog, post1. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = ['home', 'about', 'blog', 'post1', 'post2', 'contact'] | Core: orphans = [p for p in pages if inbound[p] == 0] | Evidence: print('orphan pages:', sorted(orphans))

🛠️ Reader to Writer Bridge

1. Read: explain find pages with no inbound internal links in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 390.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 392 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('orphan pages:', sorted(orphans))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = ['home', 'about', 'blog', 'post1', 'post2', 'contact']` and say why this line, value, import, or entry point is needed before the rest of the Python

can work.

3. Transfer: change one small part of find pages with no inbound internal links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Initialising every known page at zero inbound, tallying targets, then keeping pages still at zero finds the orphans even though they never appear as a link target.

```
pages = ['home', 'about', 'blog', 'post1', 'post2', 'contact']
internal_links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['post1'],
    'post1': ['blog'],
    'post2': ['blog'],
    'contact': [],
}
inbound = {p: 0 for p in pages}
for outs in internal_links.values():
    for t in outs:
        inbound[t] += 1
orphans = [p for p in pages if inbound[p] == 0]
print('orphan pages:', sorted(orphans))
```

```
output
orphan pages: ['contact', 'post2']
```

How it works:

1. pages lists all six known URLs, and internal_links maps each to its outbound targets.
2. inbound starts every page at zero, then nested loops increment each target's count.
3. orphans is a comprehension keeping pages whose inbound count is still zero.
4. Sorted orphans print, surfacing contact and post2 as unreached pages.

Try it:

1. Suggest a sensible parent page that could link to each orphan
2. Treat pages reachable only from the sitemap as still orphaned
3. Count near-orphans with exactly one inbound link as well
4. Link `home` to `contact` and watch it leave the orphan list.

⚠ Common Mistakes

- Building the inbound count only from targets misses orphans entirely (they never appear).
- Confusing pages with no out-links for orphans, which is the opposite direction.
- Treating the homepage as an orphan when external links or nav usually reach it.

Skills gained orphan pages | in-degree | crawlability

→ Where You'll Use This: Orphan detection is a standard technical-SEO finding, and fixing it by adding internal links from relevant pages restores both crawl access and equity flow to stranded content.

Mental Model

An orphan page is a room with no doors. The crawler can only find rooms it can walk into, so a doorless room stays invisible.

Project 392 Rank the Top Internally Linked Pages

The Idea Behind It

Sorting pages by inbound internal links reveals where your own site concentrates equity. This project tallies in-degree with a Counter, then sorts pages by descending count with a secondary alphabetical tiebreak before printing the top three. Whether the leaders match your intended priority pages is the test of an intentional internal-linking structure.

What You'll Build & Learn

Rank the most internally linked pages so you can confirm equity flows to your priority URLs.

- Ranking pages by inbound internal links
- Descending sort with alphabetical tiebreak
- Slicing the top results

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 391: find pages with no inbound internal links. Project 393 changes the surface problem while preserving the underlying method.

progress check

Reading target: rank the top internally linked pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{p}: {indeg[p]} inbound')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`for outs in links.values():`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{p}: {indeg[p]} inbound')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for outs in links.values():`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Rank the Top Internally Linked Pages: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, links, home, blog. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import Counter | Core: for outs in links.values(): | Evidence: print(f'{p}: {indeg[p]} inbound')

🛠️ Reader to Writer Bridge

1. Read: explain rank the top internally linked pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 391.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 393 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p}: {indeg[p]} inbound')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of rank the top internally linked pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

After tallying in-degree, sorting by negative count with the page name as a tiebreaker gives a deterministic top-N of the most internally linked pages.

```
from collections import Counter

links = {
    'home': ['blog', 'shop', 'about'],
    'blog': ['shop', 'post1'],
    'about': ['shop'],
    'post1': ['shop', 'blog'],
    'shop': [],
}
indeg = Counter()
for outs in links.values():
    for t in outs:
        indeg[t] += 1
ranked = sorted(indeg, key=lambda p: (-indeg[p], p))
for p in ranked[:3]:
    print(f'{p}: {indeg[p]} inbound')
```

```
output
shop: 4 inbound
blog: 2 inbound
about: 1 inbound
```

How it works:

1. links maps each page to its outbound targets, with shop appearing as a target repeatedly.
2. A Counter named indeg accumulates inbound counts across every target list.
3. sorted ranks pages by negative in-degree then name, so ties break alphabetically.
4. The top three slice prints shop, blog, and about with their inbound totals.

Try it:

1. Print all pages, not just the top three
2. Break ties by out-degree instead of alphabetical order
3. Compare the ranking against a hand-listed set of priority pages
4. Add two links to `post1` and watch it climb the ranking.

⚠ Common Mistakes

- Sorting by `indeg[p]` ascending lists the least-linked pages first.
- Omitting the page-name tiebreaker makes equal-count ties order unpredictably.
- Slicing before sorting returns an arbitrary subset, not the true top three.

Skills gained internal ranking | Counter | sorting

→ Where You'll Use This: This ranking validates an internal-linking strategy: if a thin page tops the list while a conversion page languishes, you rebalance links to send equity where revenue lives.

⚡ Mental Model

It is a leaderboard of which pages your site cheers loudest for. The names at the top should be the ones you actually want winning.

Project 393 Score Anchor-Text Diversity

💡 The Idea Behind It

A natural backlink profile spreads across many different anchors, while a manipulated one repeats the same phrase. This project rewards that variety by combining two factors: the ratio of unique anchors to total, and one minus the dominant anchor's share. Multiplying them yields a score that drops when either uniqueness is low or one anchor dominates.

What You'll Build & Learn

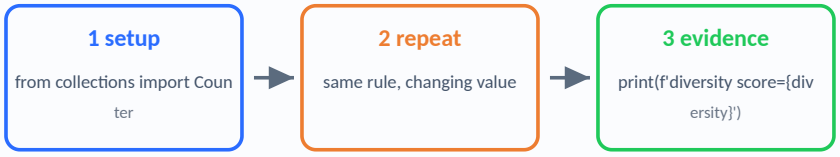
Score anchor-text diversity by combining unique-anchor share with how much the top anchor dominates.

- Diversity rewards many distinct anchors
- Penalising a single dominant anchor
- Combining two factors into one score

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 392: rank the top internally linked pages. Project 394 changes the surface problem while preserving the underlying method.

progress check



Reading target: score anchor-text diversity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'diversity score={diversity}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`counts = Counter(a.lower() for a in anchors)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'diversity score={diversity}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `counts = Counter(a.lower() for a in anchors)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Anchor-Text Diversity: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, anchors, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: counts = Counter(a.lower() for a in anchors) | Evidence: print(f'diversity score={diversity}')

🛠️ Reader to Writer Bridge

1. Read: explain score anchor-text diversity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 392.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 394 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'diversity score={diversity}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of score anchor-text diversity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Multiplying the unique-anchor ratio by `1 minus the top anchor's share` gives a score that drops both when anchors repeat and when one phrase dominates.

```
from collections import Counter

anchors = ['running shoes', 'click here', 'Acme', 'running shoes', 'shoes',
'read more']
counts = Counter(a.lower() for a in anchors)
total = len(anchors)
unique = len(counts)
top_share = max(counts.values()) / total
diversity = round(unique / total * (1 - top_share), 3)
print(f'unique anchors={unique}/{total}')
print(f'top anchor share={round(top_share, 3)}')
print(f'diversity score={diversity}')
```

```
output
unique anchors=5/6
top anchor share=0.333
diversity score=0.556
```

How it works:

1. anchors is six entries, with running shoes appearing twice after lowercasing.
2. Counter gives per-anchor counts, unique is the distinct count, total is six.
3. top_share is the most common anchor's count over total, here a third.
4. diversity multiplies unique over total by one minus top_share, printing 0.556.

Try it:

1. Weight branded anchors so they boost the diversity score
2. Use the count distribution's entropy as an alternative score
3. Report which anchor is the dominant one alongside the score
4. Make every anchor identical and watch the score collapse to zero.

⚠ Common Mistakes

- Using unique-over-total alone ignores one anchor that dominates the rest.
- Counting anchors case-sensitively splits `Shoes` and `shoes` into two.
- Dividing by unique anchors rather than total inverts the ratio.

Skills gained anchor diversity scoring Counter

→ Where You'll Use This: A diversity score lets you compare anchor profiles across pages or against competitors, and flags when a link campaign is leaning too hard on one keyword phrase.

Mental Model

A choir of many voices sounds rich; one voice drowning the rest sounds forced. The score rewards the choir and docks the soloist.

Project 394 Find Backlinks Pointing at a 404

The Idea Behind It

A backlink pointing at a page that now returns 404 wastes its equity completely. This project cross-checks each backlink's recorded status code, filters to those that are not 200, and lists the broken ones with their source and target. The wasted-equity total it reports is reclaimable: a redirect on each dead target recovers the lost link power.

What You'll Build & Learn

Find backlinks whose targets return a 404 so their wasted equity can be reclaimed with redirects.

- Backlinks to 404 pages waste equity
- Filtering records by status code
- Equity is reclaimable via redirects

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 393: score anchor-text diversity. Project 395 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find backlinks pointing at a 404 is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.

- Evidence: `print('total wasted:', len(broken))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`broken = [b for b in backlinks if b['status'] != 200]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('total wasted:', len(broken))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `broken = [b for b in backlinks if b['status'] != 200]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Backlinks Pointing at a 404: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, https, com, to, shoes. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: backlinks = [| Core: broken = [b for b in backlinks if b['status'] != 200] | Evidence: print('total wasted:', len(broken))

🛠️ Reader to Writer Bridge

1. Read: explain find backlinks pointing at a 404 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 393.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 395 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total wasted:', len(broken))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find backlinks pointing at a 404 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the backlinks for any non-200 target status surfaces the broken ones whose passed equity is currently lost.

```
backlinks = [
    {'from': 'https://a.com', 'to': '/shoes', 'status': 200},
    {'from': 'https://b.com', 'to': '/old-page', 'status': 404},
    {'from': 'https://c.com', 'to': '/boots', 'status': 200},
    {'from': 'https://d.com', 'to': '/gone', 'status': 404},
]
broken = [b for b in backlinks if b['status'] != 200]
print('broken backlinks (link equity wasted):')
for b in sorted(broken, key=lambda x: x['from']):
    print(f"  {b['from']} -> {b['to']} ({b['status']})")
print('total wasted:', len(broken))
```

```
output
broken backlinks (link equity wasted):
  https://b.com -> /old-page (404)
  https://d.com -> /gone (404)
total wasted: 2
```

How it works:

1. backlinks is a list of dicts each holding from, to, and a status code.
2. broken is a comprehension keeping backlinks whose status is not 200.
3. The broken links print sorted by source URL with their target and status.
4. A final line reports two wasted backlinks pointing at 404 pages.

Try it:

1. Include 410 and 500 statuses as wasted alongside 404
2. Suggest a redirect target for each broken backlink
3. Sum the wasted equity weighted by each source's authority
4. Add a 301 target and decide whether it should count as broken.

⚠ Common Mistakes

- Checking only for 404 misses 410 and 5xx targets that also waste the link.
- Treating a 301 target as broken when it actually still forwards the equity.
- Sorting by status instead of source URL makes the report order unstable.

Skills gained broken backlinks | status codes | filtering

→ Where You'll Use This: Finding backlinks to dead pages is a high-value quick win: a single redirect recovers authority that has been sitting unused, often lifting rankings with no new outreach.

Mental Model

A backlink to a 404 is a cheque written to a closed account. The money is real, but it bounces until you reopen the account with a redirect.

Project 395 Find the Link Gap Versus a Competitor

The Idea Behind It

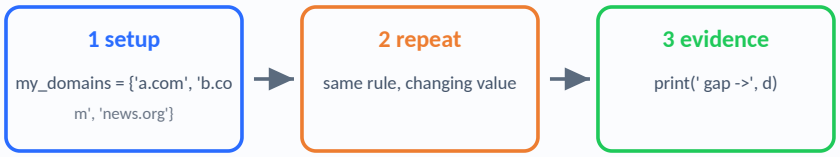
A link-gap analysis lists the domains linking to a competitor but not to you, the most actionable backlink-prospecting output there is. This project models both profiles as sets of domains and uses set subtraction to compute the gap in a single operation. The two domains it surfaces are concrete outreach targets that already link to similar content.

What You'll Build & Learn

Compute the link gap by subtracting your referring domains from a competitor's set.

- Link-gap analysis finds prospect domains
- Set subtraction for the difference
- Gap domains are outreach targets

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 394: find backlinks pointing at a 404. Project 396 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find the link gap versus a competitor is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `my_domains = {'a.com', 'b.com', 'news.org'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(' gap ->', d)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`my_domains = {'a.com', 'b.com', 'news.org'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`for d in sorted(gap):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(' gap ->', d)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for d in sorted(gap):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find the Link Gap Versus a Competitor: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: my_domains, com, news, org, competitor_domains. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: my_domains = {'a.com', 'b.com', 'news.org'} | Core: for d in sorted(gap): | Evidence: print(' gap ->', d)

🛠️ Reader to Writer Bridge

1. Read: explain find the link gap versus a competitor in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 394.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 396 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' gap ->', d)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `my_domains = {'a.com', 'b.com', 'news.org'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find the link gap versus a competitor and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Subtracting your referring-domain set from the competitor's reveals exactly the domains you are missing and could pitch for a link.

```
my_domains = {'a.com', 'b.com', 'news.org'}
competitor_domains = {'a.com', 'news.org', 'forbes.com', 'wired.com', 'b.com'}
gap = competitor_domains - my_domains
print('competitor backlink domains:', len(competitor_domains))
print('domains we are missing:', len(gap))
```

```
    for d in sorted(gap):
        print('  gap ->', d)
```

```
output
competitor backlink domains: 5
domains we are missing: 2
  gap -> forbes.com
  gap -> wired.com
```

How it works:

1. my_domains and competitor_domains are two sets of referring hosts.
2. gap is competitor_domains minus my_domains, the domains they have that you lack.
3. The competitor's total and the gap size print as counts.
4. Each gap domain lists sorted, surfacing forbes.com and wired.com as prospects.

Try it:

1. Compute the gap against several competitors at once and union the results
2. Report the overlap of domains linking to both you and the rival
3. Rank gap domains by an attached DR value before listing
4. Add a domain you both share and confirm it is not in the gap.

⚠ Common Mistakes

- Subtracting in the wrong order returns domains only you have, not the gap.
- Comparing lists instead of sets breaks the subtraction and keeps duplicates.
- Forgetting to sort the gap makes the prospecting list nondeterministic.

Skills gained link gap | set difference | prospecting

→ Where You'll Use This: Link-gap reports drive real outreach plans: a site already linking your rival is far likelier to link you, making the gap list the warmest set of prospects available.

Mental Model

It is a guest list comparison: who came to your rival's party but skipped yours. Those are precisely the people worth inviting next.

Project 396 Band Referring Domains by Domain Rating

The Idea Behind It

Linking domains are not equal; a DR 80 site dwarfs a DR 15 one. This project bands each referring domain into high, mid, or low tiers using simple threshold rules in a band function, then tallies the bands with a Counter.

The resulting shape, two high and two low here, describes the quality profile rather than just the quantity.

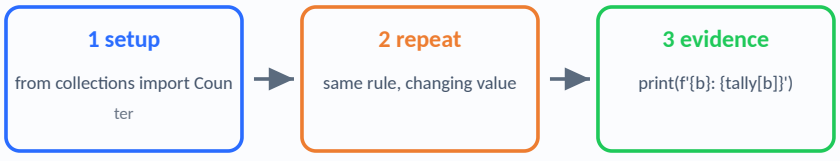
What You'll Build & Learn

Band referring domains into high, mid, and low tiers by domain rating to show profile quality.

- Domain rating reflects link value
- Banding values with threshold rules
- Tallying bands with Counter

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 395: find the link gap versus a competitor. Project 397 changes the surface problem while preserving the underlying method.



progress check

Reading target: band referring domains by domain rating is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{b}: {tally[b]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if dr >= 70:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{b}: {tally[b]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if dr >= 70:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Band Referring Domains by Domain Rating: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, backlinks, domain, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: if dr >= 70: | Evidence: print(f'{b}: {tally[b]}')

🛠️ Reader to Writer Bridge

1. Read: explain band referring domains by domain rating in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 395.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 397 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{b}: {tally[b]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of band referring domains by domain rating and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A small banding function buckets each domain rating into high, mid, or low, and a Counter tallies how the profile's authority is distributed.

```
from collections import Counter

backlinks = [
    {'domain': 'a.com', 'dr': 80},
    {'domain': 'b.com', 'dr': 30},
    {'domain': 'c.com', 'dr': 75},
    {'domain': 'd.com', 'dr': 15},
    {'domain': 'e.com', 'dr': 60},
]
def band(dr):
    if dr >= 70:
        return 'high'
    if dr >= 40:
        return 'mid'
    return 'low'
tally = Counter(band(b['dr']) for b in backlinks)
for b in ('high', 'mid', 'low'):
    print(f'{b}: {tally[b]}')
```

```
output
high: 2
mid: 1
low: 2
```

How it works:

1. backlinks is a list of dicts each with a domain and a dr rating.
2. band returns high at 70 and above, mid at 40 and above, otherwise low.
3. Counter tallies the band of every backlink's rating.
4. The three bands print in a fixed high-mid-low order with their counts.

Try it:

1. Add a fourth elite band for DR 90 and above
2. Weight each band when summing into an overall score
3. Print the actual domains within each band, not just counts
4. Move a band edge to 50 and watch a domain change bands.

⚠ Common Mistakes

- Off-by-one band edges (using `>` instead of `>=`) misfile a domain on the boundary.
- Iterating the Counter for output gives nondeterministic band order.
- Averaging the ratings hides a profile that is all high or all low.

Skills gained domain rating | banding | Counter

→ Where You'll Use This: Banding by DR shows whether your authority comes from a few strong domains or a long tail of weak ones, guiding whether to chase quality or breadth next.

⚡ Mental Model

Sorting links by DR is like grading references by who wrote them. A note from a CEO outweighs ten from strangers, so you band them accordingly.

Project 397 Express PageRank as a Share of Equity

💡 The Idea Behind It

Raw PageRank values are abstract decimals that mean little to a stakeholder. This project runs the full damped PageRank to convergence, then divides each page's rank by the total and multiplies by a hundred to express its equity as a percentage. The same converged numbers become a share-of-equity split that a non-technical audience can immediately grasp.

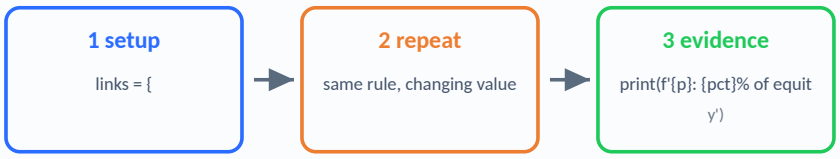
What You'll Build & Learn

Convert converged PageRank values into percentage shares of total equity for easy communication.

- Raw PageRank is hard to interpret
- Normalising rank into a percentage
- Communicating equity to stakeholders

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 396: band referring domains by domain rating. Project 398 changes the surface problem while preserving the underlying method.



progress check

Reading target: express pagerank as a share of equity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f'{p}: {pct}% of equity')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus:

Move	Code to inspect	Why it matters
		model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`rank = {p: 1.0 / N for p in links}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{p}: {pct}% of equity')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `rank = {p: 1.0 / N for p in links}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Express PageRank as a Share of Equity: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: links, home, len, rank, range. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: rank = {p: 1.0 / N for p in links} | Evidence: print(f'{p}: {pct}% of equity')

Reader to Writer Bridge

1. Read: explain express pagerank as a share of equity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 396.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 398 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p}: {pct}% of equity')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of express pagerank as a share of equity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Running the damped power method to convergence then dividing each page's rank by the total turns the stationary vector into readable percentage shares.

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
d = 0.85
rank = {p: 1.0 / N for p in links}
for _ in range(50):
    nxt = {p: (1 - d) / N for p in links}
    for p, outs in links.items():
        share = rank[p] / len(outs)
        for t in outs:
            nxt[t] += d * share
    rank = nxt
total = sum(rank.values())
for p in sorted(rank):
    pct = round(100 * rank[p] / total, 1)
    print(f'{p}: {pct}% of equity')
```

```
output
a: 17.4% of equity
b: 17.4% of equity
c: 33.3% of equity
home: 32.0% of equity
```

How it works:

1. The familiar four-page graph runs damped PageRank for fifty iterations.
2. total sums all converged ranks, expected to be close to one.
3. For each page, pct is 100 times its rank over total, rounded to one place.
4. Output reads as percentages, with c holding 33.3 percent of the equity.

Try it:

1. Render the percentages as a simple text bar chart
2. Print the page holding the largest equity share explicitly
3. Show the percentage change after adding one new internal link
4. Add a link into `a` and watch its equity share rise.

⚠ Common Mistakes

- Dividing by `N` instead of the rank total gives the wrong percentage when ranks vary.
- Reading raw ranks as percentages already, which only holds if they sum to exactly 100.
- Too few iterations reports shares before the ranks have settled.

Skills gained PageRank normalisation reporting

→ Where You'll Use This: Presenting internal authority as percentage shares makes link-structure recommendations land with clients and executives who would glaze over at raw 0.33 figures.

Mental Model

Saying a page has 0.33 PageRank means nothing; saying it holds a third of the site's authority pie makes the slice instantly clear.

Project 398 Pick the Strongest Backlink

The Idea Behind It

When reporting wins or prioritising outreach, the single best backlink is a dofollow link from the highest-authority domain. This project finds it with one max call over a tuple key that ranks dofollow status first, then DR, then domain name for a stable tiebreak. The tuple ordering encodes the priority logic in a single readable line.

What You'll Build & Learn

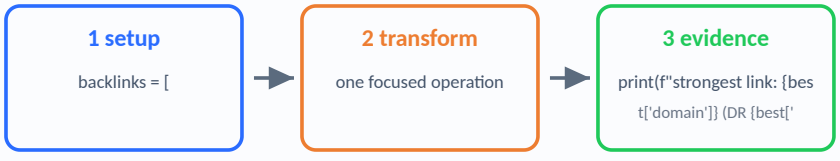
Pick the strongest backlink using a tuple sort that prioritises dofollow then domain rating.

- Strongest link is dofollow and high DR
- Tuple keys for multi-level sorting
- Booleans sort after numbers in a tuple

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 397: express pagerank as a share of equity. Project 399 changes the surface problem while preserving the underlying method.

progress check



Reading target: pick the strongest backlink is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f"strongest link: {best['domain']} (DR {best['dr']}, {best['rel']})")` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`best = max(backlinks, key=lambda b: (b['rel'] == 'dofollow', b['dr'], b['domain']))`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(f"strongest link: {best['domain']} (DR {best['dr']}, {best['rel']})")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `best = max(backlinks, key=lambda b: (b['rel'] == 'dofollow', b['dr'], b['domain']))`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Pick the Strongest Backlink: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: backlinks, domain, com, dr, rel. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: backlinks = [| Core: best = max(backlinks, key=lambda b: (b['rel'] == 'dofollow', b['dr'], b... | Evidence: print(f"strongest link: {best['domain']} (DR {best['dr']}, {best['rel']}...

🛠️ Reader to Writer Bridge

1. Read: explain pick the strongest backlink in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 397.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 399 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"strongest link: {best['domain']} (DR {best['dr']}, {best['rel']})")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `backlinks = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pick the strongest backlink and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `max` keyed on a tuple of `(is dofollow, domain rating, domain)` ranks equity-passing links first, then by rating, with the name as a deterministic tiebreaker.

```
backlinks = [
    {'domain': 'a.com', 'dr': 80, 'rel': 'dofollow'},
    {'domain': 'b.com', 'dr': 20, 'rel': 'nofollow'},
    {'domain': 'c.com', 'dr': 50, 'rel': 'dofollow'},
    {'domain': 'd.com', 'dr': 90, 'rel': 'dofollow'},
]
best = max(backlinks, key=lambda b: (b['rel'] == 'dofollow', b['dr'],
b['domain']))
print(f"strongest link: {best['domain']} (DR {best['dr']}, {best['rel']})")
```

```
output
strongest link: d.com (DR 90, dofollow)
```

How it works:

1. backlinks is four dicts each carrying a domain, a dr, and a rel value.
2. max uses a tuple key of dofollow truth, then dr, then domain name.
3. Python compares the tuples left to right, so dofollow status dominates the choice.
4. The winner d.com prints with its DR 90 and dofollow status.

Try it:

1. Return the top three strongest links instead of just one
2. Penalise toxic-TLD domains so they never win
3. Break DR ties by the freshest link date
4. Make `d.com` nofollow and watch the winner change to `c.com`.

⚠ Common Mistakes

- Keying on domain rating alone could crown a high-DR nofollow link that passes no equity.
- Omitting the domain tiebreaker makes equal-rated links resolve unpredictably.
- Comparing the boolean after the rating lets a strong nofollow link beat a weak dofollow one.

Skills gained best backlink | tuple sort | max

→ Where You'll Use This: Highlighting the single strongest backlink gives reports a clear headline win, and the same priority logic ranks outreach prospects when you can only pursue a few.

⚡ Mental Model

It is picking the trophy reference from a stack: first toss the ones that do not count, then take the most prestigious name remaining.

Project 399 Measure a New Link's PageRank Lift

💡 The Idea Behind It

To prove an internal-linking change actually moved equity, you compute PageRank before and after the change and compare. This project wraps PageRank in a reusable function, runs it on a base graph and a boosted graph that adds one link, then prints each page's rank as a before-and-after delta. The shift in b's rank is the equity the new link moved.

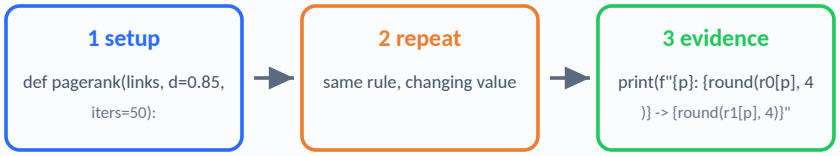
What You'll Build & Learn

Quantify a new link's impact by comparing PageRank before and after the link is added.

- Refactoring PageRank into a function
- A B comparison of two link graphs

- Reading the delta as moved equity

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 398: pick the strongest backlink. Project 400 changes the surface problem while preserving the underlying method. *progress check*

Reading target: measure a new link's pagerank lift is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def pagerank(links, d=0.85, iters=50):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print(f"{p}: {round(r0[p], 4)} -> {round(r1[p], 4)}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def pagerank(links, d=0.85, iters=50):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`share = rank[p] / len(outs) if outs else 0.0`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{p}: {round(r0[p], 4)} -> {round(r1[p], 4)}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `share = rank[p] / len(outs) if outs else 0.0`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Measure a New Link's PageRank Lift: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: pagerank, links, iters, len, rank. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def pagerank(links, d=0.85, iters=50): | Core: share = rank[p] / len(outs) if outs else 0.0 | Evidence: print(f"{p}: {round(r0[p], 4)} -> {round(r1[p], 4)}")

Reader to Writer Bridge

1. Read: explain measure a new link's pagerank lift in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 398.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 400 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{p}: {round(r0[p], 4)} -> {round(r1[p], 4)}")`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `def pagerank(links, d=0.85, iters=50):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure a new link's pagerank lift and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Wrapping the damped power method in a function lets you run it on the base and boosted graphs and print each page's before-to-after rank shift.

```
def pagerank(links, d=0.85, iters=50):
    N = len(links)
    rank = {p: 1.0 / N for p in links}
    for _ in range(iters):
        nxt = {p: (1 - d) / N for p in links}
        for p, outs in links.items():
            share = rank[p] / len(outs) if outs else 0.0
            for t in outs:
                nxt[t] += d * share
        rank = nxt
    return rank

base = {'home': ['a'], 'a': ['home'], 'b': ['home']}
boosted = {'home': ['a'], 'a': ['home', 'b'], 'b': ['home']}
r0 = pagerank(base)
r1 = pagerank(boosted)
for p in sorted(base):
    print(f"{p}: {round(r0[p], 4)} -> {round(r1[p], 4)}")
```

```
output
a: 0.4636 -> 0.3878
b: 0.05 -> 0.2148
home: 0.4864 -> 0.3974
```

How it works:

1. pagerank is a reusable function returning converged ranks for any links dict.
2. base and boosted differ by one link: a now also points at b in boosted.
3. r0 and r1 hold the converged ranks for the two graphs.
4. Each page prints its before-and-after value, with b rising from 0.05 to 0.2148.

Try it:

1. Add several links at once and attribute the total lift
2. Report each page's percentage change rather than the raw delta
3. Test removing a link and confirm the equity flows back
4. Add the new link from `b` instead and compare which placement lifts `b` more.

⚠ Common Mistakes

- Reusing one `rank` dict across both runs leaks the first result into the second.
- Comparing ranks from different iteration counts is not a fair before-and-after.
- Forgetting the dangling guard `if outs` crashes when a node has no out-links.

Skills gained before after | PageRank function | deltas

→ Where You'll Use This: Modelling a link change before shipping it lets you predict and then prove its effect, turning internal-linking work from guesswork into a measured, defensible recommendation.

Mental Model

It is a before-and-after photo for link equity. Lay the two PageRank snapshots side by side and the difference is the change you made.

Project 400 Judge Anchor-Profile Health

The Idea Behind It

Two signals together flag an unnatural backlink profile: an exact-match anchor share that is too high and too few distinct anchors. This project computes both, the exact-match percentage and the unique-anchor ratio, and collects any triggered warnings into a flags list. A non-empty list yields a RISKY verdict with reasons, while a clean one reads HEALTHY.

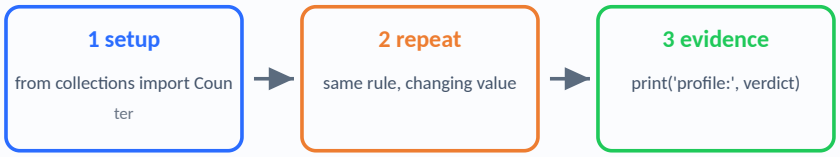
What You'll Build & Learn

Combine exact-match share and anchor uniqueness into one healthy-or-risky profile verdict.

- Two signals combine for a verdict
- Collecting reasons in a flags list
- Building a verdict string from flags

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 399: measure a new link's pagerank lift. Project 401 changes the surface problem while preserving the underlying method.



progress check

Reading target: judge anchor-profile health is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print('profile:', verdict)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`if exact_pct > 30:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('profile:', verdict)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if exact_pct > 30:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Judge Anchor-Profile Health: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, anchors, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import Counter | Core: if exact_pct > 30: | Evidence: print('profile:', verdict)

🛠️ Reader to Writer Bridge

1. Read: explain judge anchor-profile health in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 399.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 401 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('profile:', verdict)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of judge anchor-profile health and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Computing the exact-match percentage and the unique-anchor ratio and testing each against a threshold collects the failing signals into a risk verdict.

```
from collections import Counter

anchors = ['running shoes', 'running shoes', 'running shoes', 'running shoes',
           'Acme', 'click here', 'shop now', 'best shoes']
target = 'running shoes'
total = len(anchors)
exact = Counter(a.lower() for a in anchors)[target]
exact_pct = round(100 * exact / total, 1)
unique = len(set(a.lower() for a in anchors))
flags = []
if exact_pct > 30:
    flags.append('exact-match over-optimised')
if unique / total < 0.5:
    flags.append('low diversity')
verdict = 'HEALTHY' if not flags else 'RISKY: ' + ', '.join(flags)
print(f'exact={exact_pct}% unique={unique}/{total}')
print('profile:', verdict)
```

```
output
exact=50.0% unique=5/8
profile: RISKY: exact-match over-optimised
```

How it works:

1. anchors stacks four exact-match phrases against four varied ones, total eight.
2. exact_pct is the exact-match share and unique is the count of distinct lowercased anchors.
3. Flags append when exact share tops 30 percent or uniqueness falls below half.
4. Because exact is 50 percent, the verdict reads RISKY with the over-optimised reason.

Try it:

1. Add a third flag for an excessive naked-url share
2. Return a numeric risk score alongside the verdict text
3. Make each threshold a tunable parameter of a function

4. Add four distinct anchors and watch the profile flip to HEALTHY.

⚠ Common Mistakes

- Reporting only the exact-match share misses a profile that repeats a branded anchor.
- Using `and` instead of collecting independent flags hides one problem behind the other.
- Counting anchors case-sensitively splits identical phrases and overstates diversity.

Skills gained profile health | multi-signal | verdict

→ Where You'll Use This: A combined health check is what an audit tool reports for a profile, letting you summarise multiple risk factors in one verdict a stakeholder can act on.

⚡ Mental Model

It is a medical checkup reading two vitals at once. Either reading alone might pass, but both off together earns a clear diagnosis.

Project 401 Summarise a Backlink Profile's Vital Signs

💡 The Idea Behind It

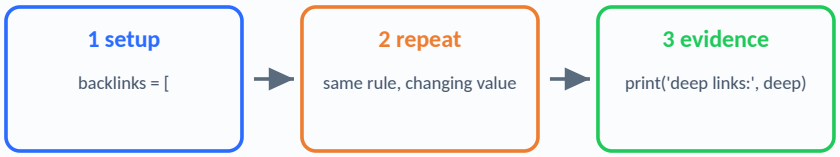
One pass over a backlink fixture should yield the numbers an SEO checks first. This project computes them together: total links, distinct referring domains via a set, dofollow count, toxic links flagged by spammy TLD, and deep links that avoid the homepage. Bundling these vital signs into one readout gives the snapshot you would open a backlink review with.

What You'll Build & Learn

Compute a backlink profile's headline vital signs in a single pass over the fixture.

- Headline backlink metrics in one pass
- Combining set, sum, and TLD checks
- Building a profile snapshot

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 400: judge anchor-profile health. Project 402 changes the surface problem while preserving the underlying method. *progress check*

Reading target: summarise a backlink profile's vital signs is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `backlinks = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print('deep links:', deep)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`backlinks = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('deep links:', deep)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')`

3. Transfer: change one small part of summarise a backlink profile's vital signs and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A handful of comprehensions over the same backlink list extract each headline metric, turning a raw link table into a profile snapshot.

```
backlinks = [
    {'domain': 'a.com', 'dr': 80, 'rel': 'dofollow', 'to': '/shoes'},
    {'domain': 'b.com', 'dr': 20, 'rel': 'nofollow', 'to': '/'},
    {'domain': 'a.com', 'dr': 80, 'rel': 'dofollow', 'to': '/'},
    {'domain': 'spam.xyz', 'dr': 5, 'rel': 'dofollow', 'to': '/shoes'},
    {'domain': 'c.com', 'dr': 60, 'rel': 'dofollow', 'to': '/boots'},
]
spammy = {'xyz', 'tk', 'gq'}
domains = {b['domain'] for b in backlinks}
dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')
toxic = sum(1 for b in backlinks if b['domain'].rsplit('.', 1)[-1] in spammy)
deep = sum(1 for b in backlinks if b['to'] != '/')
print('total backlinks:', len(backlinks))
print('referring domains:', len(domains))
print('dofollow:', dofollow)
print('toxic links:', toxic)
print('deep links:', deep)
```

```
output
total backlinks: 5
referring domains: 4
dofollow: 4
toxic links: 1
deep links: 3
```

How it works:

1. backlinks is five dicts each with a domain, dr, rel, and to path.
2. domains is the set of distinct domains and dofollow sums the equity-passing links.
3. toxic counts links whose TLD is in the spammy set, and deep counts non-root targets.
4. Five labelled lines print total links, domains, dofollow, toxic, and deep counts.

Try it:

1. Add anchor diversity as a sixth vital sign
2. Return the metrics as a dict instead of printing them
3. Compute the dofollow share as a percentage of total

4. Add a backlink from a fifth domain and watch the domain count rise.

⚠ Common Mistakes

- Counting links where you meant referring domains conflates volume with reach.
- Reading the TLD with the wrong split flags clean domains as toxic.
- Treating an empty-path target as deep miscounts the deep-link total.

Skills gained profile snapshot | vital signs | aggregation

→ Where You'll Use This: These five numbers are the top of any backlink dashboard, so a one-pass summary like this is the natural first screen of a monitoring or reporting tool.

Mental Model

It is the patient chart at the foot of the bed: a few key vitals glanced at first to judge whether the profile is healthy.

Project 402 Run a Full Off-Page Authority Audit

The Idea Behind It

This capstone ties the chapter together by running every off-page check on a single backlink fixture. From one list of dicts it derives backlink and referring-domain counts, the dofollow split, toxic links by TLD, anchor diversity via a Counter, and a blended authority score that rewards domains and dofollow while subtracting heavily for toxic links. The printed audit reads like a real report.

What You'll Build & Learn

Run a complete off-page audit that reports every key backlink metric and a blended score at once.

- Combining every off-page metric in one audit
- Penalising toxic links in the score
- Anchor diversity via Counter

Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 401: summarise a backlink profile's vital signs. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full off-page authority audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
- Evidence: `print('authority score:', score)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
2. Apply the rule	`dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('authority score:', score)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Off-Page, Links and Authority becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run a Full Off-Page Authority Audit: connect the surface task to the chapter skill, model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics.
Names	Watch these names first: collections, Counter, backlinks, domain, news. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow') | Evidence: print('authority score:', score)

🛠️ Reader to Writer Bridge

1. Read: explain run a full off-page authority audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 401.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('authority score:', score)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of run a full off-page authority audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Set, sum, and Counter operations over the same backlink records compute every off-page metric at once, then a weighted formula that penalises toxic links yields the headline score.

```
from collections import Counter

backlinks = [
    {'domain': 'news.org', 'dr': 75, 'rel': 'dofollow', 'to': '/shoes',
'anchor': 'running shoes'},
    {'domain': 'blog.com', 'dr': 40, 'rel': 'dofollow', 'to': '/', 'anchor':
'Acme'},
    {'domain': 'spam.xyz', 'dr': 5, 'rel': 'dofollow', 'to': '/shoes',
'anchor': 'cheap pills'},
    {'domain': 'forum.net', 'dr': 30, 'rel': 'nofollow', 'to': '/boots',
'anchor': 'click here'},
    {'domain': 'news.org', 'dr': 75, 'rel': 'dofollow', 'to': '/boots',
'anchor': 'winter boots'},
]
spammy = {'xyz', 'tk', 'gq'}
domains = {b['domain'] for b in backlinks}
dofollow = sum(1 for b in backlinks if b['rel'] == 'dofollow')
toxic = [b for b in backlinks if b['domain'].rsplit('.', 1)[-1] in spammy]
anchors = Counter(b['anchor'].lower() for b in backlinks)
score = len(domains) * 5 + dofollow * 2 - len(toxic) * 10
print('=== Off-Page Audit ===')
print('backlinks:', len(backlinks))
print('referring domains:', len(domains))
print('dofollow/nofollow:', f'{dofollow}/{len(backlinks) - dofollow}')
print('toxic links:', len(toxic))
print('anchor diversity:', f'{len(anchors)}/{len(backlinks)}')
print('authority score:', score)
```

```
output
=== Off-Page Audit ===
backlinks: 5
referring domains: 4
dofollow/nofollow: 4/1
toxic links: 1
anchor diversity: 5/5
authority score: 18
```

How it works:

1. backlinks is five dicts carrying domain, dr, rel, to path, and anchor.

2. domains, dofollow, and toxic are derived as sets and sums, with anchors counted.
3. score adds five per domain and two per dofollow, then subtracts ten per toxic link.
4. A titled block prints backlinks, domains, the dofollow split, toxic, diversity, and the score of 18.

Try it:

1. Add a deep-link ratio line to the audit block
2. Flag the audit as risky when the score drops below zero
3. Export the full audit as a JSON object instead of printed lines
4. Disavow the `spam.xyz` link first and watch the score climb.

⚠ Common Mistakes

- Letting toxic links count toward authority instead of subtracting overstates the score.
- Counting links rather than unique domains lets one site dominate the score.
- Building the anchor Counter without lowercasing splits identical anchors.

Skills gained off-page audit | blended score | reporting

→ Where You'll Use This: A consolidated audit like this is the deliverable a client expects: every signal computed from one dataset and rolled into a single headline authority figure they can track.

Mental Model

It is the full physical, not a single vital. Every test from the chapter runs on one sample and the results print as one chart.

✅ Chapter Progress Checkpoint

What this chapter added: after 32 mini-projects, Off-Page, Links and Authority should feel like a reusable Python move: model internal link equity with a toy pagerank, anchor-text distribution and backlink-profile metrics. *chapter checkpoint*

1 Read
Open any project from Projects 371-402 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 12 (Local and Map SEO) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

9 questions · 4 categories · graded

2 Recall | 2 Meaning | 2 Structure | 3 Transfer

11.1.Q1 Transfer · MEDIUM

Turn back to Project 386 (Apply Google's First-Link-Counts Rule). Without running it, what exactly does it print?

11.1.Q2 Meaning · MEDIUM

Turn back to Project 381 (Score Linking-Domain Diversity). Without running it, what exactly does it print?

11.1.Q3 Structure · MEDIUM

Turn back to Project 398 (Pick the Strongest Backlink). Without running it, what exactly does it print?

11.1.Q4 Transfer · MEDIUM

Turn back to Project 388 (Compute an Authority Score From a Profile). Without running it, what exactly does it print?

11.1.Q5 Recall · EASY

Which backlink profile is strongest, all else equal?

- A. 100 links from 1 domain
- B. 50 links from 2 domains
- C. 20 links from 20 different domains
- D. 200 links from 1 domain

11.1.Q6 Meaning · MEDIUM

In the toy PageRank with damping d = 0.85, why does each iteration seed every page with (1 - d)/N before adding the link flow, and why do the final ranks sum to 1.0?

11.1.Q7 Structure · MEDIUM

A page has rank 0.4 and you increase its out-links from 2 to 4. What happens to the equity each out-link passes (even-split rule)?

- A. Stays 0.2 each
- B. Doubles to 0.4 each
- C. Halves from 0.2 to 0.1 each
- D. Goes to zero

11.1.Q8 Transfer · MEDIUM

Your monitoring shows 80% of a page's backlinks use the exact phrase "running shoes" as anchor text. Why is this a red flag rather than a win?

11.1.Q9 Recall EASY What is the difference between a dofollow and a nofollow link for ranking?

- A Nofollow links are faster to crawl
- B Only dofollow links pass equity (vote); nofollow signals interest but passes no PageRank
- C Nofollow links rank higher
- D They are identical

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 11 – Off-Page, Links and Authority

11.1.Q1. `/boots: counts anchor 'boots'` then `/shoes: counts anchor 'running shoes'`

11.1.Q2. `links=6 unique domains=3 diversity=0.5`

11.1.Q3. `strongest link: d.com (DR 90, dofollow)`

11.1.Q4. `ref domains=4 dofollow links=3` then `authority score=26`

11.1.Q5. C referring domains are independent votes; 20 distinct domains beat any number of links from just one or two sites.

11.1.Q6. The (1 - d)/N term is the 15% "teleport" baseline a random surfer keeps regardless of links, so no page starves; equity is only redistributed, never created or destroyed, so the total is conserved at 1.0.

11.1.Q7. C 0.4 split over 2 links is 0.2 each; split over 4 it is 0.1 each. More out-links dilute every link's share.

11.1.Q8. Natural profiles spread anchors across branded, generic, naked-URL and partial phrases. An 80% exact-match share looks bought/manipulated (over-optimized) and risks a penalty; a ~30% line typically separates natural from suspicious.

11.1.Q9. B dofollow links pass equity and count as votes; nofollow links may drive traffic but do not move PageRank.

Chapter 12 · Local and Map SEO

Check NAP consistency across citations, score local signals, and audit business-profile completeness.

Chapter Skill Map

What this chapter adds: In Local and Map SEO, the focus is check nap consistency across citations, score local signals, and audit business-profile completeness. You practise it across 30 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 12 assumes the reading habits from Chapter 11: Off-Page, Links and Authority. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 13, Log-File and Server Analysis, reuses this chapter's discipline with a new kind of problem.

1 **Projects 403-412**	2 **Projects 413-422**	3 **Projects 423-432**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Local ranking is three forces: relevance × distance × prominence, all resting on one foundation — your NAP being the *same* everywhere. *who you are, how near, how trusted*

When you search "plumber near me" Google does not show ten blue links first — it shows a local pack: a map and three business profiles. Getting into that pack is a different game from ranking a web page. Google answers one question: *of the verified businesses that could serve this searcher, which three are the best match?* It weighs three signals — relevance (does the business do what was asked), distance (how near is it to the searcher), and prominence (how well-known and trusted is it).

All three rest on a quieter foundation: NAP — your business **N**ame, **A**ddress, and **P**hone. Google sees your business not as one record but as dozens of mentions scattered across Yelp, Apple Maps, Facebook, directories, and your own site. These mentions are called citations. When they all state the *same* name, address, and phone, Google is confident they describe one real business and trusts it more. When they drift — "Acme Plumbing" here, "Acme Plumbing Co" there, two different phone numbers — confidence drops and so does ranking.

So the first job of local SEO is mechanical, not creative: prove that every citation says the same thing. The trouble is that humans type the same facts a dozen ways. Before you can compare two citations you must normalize them — strip case, whitespace, and noise down to a canonical form. A phone number is the cleanest example: (415) 555-0199 and +1 415-555-0199 are the same number, so reduce every variant to bare digits and compare those:

```
phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199']
def digits(p):
```

```
    d = ''.join(c for c in p if c.isdigit())
    if len(d) == 11 and d.startswith('1'):
        d = d[1:]          # drop the US country code
    return d
norms = {digits(p) for p in phones}
print('distinct numbers:', len(norms))
```

```
output
distinct numbers: 1
```

Three spellings collapse to one number, so these citations agree. Run the same idea on names (drop "LLC", "Inc") and addresses ("Street" → "St", "North" → "N") and you can diff any two citations field by field. Consistency is something you measure, not something you eyeball — and once it is a number, you can score it, track it, and fix the worst offenders first. *normalize, then compare*

Relevance and prominence then build on top: relevance comes from picking the right business categories and a complete profile; prominence comes from reviews (count, rating, freshness) and from being cited across many kinds of sources. Distance you cannot change — but knowing it explains the pack you compete in.

NAP

Name, Address, Phone — the three core facts that identify a business. Local SEO hinges on these being byte-for-byte identical across every place the business is listed.

CITATION

Any online mention of a business's NAP — a Yelp page, an Apple Maps listing, a directory entry, a chamber-of-commerce page. The more citations agree, the more Google trusts the data.

NAP CONSISTENCY

The share of a business's citations whose NAP exactly matches the canonical record. A core local-SEO health metric: a high percentage signals one trustworthy business, a low one signals confusion.

LOCAL PACK (MAP PACK)

The block of (usually three) business profiles shown on a map at the top of a local-intent search. Appearing here generally requires a verified profile with a rating, reviews, and a category.

RELEVANCE / DISTANCE / PROMINENCE

Google's three stated local-ranking factors. Relevance = does the business match the query; Distance = how near it is to the searcher; Prominence = how well-known and reviewed it is.

GOOGLE BUSINESS PROFILE (GBP)

The business's listing on Google — name, address, phone, hours, categories, description, photos. Completeness and verification of this profile feed relevance and prominence.

Normalize before you compare

You cannot diff two citations until they are written the same way. The canonical form strips everything that is noise: leading/trailing spaces, case, and legal suffixes like "LLC" or "Inc". Only then does "Joe's Coffee House, LLC" line up with "joe's coffee house". This same normalize-then-compare pattern runs through the whole chapter — for names, phones, and addresses alike:

```
name = "  Joe's Coffee House, LLC  "
suffixes = (' llc', ' inc', ' inc.', ' co', ' co.', ' ltd')
norm = name.strip().lower()
for s in suffixes:
    if norm.endswith(s):
        norm = norm[:-len(s)].rstrip(' ,')
        break
print('normalized:', repr(norm))
```

```
output
normalized: "joe's coffee house"
```

Addresses differ only by abbreviation — "North Main Street" versus "N Main St" — so map words to canonical short forms and the two spellings compare equal. Normalization turns "looks the same to a human" into "is equal to a computer."

Score NAP consistency as one number

Per-source diffs tell you *which* field drifted on *which* directory. But you also want one headline figure: what share of your citations exactly match the canonical NAP. That percentage is the metric you report and track over time. Here five directories are checked against the canonical `(name, phone, zip)`:

```
canonical = ('acme plumbing', '4155550199', '94110')
citations = {
    'Yelp':       ('acme plumbing',    '4155550199', '94110'),
    'Bing':       ('acme plumbing',    '4155550199', '94110'),
    'Apple':      ('acme plumbing co', '4155550199', '94110'),  # name drift
```

```
    'Facebook':   ('acme plumbing',    '4155550100', '94110'),  # phone drift
    'Foursquare': ('acme plumbing',    '4155550199', '94110'),
}
consistent = sum(1 for c in citations.values() if c == canonical)
total = len(citations)
print('NAP consistency:', round(100 * consistent / total, 1), '%')
```

```
output
NAP consistency: 60.0 %
```

Three of five match, so consistency is 60%. The two offenders are not random: a stray "co" suffix and a transposed phone digit. Fixing those two listings is the single highest-leverage local-SEO action here — it lifts the headline number and removes the confusion that suppresses ranking.

Relevance: a complete, correctly-categorized profile

Relevance is "does this business do what was asked." Two things drive it: choosing the right `categories` (exactly one *primary*, the rest secondary, all genuinely on-topic) and filling out the profile. A profile with hours, a description, and photos signals a real, relevant business and outranks a bare one. Score completeness by counting filled fields:

```
profile = {'name': 'Acme Plumbing', 'hours': {'mon': '9–5'},
           'categories': ['Plumber'], 'photos': 6,
           'description': '', 'website': 'https://acme.example',
           'phone': '4155550199'}
fields = ['name', 'hours', 'categories', 'photos',
          'description', 'website', 'phone']
missing = [f for f in fields if not profile.get(f)]
print('missing:', missing)
print('completeness:', round(100 * (len(fields) - len(missing)) / len(fields), 1),
'%')
```

```
output
missing: ['description']
completeness: 85.7 %
```

One empty field — the description — caps this profile at 85.7%. A common trap is "improving" relevance by stuffing the *name* with a keyword ("San Francisco Plumber Co"). That is against Google's rules and risks suspension: your name field must be your real name, and an off-topic category like "Coffee Shop" on a plumber actively hurts you.

Prominence: reviews are the loudest signal

Prominence is "how well-known and trusted." For a local business the loudest prominence signal is reviews — and not just the average. Three numbers matter: the `count`, the `average rating`, and the `velocity` (a steady stream of fresh reviews signals an active business). Replying to reviews, especially negative ones, is itself a trust signal:

```
reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5]
n = len(reviews)
```

```
avg = sum(reviews) / n
print('count:', n, '| average:', round(avg, 2), '| stars:', round(avg))
```

```
output
count: 10 | average: 4.2 | stars: 4
```

Ten reviews averaging 4.2 round to a four-star snippet in results. But an average hides shape — a 4.2 made of all 4s and 5s is healthier than a 4.2 with a pile of 1s pulled up by 5s — so a real audit also builds a star-by-star histogram and watches for a *falling* average, which is the earliest warning of a problem.

Distance and the local pack

Distance you cannot edit, but you can compute it. With latitude and longitude you approximate kilometres by flat-earth scaling — degrees times 111 km, with longitude shrunk by the cosine of the latitude — and rank businesses by nearness to the searcher. To even *be* a candidate for the pack, a profile generally needs a rating, enough reviews, a category, and verification:

```
profile = {'rating': 4.5, 'reviews': 27,
           'category': 'Plumber', 'verified': True}
checks = {'has rating': profile['rating'] > 0,
          'has reviews': profile['reviews'] >= 5,
          'has category': bool(profile['category']),
          'verified': profile['verified']}
print('local-pack eligible:', all(checks.values()))
```

```
output
local-pack eligible: True
```

All four gates pass, so this profile is eligible. Real ranking then blends the signals at different weights — NAP consistency, reviews, proximity, completeness, categories — into one composite score. You cannot move distance, so you compete on the levers you *can* move: consistency, completeness, and reviews.

relevance and prominence are the levers; distance is the field

Example 1

Your Yelp listing shows phone "(415) 555-0199" and your Google profile stores "4155550199". A teammate says they mismatch. Are these citations consistent?

SOLUTION

1. Normalize both to bare digits — strip everything that is not a digit. Yelp: "(415) 555-0199" → `4155550199`.
2. Google already stores "4155550199" → `4155550199`. Neither has a leading "1" country code to drop.
3. Compare the canonical forms: 4155550199 == 4155550199.

They are consistent — the phones are identical once normalized.

formatting is not a mismatch; only the digits matter

Example 2

A business is checked against four citations. Three exactly match its canonical NAP and one has a different phone. The owner asks for a single health number. What is the NAP consistency, and what is the fix?

SOLUTION

1. Count the citations whose full NAP matches the canonical record: `3 of 4`.
2. NAP consistency = 100 × consistent / total = 100 × 3 / 4 = `75.0%`.
3. The one offender drifted on the *phone* field, so correct that listing's phone to the canonical number.

NAP consistency is 75.0%; fixing the single mismatched phone restores it toward 100%.

one wrong field on one source measurably lowers the headline metric

Example 3

A plumber's profile has a 4.5 rating, 27 reviews, a "Plumber" category, and is verified — but its name field reads "Cheap #1 Plumber Near Me". Is it local-pack eligible, and is anything wrong?

SOLUTION

1. Run the four eligibility gates: rating > 0 (yes), reviews ≥ 5 (yes), has a category (yes), verified (yes) — all pass, so it is `eligible`.
2. But the name embeds a keyword and a promotional symbol; the real name is not "Cheap #1 Plumber Near Me".
3. A keyword-stuffed name violates Google's naming rules and `risks suspension`, which would remove it from the pack entirely.

Eligible on the four gates, but the stuffed name is a suspension risk — fix the name to the real business name.

eligibility is necessary, not sufficient; rule violations can still pull you

Mental-Math Shortcut

Same facts everywhere, then earn the three R's. First make your Name, Address, Phone *identical* across every citation — normalize and diff, do not eyeball. Then work the levers you control: **R**elevance (right categories, complete profile), p**R**ominence (more, fresher, answered reviews). Distance is the one R you cannot move, so never let a fixable consistency or review problem be the reason you lose to a nearer rival.

⚠ Common Mistakes

- Eyeballing NAP instead of normalizing it — "(415) 555-0199" and "4155550199" look different but are the same number, while "Acme Plumbing" and "Acme Plumbing Co" look the same but are a real mismatch.
- Keyword-stuffing the business name ("San Francisco Plumber Co") or adding off-topic categories ("Coffee Shop" on a plumber) — both violate Google's rules and can get the profile suspended rather than boosted.

- Chasing the average star rating while ignoring review count, velocity, and replies — a stale 5.0 with three reviews loses to an active 4.4 with two hundred answered ones.
- Letting duplicate listings stand — two profiles for one business split the reviews and confuse Google; merge or remove duplicates detected by a normalized (name, phone) key.

This chapter contains 30 hands-on mini-projects (Projects 403–432). Type each one out, run it, and experiment.

Project 403 Normalize a Business Name for Matching

The Idea Behind It

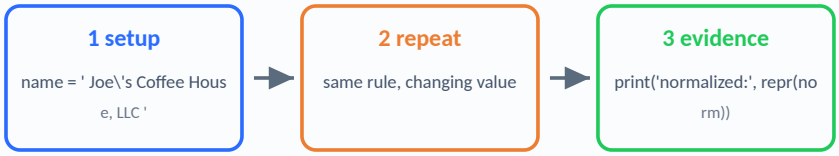
Directories spell the same business a dozen ways, so before any comparison you fold a name to one canonical form. This code lowercases and strips the string, then walks a tuple of legal suffixes and, when the name ends with one, slices it off and trims trailing commas and spaces, turning Joe's Coffee House, LLC into a clean key.

What You'll Build & Learn

Reduce a messy business name to a canonical lowercase form with legal suffixes removed, ready for cross-directory matching.

- String stripping and lowercasing
- Matching with endswith against a tuple
- Slicing and rstrip to drop suffixes

Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 404 changes the surface problem while preserving the underlying method. *progress check*

Reading target: normalize a business name for matching is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `name = ' Joe\'s Coffee House, LLC '` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('normalized:', repr(norm))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`name = ' Joe\'s Coffee House, LLC '`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`if norm.endswith(s):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('normalized:', repr(norm))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if norm.endswith(s):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Normalize a Business Name for Matching: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: name, Joe, Coffee, House, suffixes. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: name = ' Joe\'s Coffee House, LLC ' | Core: if norm.endswith(s): | Evidence: print('normalized:', repr(norm))

🛠️ Reader to Writer Bridge

1. Read: explain normalize a business name for matching in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 404 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('normalized:', repr(norm))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `name = ' Joe\'s Coffee House, LLC '` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize a business name for matching and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Lowercasing, trimming whitespace, and chopping a trailing legal suffix collapses cosmetic variants into one comparable key, which is the basis of every NAP match.

```
name = '  Joe\'s Coffee House, LLC  '
suffixes = (' llc', ' inc', ' inc.', ' co', ' co.', ' ltd')
norm = name.strip().lower()
for s in suffixes:
    if norm.endswith(s):
        norm = norm[:-len(s)].rstrip(' ,')
```

```
        break
print(repr(name.strip()))
print('normalized:', repr(norm))
```

```
output
"Joe's Coffee House, LLC"
normalized: "joe's coffee house"
```

How it works:

1. The raw name carries surrounding spaces, mixed case, and a trailing LLC suffix that must all go before comparison.
2. norm = name.strip().lower() removes outer whitespace and folds case into one baseline.
3. The for loop tests each suffix with endswith, and on a hit slices it away with norm[:-len(s)] then rstrips stray commas and spaces.
4. break stops after the first matching suffix, and the prints show the trimmed original beside the normalized key.

Try it:

1. Add more suffixes such as corp, llp, and pllc to the tuple and confirm each gets stripped.
2. Strip a registered-trademark or copyright symbol from the name before the suffix loop runs.
3. Collapse repeated internal spaces so double spaces between words become one.
4. Add ' corporation' to the suffix tuple and feed in 'Acme Corporation'.

⚠ Common Mistakes

- Checking suffixes before lowercasing means ' LLC' never matches the lowercase ' llc' list.
- Forgetting to `rstrip(' ,')` after slicing leaves a dangling comma like 'joe's coffee house,'.
- Not `break`-ing after the first match could strip two suffixes from a name that ends in two suffix-like words.

Skills gained string normalization | suffix stripping | canonicalization

→ Where You'll Use This: Every citation-cleanup tool starts here: you canonicalize business names so the same listing on Yelp, Bing, and Apple Maps collapses to a single entity you can audit.

Mental Model

Like filing every spelling of a customer's name under one index card so two paperwork piles about the same person finally meet.

Project 404 Normalize a Phone Number to Digits

The Idea Behind It

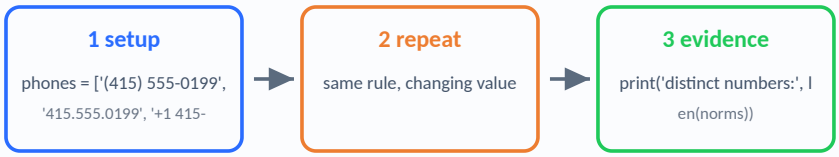
A single phone number wears many costumes: parentheses, dots, a country code, or bare digits. The digits function keeps only characters that pass isdigit, then drops a leading 1 from any eleven-digit result so a US country code does not split otherwise-identical numbers. Feeding every variant through a set proves they collapse to one distinct value.

What You'll Build & Learn

Turn formatted phone strings into bare ten-digit numbers and count how many distinct numbers a list really contains.

- Filtering characters with isdigit
- Stripping a leading country code
- Using a set to count distinct values

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 403: normalize a business name for matching. Project 405 changes the surface problem while preserving the underlying method. *progress check*

Reading target: normalize a phone number to digits is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199', '4155550199']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('distinct numbers:', len(norms))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199', '4155550199']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`d = ''.join(c for c in p if c.isdigit())`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('distinct numbers:', len(norms))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `d = ''.join(c for c in p if c.isdigit())`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Normalize a Phone Number to Digits: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: phones, digits, join, isdigit, len. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199', '4155550... | Core: d = ''.join(c for c in p if c.isdigit()) | Evidence: print('distinct numbers:', len(norms))

🛠️ Reader to Writer Bridge

1. Read: explain normalize a phone number to digits in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 403.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 405 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('distinct numbers:', len(norms))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199', '4155550199']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize a phone number to digits and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Keeping only `isdigit()` characters and trimming a leading US '1' on 11-digit numbers maps every formatting style onto one canonical 10-digit string.

```
phones = ['(415) 555-0199', '415.555.0199', '+1 415-555-0199', '4155550199']
def digits(p):
    d = ''.join(c for c in p if c.isdigit())
    if len(d) == 11 and d.startswith('1'):
        d = d[1:]
    return d
```

```
    norms = {digits(p) for p in phones}
    for p in phones:
        print(f'{p:18} -> {digits(p)}')
    print('distinct numbers:', len(norms))
```

```
output
(415) 555-0199     -> 4155550199
415.555.0199       -> 4155550199
+1 415-555-0199    -> 4155550199
4155550199         -> 4155550199
distinct numbers: 1
```

How it works:

1. The phones list holds four formats of the same number, differing only in punctuation and a country code.
2. digits joins characters where c.isdigit is true, discarding parentheses, dots, plus signs, and spaces.
3. When the result is eleven digits starting with 1, d = d[1:] removes the US country code so it matches the ten-digit forms.
4. A set comprehension over all four strings yields norms, and len(norms) prints 1, confirming every variant is the same number.

Try it:

1. Handle a leading plus and country code longer than one digit, such as a UK or German number.
2. Validate that the cleaned result has exactly ten digits and flag anything shorter as malformed.
3. Format the normalized digits back into a readable parenthesized display string.
4. Add an extension like '4155550199 x12' and decide how to handle the extra digits.

⚠ Common Mistakes

- Stripping the '1' from any 11-digit string would corrupt a real number that legitimately has 11 digits but no country code.
- Using `str.replace` for each separator misses unexpected ones; filtering on `isdigit()` catches them all.
- Comparing the formatted strings instead of the digit forms reports false mismatches.

Skills gained phone normalization | set deduplication | f-string formatting

→ Where You'll Use This: Phone numbers are the P in NAP, and matching them across listings depends on this digit-only canonical form before you ever flag a mismatch in real local-SEO work.

Mental Model

Like wiping the wrapper off a candy so you can tell whether two pieces from different shops are actually the same flavor.

Project 405 Normalize a Street Address

The Idea Behind It

Two addresses can mean one place yet read differently because of abbreviations. The code lowercases the address, replaces commas with spaces, and splits into words, then maps each word through a dictionary that turns street into st, avenue into ave, north into n, and suite into ste. Words absent from the map pass through unchanged via the dict default.

What You'll Build & Learn

Canonicalize a street address by abbreviating common words so two spellings of the same location compare equal.

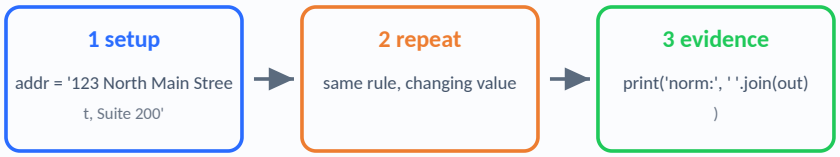
- Tokenizing a string into words
- Dictionary get with a fallback default
- List comprehension to rewrite tokens

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 404: normalize a phone number to digits. Project 406 changes the surface problem while preserving the underlying method.

progress check

Reading target: normalize a street address is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `addr = '123 North Main Street, Suite 200'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('norm:', ' '.join(out))` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`addr = '123 North Main Street, Suite 200'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`out = [repl.get(w, w) for w in parts]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('norm:', ' '.join(out))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `out = [repl.get(w, w) for w in parts]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Normalize a Street Address: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: addr, North, Main, Street, Suite. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: addr = '123 North Main Street, Suite 200' | Core: out = [repl.get(w, w) for w in parts] | Evidence: print('norm:', ' '.join(out))

🛠️ Reader to Writer Bridge

1. Read: explain normalize a street address in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 404.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 406 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('norm:', ' '.join(out))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `addr = '123 North Main Street, Suite 200'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize a street address and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Lowercasing, flattening commas to spaces, and substituting each token through an abbreviation dictionary turns free-form address text into a normalized token stream.

```
addr = '123 North Main Street, Suite 200'
repl = {'street': 'st', 'avenue': 'ave', 'north': 'n', 'suite': 'ste'}
parts = addr.lower().replace(',', ' ').split()
out = [repl.get(w, w) for w in parts]
print('raw: ', addr)
print('norm:', ' '.join(out))
```

```
output
raw:  123 North Main Street, Suite 200
norm: 123 n main st ste 200
```

How it works:

1. repl maps long forms like street and avenue to their short canonical abbreviations.
2. addr.lower().replace(',', ' ').split() lowercases, swaps the comma for a space, and breaks the address into a word list.
3. The comprehension calls repl.get(w, w) on each word, substituting the abbreviation when present and otherwise leaving the word alone.
4. Joining the rewritten tokens prints 123 n main st ste 200 beneath the raw address.

Try it:

1. Extend the repl map with road, boulevard, drive, and their abbreviations and test a new address.
2. Make the mapping case-insensitive while preserving the numeric house number untouched.
3. Add directional suffixes so southwest and northeast also fold to short forms.
4. Add 'road':'rd' and 'boulevard':'blvd' to the replacement map.

⚠ Common Mistakes

- Replacing on the raw string (not per-token) would turn 'streetlight' into 'stlight'.
- Forgetting to drop the comma leaves 'street,' which never matches the 'street' key.
- A one-way map ('street'->'st') will not normalize an address already written as 'st'.

Skills gained address normalization | token mapping | dictionary lookup

→ Where You'll Use This: Address normalization underpins NAP audits and duplicate detection, where North Main Street and N Main St must register as the same address rather than two competing listings.

⚡ Mental Model

Like a translator who rewrites every dialect of an address into one official shorthand the post office recognizes.

Project 406 Compare NAP Across Citations and Flag Mismatches

💡 The Idea Behind It

NAP means Name, Address, Phone, the trio that must agree everywhere you appear. This code holds a canonical record and a dictionary of citations, then for each source builds a sorted list of fields whose value differs from the canonical. An empty list prints match; otherwise it names exactly which fields drifted, so Yelp passes while YellowPages and Facebook each fail one field.

What You'll Build & Learn

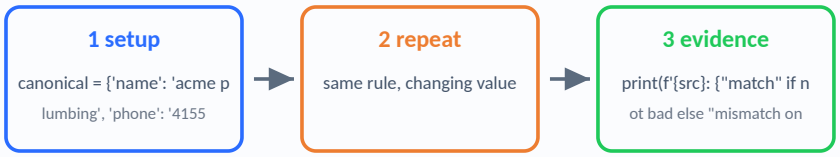
Diff each external citation against a canonical NAP record and report precisely which fields are inconsistent per source.

- Comparing nested dictionaries field by field
- Building a list with a filtered comprehension
- Conditional expression inside a print

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 405: normalize a street address. Project 407 changes the surface problem while preserving the underlying method.

progress check



Reading target: compare nap across citations and flag mismatches is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `canonical = {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94110'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print(f'{src}: {"match" if not bad else "mismatch on " + ",".join(bad)}')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compare NAP Across Citations and Flag Mismatches: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: canonical, name, acme, plumbing, phone. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: canonical = {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94... | Core: bad = sorted(f for f in canonical if c[f] != canonical[f]) | Evidence: print(f'{src}: {"match" if not bad else "mismatch on " + ",".join(bad)}...

🛠️ Reader to Writer Bridge

1. Read: explain compare nap across citations and flag mismatches in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 405.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 407 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{src}: {"match" if not bad else "mismatch on " + ",".join(bad)}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `canonical = {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94110'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare nap across citations and flag mismatches and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Comparing each citation field to the canonical dict and collecting the keys that differ pinpoints the precise NAP fields that need fixing per source.

```
canonical = {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94110'}
citations = {
    'Yelp': {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94110'},
    'YellowPages': {'name': 'acme plumbing co', 'phone': '4155550199', 'zip':
'94110'},
    'Facebook': {'name': 'acme plumbing', 'phone': '4155550100', 'zip':
'94110'},
}
for src, c in citations.items():
    bad = sorted(f for f in canonical if c[f] != canonical[f])
    print(f'{src}: {"match" if not bad else "mismatch on " + ",".join(bad)}')
```

```
output
Yelp: match
YellowPages: mismatch on name
```

```
Facebook: mismatch on phone
```

How it works:

1. canonical defines the source-of-truth name, phone, and zip the listings should match.
2. citations maps three sources to their own NAP dictionaries, with deliberate drift in name and phone.
3. For each source, the comprehension collects sorted field names where c[f] differs from canonical[f].
4. The print emits match when bad is empty, otherwise mismatch on followed by the joined offending field names.

Try it:

1. Add an address field to the canonical and citation records and include it in the diff.
2. Normalize each value with the earlier helpers before comparing so formatting differences are forgiven.
3. Aggregate a count of how many sources mismatched on each individual field.
4. Add an 'address' field to every record and a citation that gets it wrong.

⚠ Common Mistakes

- Printing only 'mismatch' without the field names hides what actually needs fixing.
- Comparing whole dicts with `==` tells you there is a problem but not which field.
- Not sorting the bad-field list makes the message order nondeterministic across runs.

Skills gained NAP diffing | field comparison | mismatch reporting

→ Where You'll Use This: Citation-audit dashboards run exactly this diff across dozens of directories, telling an SEO which listings need editing to bring a clients name, address, and phone back into agreement.

Mental Model

Like proofreading photocopies against a master document, circling on each copy the lines that no longer match the original.

Project 407 Score Overall NAP Consistency

The Idea Behind It

Per-source diffs are useful, but managers want a single headline figure. Here the canonical NAP is a tuple, and each citation is a tuple compared with a plain equality test. Counting how many citations exactly equal the canonical, dividing by the total, and multiplying by one hundred yields a consistency percentage that summarizes overall listing health in one number.

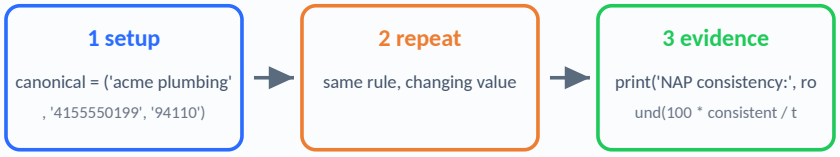
What You'll Build & Learn

Compute the share of citations that exactly match the canonical NAP, producing a single consistency percentage.

- Comparing whole tuples for equality
- Counting matches with sum over a generator
- Converting a ratio to a rounded percentage

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 406: compare nap across citations and flag mismatches. Project 408 changes the surface problem while preserving the underlying method. *progress check*



Reading target: score overall nap consistency is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `canonical = ('acme plumbing', '4155550199', '94110')` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('NAP consistency:', round(100 * consistent / total, 1), '%')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`canonical = ('acme plumbing', '4155550199', '94110')`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`consistent = sum(1 for c in citations.values() if c == canonical)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('NAP consistency:', round(100 * consistent / total, 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `consistent = sum(1 for c in citations.values() if c == canonical)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Overall NAP Consistency: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: canonical, acme, plumbing, citations, Yelp. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: canonical = ('acme plumbing', '4155550199', '94110') | Core: consistent = sum(1 for c in citations.values() if c == canonical) | Evidence: print('NAP consistency:', round(100 * consistent / total, 1), '%')

Reader to Writer Bridge

1. Read: explain score overall nap consistency in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 406.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 408 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('NAP consistency:', round(100 * consistent / total, 1), '%')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `canonical = ('acme plumbing', '4155550199', '94110')` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score overall nap consistency and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

Counting citations whose full NAP tuple equals the canonical tuple, then dividing by the total, yields a single consistency percentage you can track over time.

```
canonical = ('acme plumbing', '4155550199', '94110')
citations = {
    'Yelp': ('acme plumbing', '4155550199', '94110'),
    'Bing': ('acme plumbing', '4155550199', '94110'),
    'Apple': ('acme plumbing co', '4155550199', '94110'),
    'Facebook': ('acme plumbing', '4155550100', '94110'),
    'Foursquare': ('acme plumbing', '4155550199', '94110'),
}
consistent = sum(1 for c in citations.values() if c == canonical)
total = len(citations)
print(f'consistent: {consistent}/{total}')
```

```
print(f'inconsistent: {total - consistent}/{total}')
print('NAP consistency:', round(100 * consistent / total, 1), '%')
```

```
output
consistent: 3/5
inconsistent: 2/5
NAP consistency: 60.0 %
```

How it works:

1. canonical is a three-element tuple of name, phone, and zip used as the reference.
2. citations maps five sources to tuples, two of which differ in name or phone.
3. consistent sums one for every citation tuple equal to canonical, giving three of five.
4. The final prints show consistent and inconsistent counts plus 100 times consistent over total rounded to 60.0 percent.

Try it:

1. Report which specific sources were inconsistent alongside the headline percentage.
2. Award partial credit so a citation matching two of three fields counts as two-thirds.
3. Raise an alert when consistency falls below a configurable threshold such as 80 percent.
4. Add a citation that matches and watch the percentage climb.

⚠ Common Mistakes

- Comparing tuples element-by-element by hand is error-prone; a direct `==` on tuples is exact.
- Dividing integers without `* 100` first can lose precision before the percentage is formed.
- Counting inconsistent as `total - consistent` is right only if every citation is classified once.

Skills gained consistency scoring | tuple equality | percentage math

→ Where You'll Use This: A NAP-consistency percentage is a core local-SEO key metric, tracked over time so an agency can show citation cleanup moving the number from 60 toward 100 percent.

⚡ Mental Model

Like a hygiene grade in a restaurant window: one percentage that distills many inspections into a figure anyone can read at a glance.

Project 408 Score Business-Profile Completeness

💡 The Idea Behind It

A profile stuffed with photos, hours, and a description outranks a skeleton one. This code defines the fields that matter, then splits them into present and missing using truthiness, so an empty description string counts as

missing while a list of categories counts as present. Dividing present by total gives a completeness percentage, here 85.7 with description the only gap.

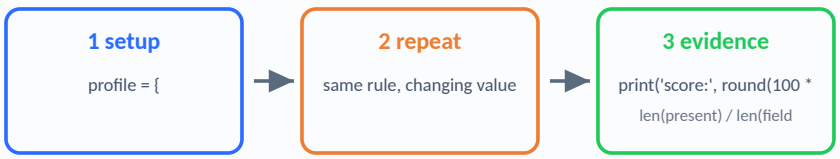
What You'll Build & Learn

Score how complete a business profile is by counting which key fields hold a truthy value.

- Truthiness of strings, lists, and numbers
- Splitting fields into present and missing
- profile.get to read fields safely

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 407: score overall nap consistency. Project 409 changes the surface problem while preserving the underlying method.



progress check

Reading target: score business-profile completeness is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `profile = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('score:', round(100 * len(present) / len(fields), 1), '%')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`profile = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`present = [f for f in fields if profile.get(f)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('score:', round(100 * len(present) / len(fields), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `present = [f for f in fields if profile.get(f)]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Business-Profile Completeness: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: profile, name, Acme, Plumbing, hours. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: profile = { | Core: present = [f for f in fields if profile.get(f)] | Evidence: print('score:', round(100 * len(present) / len(fields), 1), '%')

🛠️ Reader to Writer Bridge

1. Read: explain score business-profile completeness in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 407.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 409 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('score:', round(100 * len(present) / len(fields), 1), '%')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `profile = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score business-profile completeness and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Treating any falsy field (empty string, zero, empty list) as absent and counting the truthy ones over the total field list produces a completeness score.

```
profile = {
    'name': 'Acme Plumbing',
    'hours': {'mon': '9–5'},
    'categories': ['Plumber'],
    'photos': 6,
    'description': '',
    'website': 'https://acme.example',
    'phone': '4155550199',
}
fields = ['name', 'hours', 'categories', 'photos', 'description', 'website',
'phone']
present = [f for f in fields if profile.get(f)]
missing = [f for f in fields if not profile.get(f)]
print('present:', len(present), 'of', len(fields))
print('missing:', missing)
print('score:', round(100 * len(present) / len(fields), 1), '%')
```

```
output
```

```
present: 6 of 7
missing: ['description']
score: 85.7 %
```

How it works:

1. profile holds seven fields, with description set to an empty string that reads as falsy.
2. fields lists the seven keys the score considers.
3. present keeps fields where profile.get(f) is truthy; missing keeps the rest, capturing only description.
4. The prints show six of seven present, the missing list, and 100 times six over seven rounded to 85.7 percent.

Try it:

1. Weight some fields heavier so a missing phone hurts the score more than a missing description.
2. Treat a photos count below a minimum threshold as missing rather than only zero.
3. Print a prioritized to-do list of the missing fields ordered by importance.
4. Fill in the description and watch the score reach 100%.

⚠ Common Mistakes

- Checking `f in profile` instead of `profile.get(f)` counts an empty-string field as present.
- Photos as `0` is falsy and correctly counts as missing; a non-empty list of zero photos would not.
- Hard-coding the denominator instead of `len(fields)` drifts when you add a field.

Skills gained completeness scoring | truthiness filtering | profile auditing

→ Where You'll Use This: Completeness scores drive client recommendations: an agency points to the missing description or empty hours as concrete, fillable gaps that lift a profiles standing in local results.

⚡ Mental Model

Like a checklist taped to a job site where every blank box is a task standing between you and sign-off.

Project 409 Check Category Relevance

💡 The Idea Behind It

Google penalizes business profiles tagged with off-topic categories. The code defines a primary category and a chosen list, then checks each chosen category for membership in an allow-list of relevant ones. Categories outside the set are labeled OFF-TOPIC, the primary is starred, and the off-topic count surfaces stray picks like Coffee Shop sitting on a plumbers profile.

What You'll Build & Learn

Flag categories that fall outside an allow-list of relevant ones and count the off-topic picks on a profile.

- Set membership testing with in
- Tagging items by a condition
- Counting violations with a comprehension

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 408: score business-profile completeness. Project 410 changes the surface problem while preserving the underlying method. *progress check*

Reading target: check category relevance is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `primary = 'Plumber'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('off-topic count:', len(off))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Category Relevance: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: primary, Plumber, chosen, Drain, Cleaning. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: primary = 'Plumber' | Core: tag = 'relevant' if cat in relevant else 'OFF-TOPIC' | Evidence: print('off-topic count:', len(off))

Reader to Writer Bridge

1. Read: explain check category relevance in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 408.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 410 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('off-topic count:', len(off))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `primary = 'Plumber'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check category relevance and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Membership tests against a relevant-category set classify each chosen category, and flagging the primary separately mirrors how the primary category carries the most ranking weight.

```
primary = 'Plumber'
chosen = ['Plumber', 'Drain Cleaning Service', 'Coffee Shop', 'Contractor']
relevant = {'Plumber', 'Drain Cleaning Service', 'Contractor', 'Water Heater
Installation'}
for cat in chosen:
    tag = 'relevant' if cat in relevant else 'OFF-TOPIC'
    star = ' (primary)' if cat == primary else ''
    print(f'{cat}: {tag}{star}')
off = [c for c in chosen if c not in relevant]
print('off-topic count:', len(off))
```

```
output
Plumber: relevant (primary)
Drain Cleaning Service: relevant
Coffee Shop: OFF-TOPIC
Contractor: relevant
off-topic count: 1
```

How it works:

1. primary names the main category, and chosen lists four categories assigned to the profile.
2. relevant is a set of categories considered on-topic for this business.
3. The loop tags each chosen category relevant or OFF-TOPIC by testing cat in relevant, adding a primary star when it matches primary.
4. off collects chosen categories not in relevant, and its length prints an off-topic count of one for Coffee Shop.

Try it:

1. Verify the primary category itself is inside the relevant set and warn if it is not.
2. Suggest relevant categories the profile is missing by diffing chosen against relevant.
3. Load the relevant set from an external list keyed by industry.
4. Add 'Emergency Plumber' to the relevant set and a chosen category to match it.

⚠ Common Mistakes

- Using a list instead of a set for `relevant` makes the membership check O(n) and slower.
- Marking the primary by position instead of by value breaks if the order changes.
- Case-sensitive matching misses 'plumber' versus 'Plumber' unless both sides are normalized.

Skills gained category auditing | allow-list check | relevance scoring

→ Where You'll Use This: Category audits keep profiles compliant: SEOs compare a clients selected categories against a vetted relevant set to remove mismatches that risk a suspension or muddy ranking signals.

Mental Model

Like a bouncer with a guest list: every category on the profile is checked against who belongs, and gatecrashers get flagged.

Project 410 Compute Review Count and Average Rating

The Idea Behind It

The two loudest review signals are how many reviews you have and their average rating. This code takes a list of star ratings, counts them with len, averages with sum over n, and rounds to two places, then rounds again to a whole star. Those numbers feed both the local pack and the star snippet shown in search results.

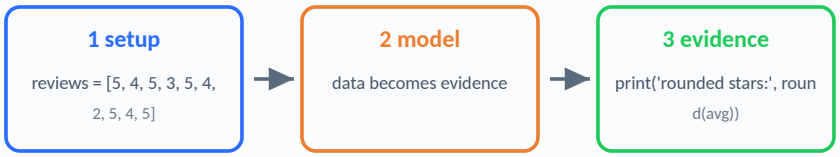
What You'll Build & Learn

Compute the review count, the average star rating, and a rounded whole-star value from a list of ratings.

- Averaging with sum divided by len
- Rounding to a chosen precision
- Distinguishing count from average

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 409: check category relevance. Project 411 changes the surface problem while preserving the underlying method.



progress check

Reading target: compute review count and average rating is the surface task; the transferable Python move is to mark setup, rule, and output before running. setup -> rule -> result

🔎 Logic Lens

- Setup: `reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('rounded stars:', round(avg))` exposes the result; match it against the output before changing the program. output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, model applies the chapter idea, and evidence proves your trace against the output. visual trace

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`print('average rating:', round(avg, 2))`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. slow line
3. Check the evidence	`print('rounded stars:', round(avg))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('average rating:', round(avg, 2))`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Compute Review Count and Average Rating: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: reviews, len, avg, sum, review. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5] | Core: print('average rating:', round(avg, 2)) | Evidence: print('rounded stars:', round(avg))

🛠️ Reader to Writer Bridge

1. Read: explain compute review count and average rating in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 409.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 411 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('rounded stars:', round(avg))`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute review count and average rating and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The count is the list length and the average is the sum over that length; rounding to two places keeps the printed float stable.

```
reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5]
n = len(reviews)
avg = sum(reviews) / n
print('review count:', n)
print('average rating:', round(avg, 2))
print('rounded stars:', round(avg))
```

```
output
review count: 10
average rating: 4.2
rounded stars: 4
```

How it works:

1. reviews is a list of ten integer star ratings.
2. n = len(reviews) captures the review count.
3. avg = sum(reviews) / n computes the mean, which round(avg, 2) trims to 4.2.
4. round(avg) produces the whole-star value of 4 shown as rounded stars.

Try it:

1. Compute the median rating alongside the mean to resist outliers.
2. Weight recent reviews more heavily than old ones in the average.
3. Print the average to one decimal place using an f-string format spec.
4. Add a one-star review and watch the average fall.

⚠ Common Mistakes

- Dividing by a hard-coded count instead of `len(reviews)` breaks when reviews change.
- Printing the raw average gives a long float like 4.2000000001 on some inputs; round it.
- Confusing the rounded star (4) with the precise average (4.2) when displaying.

Skills gained rating average review counting rounding

→ Where You'll Use This: Review count and average rating are the headline figures in any local-SEO scorecard, mirroring the star and review-count badge that Google shows beside a listing in the map pack.

Mental Model

Like reading a thermometer and a crowd headcount at once: one tells you how warm the room feels, the other how full it is.

Project 411 Build a Rating Distribution Histogram

The Idea Behind It

An average hides the shape of opinion, since a 4.2 from all fours and fives differs from a 4.2 spiked with ones. This code uses Counter to tally ratings, then loops stars from five down to one, printing each count and a hash-mark bar of that length. The text histogram exposes the real distribution behind the mean.

What You'll Build & Learn

Build a text histogram of review ratings so the spread of stars is visible, not just the average.

- Tallying values with collections.Counter
- Iterating a descending range
- Drawing a bar by repeating a character

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 410: compute review count and average rating. Project 412 changes the surface problem while preserving the underlying method. *progress check*

Reading target: build a rating distribution histogram is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.

- Evidence: `print('total:', n)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`for star in range(5, 0, -1):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('total:', n)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for star in range(5, 0, -1):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Rating Distribution Histogram: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: collections, Counter, reviews, dist, len. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: for star in range(5, 0, -1): | Evidence: print('total:', n)

🛠️ Reader to Writer Bridge

1. Read: explain build a rating distribution histogram in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 410.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 412 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total:', n)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a rating distribution histogram and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A `Counter` tallies each star value, and iterating from 5 down to 1 prints a fixed-order bar chart that is deterministic regardless of input order.

```
from collections import Counter
reviews = [5, 4, 5, 3, 5, 4, 2, 5, 4, 5, 1, 5]
dist = Counter(reviews)
n = len(reviews)
for star in range(5, 0, -1):
```

```
    c = dist.get(star, 0)
    bar = '#' * c
    print(f'{star}* {c:2} {bar}')
print('total:', n)
```

```
output
5*  6 ######
4*  3 ###
3*  1 #
2*  1 #
1*  1 #
total: 12
```

How it works:

1. Counter(reviews) tallies how many times each star value appears in the twelve-rating list.
2. The loop runs star from 5 down to 1 with range(5, 0, -1).
3. dist.get(star, 0) fetches the count for each star, defaulting to zero when absent.
4. '#' * c builds a bar whose width equals the count, and the f-string aligns the number before printing the total.

Try it:

1. Show the percentage of reviews each star represents next to its bar.
2. Scale the bar so the longest count fits a fixed width regardless of volume.
3. Highlight any star whose count exceeds a concerning threshold.
4. Print the percentage each star represents next to its bar.

⚠ Common Mistakes

- Iterating `dist` directly prints stars in insertion order, not 5-to-1.
- Using `dist[star]` instead of `dist.get(star, 0)` raises nothing but a missing star would be absent if you looped over keys.
- Building bars by string multiplication with a float count would raise a TypeError.

Skills gained rating histogram | Counter tallying | ascii bar chart

→ Where You'll Use This: Distribution histograms help diagnose review health: a fat one-star bar behind a decent average warns an SEO that hidden dissatisfaction could erode trust and click-through over time.

⚡ Mental Model

Like sorting a jar of coins into stacks by denomination so you see at a glance whether it is mostly quarters or pennies.

Project 412 Measure Review Velocity Over Months

The Idea Behind It

A steady drip of fresh reviews signals an active, trusted business. This code stores monthly review counts in a dictionary, sums and averages them, then splits the six months into a first quarter and last quarter, averaging each half. Comparing the two halves labels the trend accelerating or slowing, here climbing from five to ten per month.

What You'll Build & Learn

Measure whether review velocity is accelerating or slowing by comparing the first half of months to the last.

- Reading values from a dict in order
- Slicing a list into halves
- Comparing period averages for a trend

Skill Roadmap

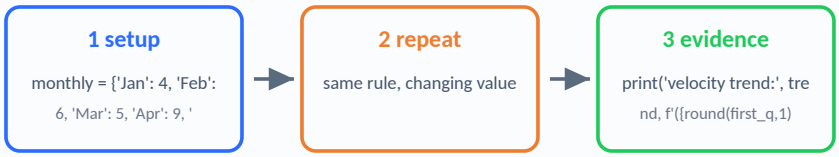
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 411: build a rating distribution histogram. Project 413 changes the surface problem while preserving the underlying method.

progress check

Reading target: measure review velocity over months is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `monthly = {'Jan': 4, 'Feb': 6, 'Mar': 5, 'Apr': 9, 'May': 11, 'Jun': 10}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('velocity trend:', trend, f'({round(first_q,1)} -> {round(last_q,1)})')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`monthly = {'Jan': 4, 'Feb': 6, 'Mar': 5, 'Apr': 9, 'May': 11, 'Jun': 10}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`trend = 'accelerating' if last_q > first_q else 'slowing'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('velocity trend:', trend, f'({round(first_q,1)} -> {round(last_q,1)})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `trend = 'accelerating' if last_q > first_q else 'slowing'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Review Velocity Over Months: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: monthly, Jan, Feb, Mar, Apr. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: monthly = {'Jan': 4, 'Feb': 6, 'Mar': 5, 'Apr': 9, 'May': 11, 'Jun': 10} | Core: trend = 'accelerating' if last_q > first_q else 'slowing' | Evidence: print('velocity trend:', trend, f'({round(first_q,1)} -> {round(last_q,...

🛠️ Reader to Writer Bridge

1. Read: explain measure review velocity over months in one sentence before touching the code; the goal gives the syntax context.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 413 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('velocity trend:', trend, f'({round(first_q,1)} -> {round(last_q,1)})')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `monthly = {'Jan': 4, 'Feb': 6, 'Mar': 5, 'Apr': 9, 'May': 11, 'Jun': 10}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure review velocity over months and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting the monthly counts into two halves and comparing their averages turns raw counts into a simple accelerating-versus-slowing trend.

```
monthly = {'Jan': 4, 'Feb': 6, 'Mar': 5, 'Apr': 9, 'May': 11, 'Jun': 10}
months = list(monthly)
counts = [monthly[m] for m in months]
```

```
total = sum(counts)
avg = total / len(months)
first_q = sum(counts[:3]) / 3
last_q = sum(counts[3:]) / 3
trend = 'accelerating' if last_q > first_q else 'slowing'
print('total reviews:', total)
print('avg per month:', round(avg, 2))
print('velocity trend:', trend, f'({round(first_q,1)} -> {round(last_q,1)})')
```

```
output
total reviews: 45
avg per month: 7.5
velocity trend: accelerating (5.0 -> 10.0)
```

How it works:

1. monthly maps six months to their review counts, and counts pulls those values in order.
2. total and avg give the overall sum and mean per month.
3. first_q averages counts[:3] and last_q averages counts[3:], the two halves of the period.
4. trend reads accelerating when last_q exceeds first_q, and the print shows the 5.0 to 10.0 climb.

Try it:

1. Compute a month-over-month percentage change instead of comparing two halves.
2. Flag any single month whose count drops sharply versus the prior one.
3. Extend to twelve months and compare quarter-by-quarter instead of halves.
4. Add three more months and adjust the quarter split.

⚠ Common Mistakes

- Hard-coding the split index instead of deriving it makes the halves wrong if months change.
- Comparing totals rather than averages would mislead if the halves had different lengths.
- Reading `monthly` order matters: dicts preserve insertion order here, but sorting keys would scramble the timeline.

Skills gained review velocity | trend detection | list slicing

→ Where You'll Use This: Velocity tracking tells an SEO whether a review-generation campaign is working, since a rising fresh-review rate is a freshness signal that supports local-pack ranking.

⚡ Mental Model

Like checking a faucet by watching whether the drips are quickening or trailing off rather than counting the total puddle.

Project 413 Compute Review Respond Rate

The Idea Behind It

Replying to reviews, especially angry ones, is both a trust and a ranking signal. This code holds reviews with a rating and a replied flag, counts overall replies over the total, then isolates reviews rated two or below and computes their reply rate separately. The negative respond rate matters more, and here it reaches a full hundred percent.

What You'll Build & Learn

Compute the overall review respond rate and the more important negative-review respond rate from a list of reviews.

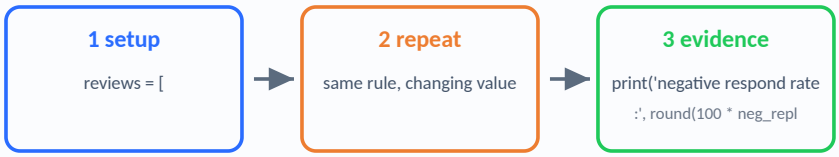
- Counting boolean flags with sum
- Filtering reviews by a rating threshold
- Computing two rates from one list

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 412: measure review velocity over months. Project 414 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute review respond rate is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `reviews = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('negative respond rate:', round(100 * neg_replied / len(neg), 1), '%')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`reviews = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`replied = sum(1 for r in reviews if r['replied'])`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('negative respond rate:', round(100 * neg_replied / len(neg), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `replied = sum(1 for r in reviews if r['replied'])`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Intent	Compute Review Respond Rate: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: reviews, rating, replied, sum, len. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: reviews = [| Core: replied = sum(1 for r in reviews if r['replied']) | Evidence: print('negative respond rate:', round(100 * neg_replied / len(neg), 1),...

🛠️ Reader to Writer Bridge

1. Read: explain compute review respond rate in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 412.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 414 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('negative respond rate:', round(100 * neg_replied / len(neg), 1), '%')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `reviews = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute review respond rate and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting replied reviews over the total gives the overall rate, while filtering to ratings of two or below isolates the negative respond rate that matters most.

```
reviews = [
    {'rating': 5, 'replied': True},
    {'rating': 1, 'replied': True},
    {'rating': 4, 'replied': False},
    {'rating': 2, 'replied': True},
    {'rating': 5, 'replied': False},
```

```
]
replied = sum(1 for r in reviews if r['replied'])
n = len(reviews)
neg = [r for r in reviews if r['rating'] <= 2]
neg_replied = sum(1 for r in neg if r['replied'])
print('overall respond rate:', round(100 * replied / n, 1), '%')
print('negative respond rate:', round(100 * neg_replied / len(neg), 1), '%')
```

```
output
overall respond rate: 60.0 %
negative respond rate: 100.0 %
```

How it works:

1. reviews is a list of dicts each carrying a rating and a replied boolean.
2. replied sums the True flags, and dividing by n yields the overall respond rate of 60 percent.
3. neg filters reviews where rating is two or below, capturing the two negatives.
4. neg_replied counts replies among those, and dividing prints the negative respond rate of 100 percent.

Try it:

1. Add a response-time field and report the average days to reply.
2. Break the respond rate out by star level rather than only negative versus all.
3. Guard against a division error when there are no negative reviews at all.
4. Add an unreplied one-star review and watch the negative rate drop.

⚠ Common Mistakes

- Dividing by `len(reviews)` for the negative rate instead of `len(neg)` understates it badly.
- Treating a missing 'replied' key as False requires `.get`; here every review has it.
- An empty negative list would divide by zero; guard it when data can lack negatives.

Skills gained respond rate | boolean counting | negative filtering

→ Where You'll Use This: Respond-rate metrics shape reputation-management work, where promptly answering one and two-star reviews is the lever an SEO pulls to rebuild trust and signal an engaged owner to Google.

⚡ Mental Model

Like grading a shop on how often it answers the phone, with extra weight on whether it picks up when a customer is upset.

Project 414 Rank Listings by Proximity to the Searcher

💡 The Idea Behind It

Local results lean hard on distance, so you need kilometres from coordinates without a mapping library. This code approximates them with flat-earth scaling: latitude and longitude differences are multiplied by 111 km, with the longitude term shrunk by the cosine of the latitude. Pythagoras combines the legs, and sorting by that distance ranks businesses by nearness to the searcher.

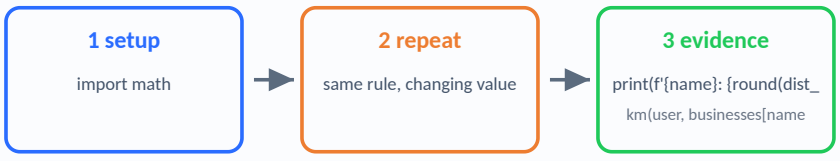
What You'll Build & Learn

Approximate distance in kilometres from latitude and longitude and rank businesses by how near they are.

- Flat-earth degree-to-km scaling
- Cosine correction for longitude
- Sorting with a distance key function

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 413: compute review respond rate. Project 415 changes the surface problem while preserving the underlying method.



progress check

Reading target: rank listings by proximity to the searcher is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import math` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print(f'{name}: {round(dist_km(user, businesses[name]), 2)} km')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import math`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`for name in sorted(businesses, key=lambda n: dist_km(user, businesses[n])):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{name}: {round(dist_km(user, businesses[name]), 2)} km')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for name in sorted(businesses, key=lambda n: dist_km(user, businesses[n])):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Rank Listings by Proximity to the Searcher: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: math, user, businesses, dist_km, dlat. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.

Layer	What to read
Evidence	Entry: import math | Core: for name in sorted(businesses, key=lambda n: dist_km(user, businesses[n... | Evidence: print(f'{name}: {round(dist_km(user, businesses[name]), 2)} km')

🛠️ Reader to Writer Bridge

1. Read: explain rank listings by proximity to the searcher in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 413.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 415 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {round(dist_km(user, businesses[name]), 2)} km')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import math` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank listings by proximity to the searcher and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Scaling latitude and longitude deltas to kilometres and taking the Euclidean distance gives a fast proximity estimate, accurate enough for local ranking over short spans.

```
import math
user = (37.7749, -122.4194)
businesses = {
    'A': (37.7750, -122.4180),
    'B': (37.8044, -122.2712),
    'C': (37.7849, -122.4094),
}
def dist_km(a, b):
    dlat = (a[0] - b[0]) * 111.0
    dlon = (a[1] - b[1]) * 111.0 * math.cos(math.radians(a[0]))
    return math.sqrt(dlat * dlat + dlon * dlon)
```

```
    for name in sorted(businesses, key=lambda n: dist_km(user, businesses[n])):
        print(f'{name}: {round(dist_km(user, businesses[name]), 2)} km')
```

```
output
A: 0.12 km
C: 1.41 km
B: 13.41 km
```

How it works:

1. user holds the searchers coordinates, and businesses maps three names to their own coordinates.
2. dist_km scales the latitude gap by 111 km and the longitude gap by 111 times the cosine of the latitude.
3. math.sqrt of the squared legs gives the planar distance in kilometres.
4. sorted orders names by dist_km, printing A nearest at 0.12 km and B farthest at 13.41 km.

Try it:

1. Replace the flat-earth math with the full haversine formula and compare results.
2. Filter out businesses beyond a service radius before ranking the rest.
3. Return distances in miles by adjusting the per-degree constant.
4. Move the user's point and watch the ranking reshuffle.

⚠ Common Mistakes

- Forgetting the `cos(lat)` longitude correction overstates east-west distance away from the equator.
- Using raw degree differences as if they were kilometres mixes units entirely.
- Sorting by `dist_km` recomputes it per comparison; caching distances first is cheaper on big lists.

Skills gained proximity ranking | geo distance math | key-based sorting

→ Where You'll Use This: Distance estimation explains the proximity factor in local ranking, letting an SEO model why a nearer competitor outranks a stronger but farther one for a given searchers location.

⚡ Mental Model

Like measuring a city map with a ruler and a fudge factor rather than walking every street with an odometer.

Project 415 Check Local-Pack Eligibility

💡 The Idea Behind It

To surface in the map pack a profile generally needs a rating, enough reviews, a category, and verification. This code packs those four conditions into a checks dictionary of booleans, prints each as yes or no, then folds them with all so eligibility is True only when every gate passes. It reproduces the eligibility screen in a few lines.

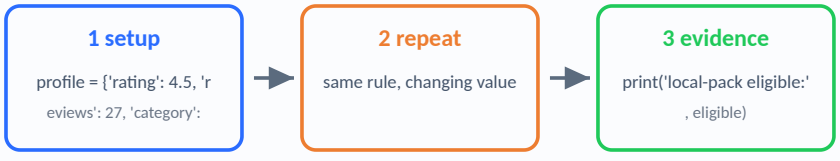
What You'll Build & Learn

Reproduce a local-pack eligibility check by requiring a rating, enough reviews, a category, and verification.

- Building a dict of boolean checks
- Combining conditions with all
- Threshold comparison on a count

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 414: rank listings by proximity to the searcher. Project 416 changes the surface problem while preserving the underlying method.



progress check

Reading target: check local-pack eligibility is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `profile = {'rating': 4.5, 'reviews': 27, 'category': 'Plumber', 'verified': True}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('local-pack eligible:', eligible)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`profile = {'rating': 4.5, 'reviews': 27, 'category': 'Plumber', 'verified': True}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`print(f'{label}: {"yes" if ok else "no"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('local-pack eligible:', eligible)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{label}: {"yes" if ok else "no"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Local-Pack Eligibility: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: profile, rating, reviews, category, Plumber. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: profile = {'rating': 4.5, 'reviews': 27, 'category': 'Plumber', 'verifi... | Core: print(f'{label}: {"yes" if ok else "no"}') | Evidence: print('local-pack eligible:', eligible)

Reader to Writer Bridge

1. Read: explain check local-pack eligibility in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 414.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 416 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('local-pack eligible:', eligible)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `profile = {'rating': 4.5, 'reviews': 27, 'category': 'Plumber', 'verified': True}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check local-pack eligibility and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Building a dict of named boolean checks makes the verdict transparent (you can print each one) and `all(...)` collapses them into a single eligibility decision.

```
profile = {'rating': 4.5, 'reviews': 27, 'category': 'Plumber', 'verified':
True}
checks = {
    'has rating': profile['rating'] > 0,
    'has reviews': profile['reviews'] >= 5,
    'has category': bool(profile['category']),
    'verified': profile['verified'],
}
for label, ok in checks.items():
    print(f'{label}: {"yes" if ok else "no"}')
eligible = all(checks.values())
print('local-pack eligible:', eligible)
```

```
output
has rating: yes
has reviews: yes
has category: yes
verified: yes
local-pack eligible: True
```

How it works:

1. profile holds a rating, review count, category, and verified flag.
2. checks maps four labels to boolean expressions, including reviews greater than or equal to five.
3. The loop prints each check as yes or no based on its boolean value.
4. all(checks.values()) is True only when every gate passes, so eligible prints True here.

Try it:

1. Add a checks entry requiring a complete address and re-evaluate eligibility.
2. Report which specific gates failed instead of only a single True or False.
3. Make the minimum review count configurable rather than hard-coded at five.
4. Drop the review count below the threshold and watch eligibility fail.

⚠ Common Mistakes

- Using `or` instead of `all` would pass a profile that meets just one condition.
- A reviews threshold of `> 0` is too lax; the pack favours a minimum like five.
- Treating `rating == 0` as valid lets an unrated profile slip through.

Skills gained eligibility gating | boolean aggregation | threshold check

→ Where You'll Use This: Eligibility gating mirrors the prerequisites Google effectively enforces for map-pack inclusion, helping an SEO confirm a new profile clears the basics before chasing finer ranking factors.

⚡ Mental Model

Like a ride-height bar at a theme park: you only get on when every requirement is cleared at once, not most of them.

Project 416 Detect Duplicate Listings

💡 The Idea Behind It

Duplicate profiles split reviews and confuse Google about which listing is real. This code groups listings by a key of their name and phone using setdefault to collect row indices, then keeps only keys appearing more than once. Because acme plumbing co normalizes differently, only the two identical acme plumbing rows surface as a duplicate pair.

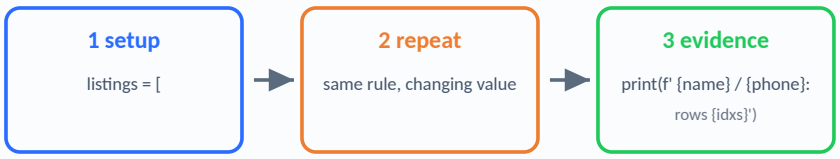
What You'll Build & Learn

Surface duplicate listings by grouping rows under a name-and-phone key and reporting keys with more than one row.

- Grouping with dict setdefault

- Tracking row indices during a loop
- Filtering groups by size

🧭 Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 415: check local-pack eligibility. Project 417 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect duplicate listings is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `listings = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print(f' {name} / {phone}: rows {idxs}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`listings = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`dups = {k: v for k, v in seen.items() if len(v) > 1}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f' {name} / {phone}: rows {idxs}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dups = {k: v for k, v in seen.items() if len(v) > 1}`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Duplicate Listings: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: listings, name, acme, plumbing, phone. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: listings = [| Core: dups = {k: v for k, v in seen.items() if len(v) > 1} | Evidence: print(f' {name} / {phone}: rows {idxs}')

Reader to Writer Bridge

1. Read: explain detect duplicate listings in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 415.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 417 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f' {name} / {phone}: rows {idxs}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `listings = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect duplicate listings and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Using `setdefault` to bucket row indices under each (name, phone) key, then keeping buckets of length over one, reveals exactly which listings duplicate each other.

```
listings = [
    {'name': 'acme plumbing', 'phone': '4155550199'},
    {'name': 'acme plumbing', 'phone': '4155550199'},
    {'name': 'acme plumbing co', 'phone': '4155550199'},
    {'name': 'bobs cafe', 'phone': '4155550111'},
]
seen = {}
for i, l in enumerate(listings):
    key = (l['name'], l['phone'])
    seen.setdefault(key, []).append(i)
dups = {k: v for k, v in seen.items() if len(v) > 1}
print('duplicate listings:')
for (name, phone), idxs in sorted(dups.items()):
    print(f'  {name} / {phone}: rows {idxs}')
```

```
output
duplicate listings:
  acme plumbing / 4155550199: rows [0, 1]
```

How it works:

1. listings is a list of four dicts, two of which share the exact same name and phone.
2. The enumerate loop builds a key tuple of name and phone and appends each row index via seen.setdefault(key, []).
3. dups keeps only keys whose index list has more than one entry.
4. The sorted print shows acme plumbing at 4155550199 occupying rows 0 and 1.

Try it:

1. Normalize the name and phone with the earlier helpers before keying so near-duplicates also group.
2. Key on name and address instead of phone and compare which finds more duplicates.
3. Print a total count of duplicate groups and the rows involved.
4. Normalize the name first so the 'co' suffix row joins the duplicate group.

⚠ Common Mistakes

- Keying on the raw dict (unhashable) instead of a tuple raises a TypeError.
- Not normalizing 'acme plumbing co' first means a real duplicate with a suffix is missed.
- Reporting any repeated name alone would merge two genuinely different businesses sharing a name.

Skills gained duplicate detection | dict grouping | key building

→ Where You'll Use This: Duplicate detection is a staple of listing cleanup, where an SEO finds and merges redundant profiles so reviews and signals consolidate onto one canonical listing rather than scattering.

Mental Model

Like sorting mail into pigeonholes by recipient, then flagging any slot that ended up with two letters for the same person.

Project 417 Define and Audit a Service Area

The Idea Behind It

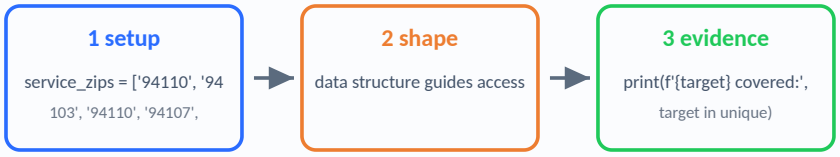
Service-area businesses declare the zip codes they cover instead of a storefront. This code takes a list with duplicate zips, dedupes it into a sorted set, reports the declared versus unique counts, and tests whether a target zip is a member. Membership confirms 94107 sits inside the declared area while exposing that two declared entries were repeats.

What You'll Build & Learn

Dedupe a service-area zip list and test whether a target zip falls inside the declared coverage.

- Deduplicating with set
- Sorting unique values
- Membership testing with in

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 416: detect duplicate listings. Project 418 changes the surface problem while preserving the underlying method. *progress check*

Reading target: define and audit a service area is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `service_zips = ['94110', '94103', '94110', '94107', '94103']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The data structure is doing part of the thinking. Ask what the collection stores, how items are found, and what order or uniqueness it promises.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print(f'{target} covered:', target in unique)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, shape applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`service_zips = ['94110', '94103', '94110', '94107', '94103']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`target = '94107'`	This line depends on the chosen data shape. Ask how items are stored, found, or ordered. *slow line*
3. Check the evidence	`print(f'{target} covered:', target in unique)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `target = '94107'`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Name the collection shape, then ask how an item is added, selected, transformed, or counted.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Define and Audit a Service Area: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: service_zips, target, unique, sorted, declared. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: service_zips = ['94110', '94103', '94110', '94107', '94103'] | Core: target = '94107' | Evidence: print(f'{target} covered:', target in unique)

🛠️ Reader to Writer Bridge

1. Read: explain define and audit a service area in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 416.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 418 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{target} covered:', target in unique)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `service_zips = ['94110', '94103', '94110', '94107', '94103']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of define and audit a service area and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `set` removes accidental duplicate zips, `sorted` makes the printed list deterministic, and an `in` test answers coverage for any target zip.

```
service_zips = ['94110', '94103', '94110', '94107', '94103']
target = '94107'
unique = sorted(set(service_zips))
print('declared zips:', len(service_zips))
print('unique zips:', unique)
print('count:', len(unique))
print(f'{target} covered:', target in unique)
```

```
output
declared zips: 5
unique zips: ['94103', '94107', '94110']
count: 3
94107 covered: True
```

How it works:

1. service_zips lists five declared zips, with 94110 and 94103 each appearing twice.
2. unique = sorted(set(service_zips)) collapses duplicates and orders the result.
3. The prints show the declared count of five against the unique count of three.
4. target in unique tests membership, printing that 94107 is covered as True.

Try it:

1. Report which declared zips were duplicates rather than only the counts.
2. Test a list of target zips at once and print coverage for each.
3. Flag a service area that declares far more zips than is realistic.
4. Add a zip outside the area and test a target that is not covered.

⚠ Common Mistakes

- Counting `len(service_zips)` as the coverage size double-counts the repeated zips.
- Printing the set unsorted gives a nondeterministic order.
- Comparing zips as integers drops a leading zero like '07030'.

Skills gained service-area audit set dedup membership test

→ Where You'll Use This: Service-area auditing supports plumbers, electricians, and other no-storefront businesses, letting an SEO verify a clients declared zips actually cover the neighborhoods they want to rank in.

Mental Model

Like checking a pizza delivery map: you collapse the scribbled-over streets into a clean boundary and ask whether one address falls inside it.

Project 418 Parse and Validate Opening Hours

The Idea Behind It

Opening hours like 09:00-17:00 must parse into an open and a close time, and close must come after open. This code loops the hours dict, prints closed days outright, otherwise splits the range on the dash and tests whether the open string sorts before the close string. The inverted Friday range 18:00-09:00 is correctly flagged invalid.

What You'll Build & Learn

Parse each days opening hours into open and close times and flag any range where close precedes open.

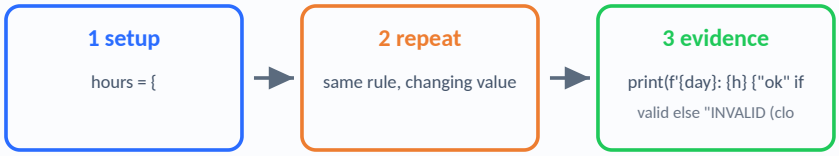
- Splitting a string on a delimiter
- Skipping with continue on a sentinel
- Lexicographic time comparison

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 417: define and audit a service area. Project 419 changes the surface problem while preserving the underlying method.

progress check

Reading target: parse and validate opening hours is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `hours = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.

- Evidence: `print(f'{day}: {h} {"ok" if valid else "INVALID (close before open)"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`hours = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`if h == 'closed':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{day}: {h} {"ok" if valid else "INVALID (close before open)"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Parse and Validate Opening Hours: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: hours, mon, tue, wed, closed. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: hours = { | Core: if h == 'closed': | Evidence: print(f'{day}: {h} {"ok" if valid else "INVALID (close before open)"}')

🛠️ Reader to Writer Bridge

1. Read: explain parse and validate opening hours in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 417.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 419 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{day}: {h} {"ok" if valid else "INVALID (close before open)"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `hours = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse and validate opening hours and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting each range on the dash and comparing the zero-padded time strings lexically (which equals chronological order for HH:MM) validates the interval without parsing to numbers.

```
hours = {
    'mon': '09:00-17:00',
    'tue': '09:00-17:00',
    'wed': 'closed',
    'thu': '09:00-12:00',
    'fri': '18:00-09:00',
}
for day, h in hours.items():
    if h == 'closed':
        print(f'{day}: closed')
        continue
    o, c = h.split('-')
    valid = o < c
    print(f'{day}: {h} {"ok" if valid else "INVALID (close before open)"}')
```

```
output
mon: 09:00-17:00 ok
tue: 09:00-17:00 ok
wed: closed
thu: 09:00-12:00 ok
fri: 18:00-09:00 INVALID (close before open)
```

How it works:

1. hours maps weekdays to time ranges, with wed marked closed and fri inverted.
2. When h equals closed the code prints closed and continues to the next day.
3. o, c = h.split('-') breaks the range into open and close strings.
4. valid = o < c compares them lexicographically, so the 18:00-09:00 Friday range prints INVALID.

Try it:

1. Detect overnight hours such as 22:00-02:00 and treat them as valid rather than inverted.
2. Parse the times into minutes and reject malformed strings that lack a colon.
3. Support split shifts where a day has a morning and an afternoon range.
4. Support an overnight shift by allowing close < open when a wrap flag is set.

⚠ Common Mistakes

- String comparison only works because times are zero-padded; '9:00' would sort wrong against '17:00'.
- Treating 'closed' as a range to split raises a ValueError without the early `continue`.
- An overnight span like 18:00-09:00 is flagged invalid here, which is correct unless you model wraparound.

Skills gained hours validation string splitting range checking

→ Where You'll Use This: Hours validation catches data-entry errors that mislead customers and search engines, a routine check when an SEO imports or audits opening times across many local listings.

Mental Model

Like checking a shift roster for a clock-out written before the clock-in, an obvious mistake that the comparison catches instantly.

Project 419 Detect a Profile Closed All Week

The Idea Behind It

A profile where every day reads closed is almost always a mistake that quietly tanks visibility. This code builds a list of days whose hours are not closed, and when that open-days list is empty it prints a warning; otherwise it lists the open days. The all-closed example yields an open-day count of zero and raises the alarm.

What You'll Build & Learn

Detect a business marked closed on every day and warn when no open days remain.

- Filtering a dict by value
- Truthiness of an empty list
- Branching on a guard condition

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 418: parse and validate opening hours. Project 420 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a profile closed all week is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `hours = {'mon': 'closed', 'tue': 'closed', 'wed': 'closed',` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.

- Evidence: `print('open day count:', len(open_days))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`hours = {'mon': 'closed', 'tue': 'closed', 'wed': 'closed',`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`open_days = [d for d, h in hours.items() if h != 'closed']`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('open day count:', len(open_days))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `open_days = [d for d, h in hours.items() if h != 'closed']`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Profile Closed All Week: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: hours, mon, closed, tue, wed. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: hours = {'mon': 'closed', 'tue': 'closed', 'wed': 'closed', | Core: open_days = [d for d, h in hours.items() if h != 'closed'] | Evidence: print('open day count:', len(open_days))

🛠️ Reader to Writer Bridge

1. Read: explain detect a profile closed all week in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 418.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 420 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('open day count:', len(open_days))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `hours = {'mon': 'closed', 'tue': 'closed', 'wed': 'closed',` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a profile closed all week and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Filtering the days whose value is not 'closed' yields the open days; an empty result means the business looks permanently closed and needs review.

```
hours = {'mon': 'closed', 'tue': 'closed', 'wed': 'closed',
         'thu': 'closed', 'fri': 'closed', 'sat': 'closed', 'sun': 'closed'}
open_days = [d for d, h in hours.items() if h != 'closed']
if not open_days:
    print('WARNING: business marked closed all week')
```

```
else:
    print('open days:', open_days)
print('open day count:', len(open_days))
```

```
output
WARNING: business marked closed all week
open day count: 0
```

How it works:

1. hours marks all seven days as closed.
2. open_days collects days where the value is not closed, leaving the list empty here.
3. if not open_days is True for the empty list, so the WARNING about being closed all week prints.
4. The final line reports an open-day count of zero.

Try it:

1. Warn when fewer than a minimum number of days are open, not only zero.
2. List the closed days when at least one day is open as a softer notice.
3. Distinguish a permanently closed marker from temporary holiday closures.
4. Open the business on one day and confirm the warning disappears.

⚠ Common Mistakes

- Checking `if open_days == []` works but `if not open_days` is the idiomatic empty test.
- Comparing to the string 'Closed' (capitalized) misses lowercase 'closed' values.
- Counting 'closed' days instead of open days inverts the logic.

Skills gained closed-week detection | value filtering | guard clause

→ Where You'll Use This: This guard catches a damaging configuration error during a profile audit, since an accidentally all-closed listing tells searchers the business is shut and suppresses it in local results.

Mental Model

Like spotting a shop whose sign reads closed every day of the week, a clear signal the sign itself is wrong.

Project 420 Audit Google Business Profile Fields

The Idea Behind It

A Google Business Profile has a known roster of fillable fields. This code lists the required ones, then builds a missing list of any field whose value is falsy, so an empty website string and a zero photos count both register

as gaps. Subtracting missing from the total and scaling to a percentage gives the 75 percent completeness at the heart of a GBP audit.

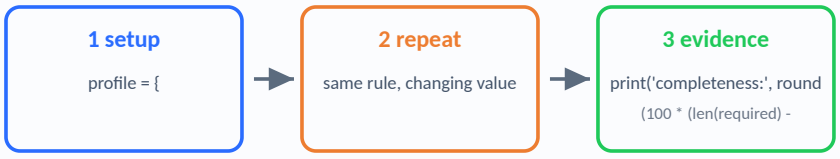
What You'll Build & Learn

Audit a Google Business Profile by listing empty required fields and scoring overall completeness.

- Defining a required-field list
- Detecting falsy values including zero
- Scoring completeness as a percentage

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 419: detect a profile closed all week. Project 421 changes the surface problem while preserving the underlying method.



progress check

Reading target: audit google business profile fields is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `profile = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('completeness:', round(100 * (len(required) - len(missing)) / len(required), 1), '%')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`profile = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`missing = [f for f in required if not profile.get(f)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('completeness:', round(100 * (len(required) - len(missing)) / len(required), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Audit Google Business Profile Fields: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: profile, name, Acme, Plumbing, address. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: profile = { | Core: missing = [f for f in required if not profile.get(f)] | Evidence: print('completeness:', round(100 * (len(required) - len(missing)) / len...

🛠️ Reader to Writer Bridge

1. Read: explain audit google business profile fields in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 419.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 421 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('completeness:', round(100 * (len(required) - len(missing)) / len(required), 1), '%')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `profile = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of audit google business profile fields and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Iterating the required fields and collecting those whose value is falsy produces a missing-field list and a completeness percentage in one pass.

```
profile = {
    'name': 'Acme Plumbing',
    'address': '123 Main St',
    'phone': '4155550199',
    'website': '',
    'hours': {'mon': '9–5'},
    'primary_category': 'Plumber',
    'description': 'Trusted plumbing.',
    'photos': 0,
}
required = ['name', 'address', 'phone', 'website', 'hours',
            'primary_category', 'description', 'photos']
missing = [f for f in required if not profile.get(f)]
print('GBP audit')
print('missing fields:', missing)
print('completeness:', round(100 * (len(required) - len(missing)) /
len(required), 1), '%')
```

```
output
GBP audit
missing fields: ['website', 'photos']
completeness: 75.0 %
```

How it works:

1. profile holds eight fields, with website an empty string and photos a zero.
2. required names the eight fields the audit expects to be filled.
3. missing keeps fields where profile.get(f) is falsy, capturing website and photos.
4. The completeness print scales required minus missing over required to 75.0 percent.

Try it:

1. Separate truly required fields from optional ones and score them differently.
2. Treat a photos count below three as incomplete rather than only zero.
3. Emit the audit as a structured dict suitable for a report rather than prints.
4. Add a 'service_area' field and mark it missing.

⚠ Common Mistakes

- An empty string website and zero photos are both falsy and correctly flagged as missing.
- Using `profile[f]` instead of `profile.get(f)` raises if a field is absent entirely.
- Counting present as `len(required) - len(missing)` assumes no field appears twice in the list.

Skills gained GBP audit | falsy detection | completeness percentage

→ Where You'll Use This: GBP audits are bread-and-butter local-SEO deliverables, where the list of empty fields and a completeness score become the action items handed to a client to strengthen their profile.

⚡ Mental Model

Like a building inspectors clipboard: every unchecked box on the required list is a defect the owner must remedy before approval.

Project 421 Detect a Map Embed on the Contact Page

💡 The Idea Behind It

Embedding a Google map on a contact page reinforces location relevance. This code runs a regex over the HTML to capture every iframe src, then checks with any whether one contains maps. The single iframe pointing at a google.com/maps/embed URL makes has_map True, and the source is printed truncated to its first forty characters.

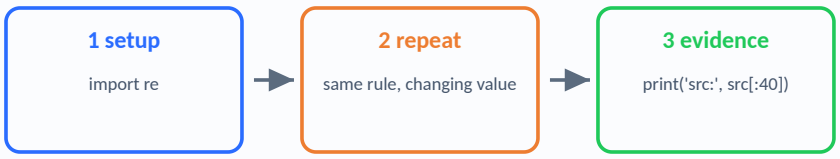
What You'll Build & Learn

Find iframe sources in a contact page and confirm whether any of them embeds a Google map.

- Extracting attributes with re.findall
- Testing a condition across items with any
- Slicing a string to truncate output

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 420: audit google business profile fields. Project 422 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a map embed on the contact page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('src:', src[:40])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a map embed on the contact page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A non-greedy regex captures each iframe's `src`, and an `any(...)` test for 'maps' in those sources confirms a map embed is present without a full HTML parse.

```
import re
page = '''<section><h2>Find Us</h2>
<iframe src="https://www.google.com/maps/embed?pb=abc" width="600"></iframe>
</section>'''
iframes = re.findall(r'<iframe[^>]*src="([^"]+)"', page)
has_map = any('maps' in src for src in iframes)
print('iframes found:', len(iframes))
print('map embed present:', has_map)
for src in iframes:
    print('src:', src[:40])
```

```
output
iframes found: 1
map embed present: True
src: https://www.google.com/maps/embed?pb=abc
```

How it works:

1. page holds a snippet of contact-page HTML containing one iframe with a maps src.
2. re.findall with the iframe src pattern captures the list of source URLs.
3. any('maps' in src for src in iframes) returns True because the URL contains maps.
4. The loop prints each src truncated to forty characters with src[:40].

Try it:

1. Match map embeds from other providers such as OpenStreetMap or Bing Maps.

2. Count how many distinct iframes appear and warn if there are none.
3. Extract the embed coordinates from the src and verify they match the business.
4. Add a second non-map iframe and confirm only the map is detected.

⚠ Common Mistakes

- A greedy `.*` in the src pattern would swallow past the closing quote on multi-attribute tags.
- Matching only lowercase 'maps' misses a capitalized host; normalize if needed.
- Assuming the first iframe is the map; a page may embed several iframes.

Skills gained map embed detection | regex extraction | any check

→ Where You'll Use This: Detecting a map embed is part of an on-page local audit, where an SEO confirms the contact page reinforces the businesss location to both visitors and search engines.

Mental Model

Like scanning a brochure for the little inset map, confirming the customer is shown exactly where to find the door.

Project 422 Check LocalBusiness Schema Completeness

The Idea Behind It

Rich results depend on complete LocalBusiness structured data. This code parses a JSON-LD string with json.loads, defines the properties a strong markup should carry, then builds a sorted list of any required property absent from the parsed object. With geo and priceRange missing, the complete flag reads False, auditing the markup directly.

What You'll Build & Learn

Parse LocalBusiness JSON-LD and report which required schema properties are missing.

- Parsing JSON-LD with json.loads
- Checking key presence in a dict
- Listing missing required properties

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 421: detect a map embed on the contact page. Project 423 changes the surface problem while preserving the underlying method.

progress check

Reading target: check localbusiness schema completeness is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('complete:', not missing)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Code Reading Stack

Layer	What to read
Intent	Check LocalBusiness Schema Completeness: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: json, schema, loads, type, LocalBusiness. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import json | Core: missing = sorted(f for f in required if f not in schema) | Evidence: print('complete:', not missing)

🛠️ Reader to Writer Bridge

1. Read: explain check localbusiness schema completeness in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 421.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 423 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('complete:', not missing)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of check localbusiness schema completeness and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Loading the JSON-LD with `json.loads` and diffing its keys against a required-property list surfaces exactly which schema fields are missing.

```
import json
schema = json.loads('''{
  "@type": "LocalBusiness",
  "name": "Acme Plumbing",
  "telephone": "+14155550199",
  "address": {"streetAddress": "123 Main St", "postalCode": "94110"},
  "openingHours": "Mo-Fr 09:00-17:00"
}''')
required = ['name', 'address', 'telephone', 'openingHours', 'priceRange',
'geo']
missing = sorted(f for f in required if f not in schema)
print('type:', schema['@type'])
print('missing schema props:', missing)
print('complete:', not missing)
```

```
output
type: LocalBusiness
missing schema props: ['geo', 'priceRange']
complete: False
```

How it works:

1. json.loads turns the JSON-LD string into a dict named schema.
2. required lists six properties a complete LocalBusiness markup should include.
3. missing keeps required properties absent from schema, sorted, yielding geo and priceRange.
4. The prints show the schema type, the missing props, and complete as False because the list is non-empty.

Try it:

1. Validate that the address sub-object itself contains required keys like streetAddress.
2. Check the value types so telephone is a string and geo holds coordinates.
3. Load several JSON-LD blocks from a page and audit each in turn.
4. Add 'geo' and 'priceRange' to the JSON and watch it report complete.

⚠ Common Mistakes

- Checking for nested properties like 'address.streetAddress' needs a deeper walk, not a top-level key test.

- Treating a present-but-empty property as complete; this checks key presence only.
- Forgetting to sort the missing list makes the output order nondeterministic.

Skills gained schema validation JSON-LD parsing property check

→ **Where You'll Use This:** Structured-data audits feed an SEOs technical recommendations, since complete LocalBusiness markup with geo, priceRange, and hours unlocks the rich features that lift local listings in search.

Mental Model

Like inspecting a passport for every required stamp before letting it through customs, noting exactly which pages are blank.

Project 423 Measure Citation Source Diversity

The Idea Behind It

Links from many kinds of sources beat a pile from one kind. This code tags each citation with a type, then uses Counter to tally how many fall into review, directory, and authority buckets. Printing the count per sorted type and the number of distinct types measures source diversity rather than raw citation volume.

What You'll Build & Learn

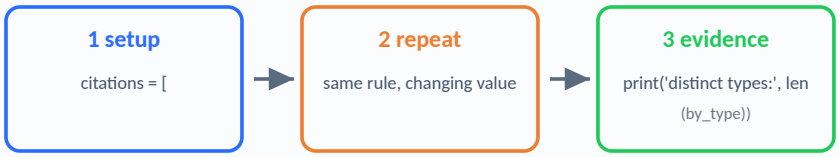
Measure citation source diversity by counting how many citations fall into each distinct type.

- Tallying categories with Counter
- Iterating sorted dictionary keys
- Counting distinct keys with len

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 422: check localbusiness schema completeness. Project 424 changes the surface problem while preserving the underlying method.

progress check



Reading target: measure citation source diversity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `citations = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('distinct types:', len(by_type))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`citations = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`by_type = Counter(c['type'] for c in citations)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('distinct types:', len(by_type))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `by_type = Counter(c['type'] for c in citations)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Citation Source Diversity: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: citations, source, Yelp, type, review. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: citations = [| Core: by_type = Counter(c['type'] for c in citations) | Evidence: print('distinct types:', len(by_type))

🛠️ Reader to Writer Bridge

1. Read: explain measure citation source diversity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 422.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 424 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('distinct types:', len(by_type))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `citations = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure citation source diversity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A `Counter` over the citation types tallies each bucket, and the number of distinct types is a simple diversity score for the backlink and citation profile.

```
citations = [
    {'source': 'Yelp', 'type': 'review'},
    {'source': 'YellowPages', 'type': 'directory'},
    {'source': 'BBB', 'type': 'authority'},
    {'source': 'Foursquare', 'type': 'review'},
    {'source': 'LocalChamber', 'type': 'authority'},
]
from collections import Counter
by_type = Counter(c['type'] for c in citations)
print('total citations:', len(citations))
for t in sorted(by_type):
    print(f'  {t}: {by_type[t]}')
print('distinct types:', len(by_type))
```

```
output
total citations: 5
  authority: 2
  directory: 1
  review: 2
distinct types: 3
```

How it works:

1. citations is a list of dicts each with a source and a type such as review or authority.
2. Counter over c['type'] tallies how many citations belong to each type.
3. The loop prints each type in sorted order with its count.
4. len(by_type) reports three distinct types across the five citations.

Try it:

1. Flag a type that dominates the mix beyond a chosen share of the total.
2. Recommend which under-represented type to pursue next based on the counts.
3. Add a domain field and count distinct domains alongside distinct types.
4. Add a 'social' type citation and watch diversity rise.

⚠ Common Mistakes

- Counting total citations alone misses that they might all be the same low-value type.
- Iterating the Counter unsorted prints types in a nondeterministic order.
- Treating two listings from the same source as separate types inflates diversity.

Skills gained diversity measurement | Counter tallying | type counting

→ Where You'll Use This: Source diversity guides link-building strategy, prompting an SEO to chase authority and directory citations rather than piling up more reviews-only sources for diminishing returns.

⚡ Mental Model

Like judging a diet by variety, not bulk: five vegetables beat five servings of the same potato for overall health.

Project 424 Separate Primary from Secondary Categories

💡 The Idea Behind It

Exactly one category should be primary while the rest stay secondary. This code reads a list of category dicts carrying a primary flag, splits the names into primary and secondary lists, and only prints a clean primary when precisely one exists, otherwise marking the count INVALID. Here Plumber is the lone primary with two secondaries listed cleanly.

What You'll Build & Learn

Validate that a profile has exactly one primary category and list the secondaries.

- Splitting items by a boolean flag
- Validating a single-element expectation
- Conditional print on a list length

🧭 Skill Roadmap

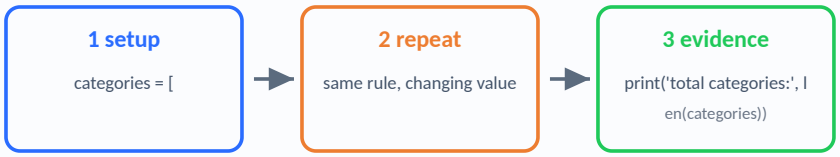
Skill step: pushes the same idea into a less automatic situation. It builds on Project 423: measure citation source diversity. Project 425 changes the surface problem while preserving the underlying method.

progress check

Reading target: separate primary from secondary categories is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens



- Setup: `categories = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('total categories:', len(categories))` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`categories = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`primary = [c['name'] for c in categories if c['primary']]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('total categories:', len(categories))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `primary = [c['name'] for c in categories if c['primary']]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Separate Primary from Secondary Categories: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.

Layer	What to read
Names	Watch these names first: categories, name, Plumber, primary, Water. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: categories = [| Core: primary = [c['name'] for c in categories if c['primary']] | Evidence: print('total categories:', len(categories))

🛠️ Reader to Writer Bridge

1. Read: explain separate primary from secondary categories in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 423.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 425 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total categories:', len(categories))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `categories = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of separate primary from secondary categories and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Partitioning categories on their `primary` flag isolates the one primary (flagging the count if not exactly one) and collects the secondary list.

```
categories = [
    {'name': 'Plumber', 'primary': True},
    {'name': 'Water Heater Installation', 'primary': False},
    {'name': 'Drain Cleaning Service', 'primary': False},
]
primary = [c['name'] for c in categories if c['primary']]
secondary = [c['name'] for c in categories if not c['primary']]
print('primary:', primary[0] if len(primary) == 1 else f'INVALID
({len(primary)})')
```

```
print('secondary:', secondary)
print('total categories:', len(categories))
```

```
output
primary: Plumber
secondary: ['Water Heater Installation', 'Drain Cleaning Service']
total categories: 3
```

How it works:

1. categories is a list of dicts each with a name and a primary boolean.
2. primary collects names where the flag is True; secondary collects the rest.
3. The print emits primary[0] only when exactly one primary exists, else INVALID with the count.
4. secondary prints the two non-primary categories and total prints the count of three.

Try it:

1. Warn explicitly when zero primaries are set versus when several are.
2. Cap the number of secondary categories at a recommended maximum.
3. Promote the first category to primary automatically when none is flagged.
4. Mark a second category primary and watch the INVALID count appear.

⚠ Common Mistakes

- Assuming `primary[0]` exists crashes when no category is marked primary.
- Allowing two primaries silently picks the first instead of flagging the conflict.
- Sorting the secondary list would change the intended display order.

Skills gained category validation | flag filtering | single-primary check

→ Where You'll Use This: Enforcing a single primary category matches how Google treats profiles, so an SEO can flag a misconfigured listing that names two primaries or none before it muddies ranking relevance.

⚡ Mental Model

Like a band needing one lead singer: backing vocalists are fine in number, but two front-and-center leads is a problem.

Project 425 Match Website NAP Against the Profile

💡 The Idea Behind It

Your own website contact details must agree with your Google profile. This code normalizes the sites formatted phone to bare digits, merges that into a copy of the website NAP, then diffs every field against the profile NAP. With the phone cleaned to match, the mismatch list is empty, confirming an in-sync footer.

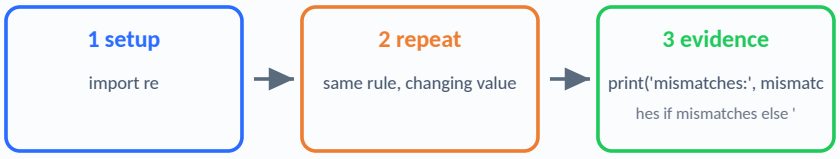
What You'll Build & Learn

Match a website's NAP against the Google profile by normalizing the phone and diffing the fields.

- Stripping non-digits from a phone
- Merging dicts with the spread operator
- Diffing fields for mismatches

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 424: separate primary from secondary categories. Project 426 changes the surface problem while preserving the underlying method.



progress check

Reading target: match website nap against the profile is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('mismatches:', mismatches if mismatches else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`return ''.join(ch for ch in p if ch.isdigit())`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('mismatches:', mismatches if mismatches else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return ''.join(ch for ch in p if ch.isdigit())`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Match Website NAP Against the Profile: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: re, website_nap, name, acme, plumbing. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: return ''.join(ch for ch in p if ch.isdigit()) | Evidence: print('mismatches:', mismatches if mismatches else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain match website nap against the profile in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 424.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 426 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('mismatches:', mismatches if mismatches else 'none')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of match website nap against the profile and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Cleaning the website phone to digits before comparison removes formatting noise so only genuine NAP discrepancies between site and profile are reported.

```
import re
website_nap = {
    'name': 'acme plumbing',
    'phone': '(415) 555-0199',
    'zip': '94110',
}
profile_nap = {'name': 'acme plumbing', 'phone': '4155550199', 'zip': '94110'}
def clean_phone(p):
    return ''.join(ch for ch in p if ch.isdigit())
norm_site = {**website_nap, 'phone': clean_phone(website_nap['phone'])}
mismatches = sorted(f for f in profile_nap if norm_site[f] != profile_nap[f])
print('website phone normalized:', norm_site['phone'])
print('mismatches:', mismatches if mismatches else 'none')
```

```
output
```

```
website phone normalized: 4155550199
mismatches: none
```

How it works:

1. website_nap holds a formatted phone while profile_nap holds the bare-digit version.
2. clean_phone keeps only digit characters from the website phone.
3. norm_site copies website_nap with the cleaned phone substituted via dict unpacking.
4. mismatches collects fields where norm_site differs from profile_nap, printing none after the phone is normalized.

Try it:

1. Extract the NAP from real page HTML instead of a hand-built dict.
2. Normalize the name and zip too so only true differences flag.
3. Report the specific old and new values for each mismatched field.
4. Change the site zip to introduce a real mismatch.

⚠ Common Mistakes

- Comparing the formatted site phone '(415) 555-0199' to the digit profile phone reports a false mismatch.
- Mutating `website_nap` in place instead of building `norm_site` would corrupt the original record.
- Not sorting the mismatch list makes the message nondeterministic.

Skills gained website NAP match | phone cleaning | field diffing

→ Where You'll Use This: Reconciling on-page NAP with the profile catches an out-of-sync footer, a common technical-SEO fix that keeps the businesss own site from contradicting its directory listings.

⚡ Mental Model

Like checking that the address on your business card matches the one on your storefront door before either misleads a customer.

Project 426 Flag a Keyword-Stuffed Business Name

The Idea Behind It

Stuffing a service keyword into your business name breaks Google's rules and risks suspension. This code scans each name for an embedded keyword by lowercasing and testing membership, labeling matches keyword-stuffed and the rest clean. San Francisco Plumber Co trips the check while Acme Plumbing and Bobs Cafe pass, and the offender count totals one.

What You'll Build & Learn

Flag business names that embed a service keyword and count how many names are stuffed.

- Case-insensitive substring search
- Labeling items by a condition
- Counting matches with sum

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 425: match website nap against the profile. Project 427 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag a keyword-stuffed business name is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `businesses = ['Acme Plumbing', 'San Francisco Plumber Co', 'Bobs Cafe']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('stuffed names:', stuffed)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`businesses = ['Acme Plumbing', 'San Francisco Plumber Co', 'Bobs Cafe']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.

Move	Code to inspect	Why it matters
2. Apply the rule	`note = 'keyword-stuffed name' if flag else 'clean'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('stuffed names:', stuffed)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag a Keyword-Stuffed Business Name: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: businesses, Acme, Plumbing, San, Francisco. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: businesses = ['Acme Plumbing', 'San Francisco Plumber Co', 'Bobs Cafe'] | Core: note = 'keyword-stuffed name' if flag else 'clean' | Evidence: print('stuffed names:', stuffed)

Reader to Writer Bridge

1. Read: explain flag a keyword-stuffed business name in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 425.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 427 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('stuffed names:', stuffed)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `businesses = ['Acme Plumbing', 'San Francisco Plumber Co', 'Bobs Cafe']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag a keyword-stuffed business name and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A case-insensitive substring test for the keyword inside each name flags listings that stuff a service term into the brand name.

```
businesses = ['Acme Plumbing', 'San Francisco Plumber Co', 'Bobs Cafe']
keyword = 'plumber'
for name in businesses:
    flag = keyword in name.lower()
    note = 'keyword-stuffed name' if flag else 'clean'
    print(f'{name}: {note}')
stuffed = sum(1 for n in businesses if keyword in n.lower())
print('stuffed names:', stuffed)
```

```
output
Acme Plumbing: clean
San Francisco Plumber Co: keyword-stuffed name
Bobs Cafe: clean
stuffed names: 1
```

How it works:

1. businesses lists three names and keyword holds the service term plumber.
2. The loop tests keyword in name.lower(), labeling a hit keyword-stuffed name and otherwise clean.
3. San Francisco Plumber Co contains plumber so it is flagged, while the others pass.
4. stuffed sums the flagged names, printing a count of one.

Try it:

1. Check against a list of many service keywords rather than a single one.
2. Use word-boundary matching so plumber inside plumbery does not false-positive.
3. Report the matched keyword alongside each flagged name.
4. Use a word-boundary regex so 'Plumberton' is not flagged.

⚠ Common Mistakes

- Case-sensitive matching misses 'Plumber' when you search for 'plumber'.
- A substring test flags 'Plumberton' (a place) as stuffed; word-boundary matching is stricter.
- Counting flagged names without listing them hides which need a rename.

Skills gained name spam check | substring search | violation counting

→ Where You'll Use This: Keyword-stuffed-name detection guards against a guideline violation that can suspend a listing, a compliance scan an SEO runs before submitting or auditing business names.

⚡ Mental Model

Like a referee watching for a player who sneaks an advertisement onto their jersey: the rule is clear and the violation stands out.

Project 427 Rank Competitors by Distance

💡 The Idea Behind It

Knowing which competitors sit nearest a searcher explains the local pack you fight in. This code skips any library, computing a plain Euclidean distance on raw coordinate pairs with the difference of squares under a square root. Sorting competitors by that distance and enumerating the result ranks PipeKing closest and FastDrain farthest from your location.

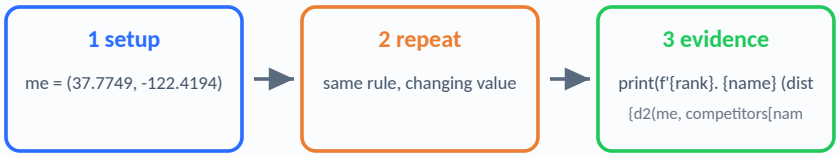
What You'll Build & Learn

Rank competitors by plain Euclidean distance on their coordinates relative to your own position.

- Euclidean distance on coordinate pairs
- Rounding a computed distance
- Sorting then enumerating ranks

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 426: flag a keyword-stuffed business name. Project 428 changes the surface problem while preserving the underlying method.



progress check

Reading target: rank competitors by distance is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `me = (37.7749, -122.4194)` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print(f'{rank}. {name} (dist {d2(me, competitors[name])})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`me = (37.7749, -122.4194)`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`for rank, name in enumerate(ranked, 1):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Rank Competitors by Distance: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: me, competitors, PlumbPro, FastDrain, PipeKing. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: me = (37.7749, -122.4194) | Core: for rank, name in enumerate(ranked, 1): | Evidence: print(f'{rank}. {name} (dist {d2(me, competitors[name])})')

Reader to Writer Bridge

1. Read: explain rank competitors by distance in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 426.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 428 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{rank}. {name} (dist {d2(me, competitors[name])})')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `me = (37.7749, -122.4194)` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank competitors by distance and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Computing the straight-line distance in degree space and sorting by it ranks competitors by nearness; degrees suffice for ordering even though they are not kilometres.

```
me = (37.7749, -122.4194)
competitors = {
    'PlumbPro': (37.7849, -122.4094),
    'FastDrain': (37.7600, -122.4500),
    'PipeKing': (37.7750, -122.4180),
}
def d2(a, b):
    return round(((a[0]-b[0])**2 + (a[1]-b[1])**2) ** 0.5, 4)
ranked = sorted(competitors, key=lambda n: d2(me, competitors[n]))
for rank, name in enumerate(ranked, 1):
    print(f'{rank}. {name} (dist {d2(me, competitors[name])})')
```

```
output
1. PipeKing (dist 0.0014)
2. PlumbPro (dist 0.0141)
3. FastDrain (dist 0.034)
```

How it works:

1. me holds your coordinates and competitors maps three rivals to their own.
2. d2 computes the square root of summed squared coordinate differences, rounded to four places.
3. sorted orders competitors by d2 from me, putting PipeKing first.
4. enumerate starting at one prints the ranked list with each rivals distance.

Try it:

1. Swap in the kilometre-accurate scaling from the earlier proximity project.
2. Include your own business in the list and show where it ranks.
3. Filter the competitor set to those within a chosen distance before ranking.
4. Add a competitor at your exact coordinates and confirm it ranks first.

⚠ Common Mistakes

- Comparing raw degree distance is fine for ranking but must not be reported as kilometres.
- Forgetting the square root still ranks correctly but the printed values are squared distances.
- Rounding before sorting could tie two competitors that the full precision separates.

Skills gained `competitor ranking` `euclidean distance` `rank enumeration`

→ Where You'll Use This: Competitor proximity ranking sharpens local competitive analysis, showing an SEO which nearby rivals share a searchers map pack and deserve the closest watch.

⚡ Mental Model

Like lining up runners by how close they stand to the finish line before the race even starts.

Project 428 Flag a Spam Listing

💡 The Idea Behind It

Spam profiles share telltale signs you can tally into a score. This code checks four flags: a name heavy with digits and symbols, a fake phone of repeated digits, a same-day review burst above ten, and a missing address. Each triggered flag joins a list, and the example listing trips all four for a maximum spam score of four.

What You'll Build & Learn

Score how spammy a listing looks by tallying flags for promotional names, fake phones, review bursts, and missing data.

- Counting digit and symbol characters
- Detecting a single repeated digit
- Accumulating flags into a list

🧭 Skill Roadmap

`Skill step:` pushes the same idea into a less automatic situation. It builds on Project 427: rank competitors by distance. Project 429 changes the surface problem while preserving the underlying method. *progress check*

`Reading target:` flag a spam listing is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `listing = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('spam score:', len(flags))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`listing = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`if sum(c.isdigit() or c in '#!' for c in listing['name']) > 3:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('spam score:', len(flags))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if sum(c.isdigit() or c in '#!' for c in listing['name']) > 3:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag a Spam Listing: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: listing, name, Best, Cheap, Plumber. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: listing = { | Core: if sum(c.isdigit() or c in '#!' for c in listing['name']) > 3: | Evidence: print('spam score:', len(flags))

🛠️ Reader to Writer Bridge

1. Read: explain flag a spam listing in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 427.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 429 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('spam score:', len(flags))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `listing = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag a spam listing and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each heuristic appends a named flag, and the flag count becomes a spam score you can threshold to triage suspicious listings.

```
listing = {
    'name': 'Best #1 Cheap Plumber Near Me 24/7',
    'phone': '0000000000',
    'reviews_same_day': 18,
    'address': '',
}
flags = []
if sum(c.isdigit() or c in '#!' for c in listing['name']) > 3:
    flags.append('promotional name')
if listing['phone'] == '0000000000' or len(set(listing['phone'])) == 1:
    flags.append('fake phone')
if listing['reviews_same_day'] > 10:
    flags.append('review burst')
if not listing['address']:
    flags.append('no address')
print('spam flags:', flags)
print('spam score:', len(flags))
```

```
output
spam flags: ['promotional name', 'fake phone', 'review burst', 'no address']
spam score: 4
```

How it works:

1. listing holds a promotional name, a zeroed phone, a same-day review burst, and an empty address.
2. The name flag counts characters that are digits or hash and bang, firing when more than three appear.
3. The phone flag fires when it equals all zeros or len(set) is one, meaning a single repeated digit.
4. Burst and address flags add when same-day reviews exceed ten or the address is empty, totaling a spam score of four.

Try it:

1. Add a flag for a name in all capital letters or excessive emoji.
2. Weight the flags so a fake phone counts more than a busy review day.
3. Return the triggered flags with a severity label rather than only a count.
4. Add a flag for a name longer than 50 characters.

⚠ Common Mistakes

- Counting only digits for the promotional-name test misses symbol stuffing like '#1' and '!!!'.
- A phone of all identical digits is caught by `len(set(phone)) == 1`; a real number rarely is.
- A high same-day review count alone is suggestive, not proof; weigh it with other flags.

Skills gained spam scoring | heuristic flags | character counting

→ Where You'll Use This: Spam scoring helps an SEO report fake or manipulative competitors to Google, where stacking several heuristic flags builds a credible case that a listing violates guidelines.

⚡ Mental Model

Like a fraud detector adding up red flags on an application: no single one convicts, but four together paint a clear picture.

Project 429 Audit Photo-Type Coverage

💡 The Idea Behind It

A complete profile shows exterior, interior, team, logo, and product photos. This code counts total images, then builds a missing list of photo types whose count is zero, here interior and product. Dividing the covered types by the expected five gives a 60 percent coverage figure that reveals gaps in visual completeness.

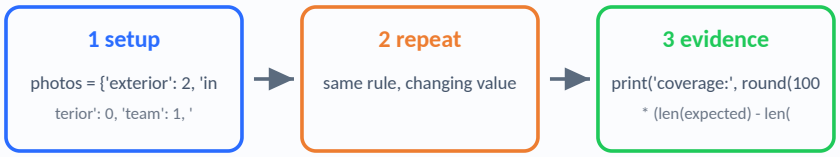
What You'll Build & Learn

Audit photo coverage by listing photo types with zero images and scoring overall visual completeness.

- Summing dict values for a total
- Finding keys with a zero value
- Scoring coverage as a percentage

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 428: flag a spam listing. Project 430 changes the surface problem while preserving the underlying method. *progress check*



Reading target: audit photo-type coverage is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `photos = {'exterior': 2, 'interior': 0, 'team': 1, 'logo': 1, 'product': 0}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('coverage:', round(100 * (len(expected) - len(missing)) / len(expected), 1), '%')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`photos = {'exterior': 2, 'interior': 0, 'team': 1, 'logo': 1, 'product': 0}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`missing = [k for k in expected if photos.get(k, 0) == 0]`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('coverage:', round(100 * (len(expected) - len(missing)) / len(expected), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [k for k in expected if photos.get(k, 0) == 0]`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Audit Photo-Type Coverage: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: photos, exterior, interior, team, logo. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: photos = {'exterior': 2, 'interior': 0, 'team': 1, 'logo': 1, 'product'... | Core: missing = [k for k in expected if photos.get(k, 0) == 0] | Evidence: print('coverage:', round(100 * (len(expected) - len(missing)) / len(exp...

🛠️ Reader to Writer Bridge

1. Read: explain audit photo-type coverage in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 428.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 430 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('coverage:', round(100 * (len(expected) - len(missing)) / len(expected), 1), '%')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `photos = {'exterior': 2, 'interior': 0, 'team': 1, 'logo': 1, 'product': 0}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of audit photo-type coverage and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the expected photo types to those with a zero count lists the missing categories and yields a coverage percentage over the expected set.

```
photos = {'exterior': 2, 'interior': 0, 'team': 1, 'logo': 1, 'product': 0}
expected = ['exterior', 'interior', 'team', 'logo', 'product']
total = sum(photos.values())
missing = [k for k in expected if photos.get(k, 0) == 0]
print('total photos:', total)
print('missing photo types:', missing)
print('coverage:', round(100 * (len(expected) - len(missing)) / len(expected),
1), '%')
```

```
output
total photos: 4
missing photo types: ['interior', 'product']
coverage: 60.0 %
```

How it works:

1. photos maps five photo types to their image counts, with interior and product at zero.
2. total sums all the counts to four images.
3. missing keeps expected types whose count is zero via photos.get(k, 0), capturing interior and product.
4. The coverage print scales expected minus missing over expected to 60.0 percent.

Try it:

1. Require a minimum count per type so one product photo still counts as thin.
2. Add categories like food or video and recompute coverage.
3. Rank the missing types by which most influences engagement.
4. Add an 'interior' photo and watch coverage rise.

⚠ Common Mistakes

- Summing the values gives a total photo count, not how many types are covered.
- Using `photos[k]` instead of `photos.get(k, 0)` raises if an expected type is absent.
- Counting a type with one photo the same as one with ten ignores depth of coverage.

Skills gained photo audit zero-value detection coverage scoring

→ Where You'll Use This: Photo-coverage audits translate into concrete client tasks, since profiles rich in exterior, interior, and team imagery earn more engagement and outrank visually bare competitors in local results.

Mental Model

Like checking a real-estate listing for the missing room shots: an album with no interior photos leaves buyers guessing.

Project 430 Track a Rating Trend and Alert

The Idea Behind It

A falling star rating is an early warning worth catching fast. This code compares a prior average to the current one, computes the signed delta, derives the new-review count from the two totals, and labels the direction dropping or rising. A sensitivity threshold of 0.3 turns the 0.4 drop into a True alert, formatted neatly with a sign.

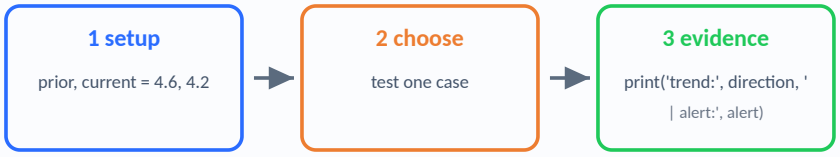
What You'll Build & Learn

Track a rating trend between two snapshots and decide whether the change warrants an alert.

- Computing a signed delta
- Deriving new reviews from two counts
- Alerting on an absolute threshold

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 429: audit photo-type coverage. Project 431 changes the surface problem while preserving the underlying method. *progress check*



Reading target: track a rating trend and alert is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `prior, current = 4.6, 4.2` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.

- Evidence: `print('trend:', direction, '| alert:', alert)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`prior, current = 4.6, 4.2`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`direction = 'dropping' if delta < 0 else 'rising'`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('trend:', direction, '| alert:', alert)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `direction = 'dropping' if delta < 0 else 'rising'`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Track a Rating Trend and Alert: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: prior, current, prior_n, current_n, new_reviews. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: prior, current = 4.6, 4.2 | Core: direction = 'dropping' if delta < 0 else 'rising' | Evidence: print('trend:', direction, '| alert:', alert)

🛠️ Reader to Writer Bridge

1. Read: explain track a rating trend and alert in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 429.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 431 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('trend:', direction, '| alert:', alert)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `prior, current = 4.6, 4.2` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of track a rating trend and alert and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Subtracting the prior rating from the current gives a signed delta; comparing its magnitude to a threshold turns a small float change into an actionable alert flag.

```
prior, current = 4.6, 4.2
prior_n, current_n = 40, 52
new_reviews = current_n - prior_n
delta = round(current - prior, 2)
direction = 'dropping' if delta < 0 else 'rising'
```

```
alert = abs(delta) >= 0.3
print(f'rating: {prior} -> {current} ({"+" if delta>=0 else ""}{delta})')
print('new reviews:', new_reviews)
print('trend:', direction, '| alert:', alert)
```

```
output
rating: 4.6 -> 4.2 (-0.4)
new reviews: 12
trend: dropping | alert: True
```

How it works:

1. prior and current hold the old and new averages, with their review counts in prior_n and current_n.
2. new_reviews subtracts the counts to twelve, and delta rounds current minus prior to negative 0.4.
3. direction reads dropping because delta is below zero.
4. alert is abs(delta) >= 0.3, which is True, and the f-string prints the signed change and verdict.

Try it:

1. Make the alert threshold configurable per client sensitivity.
2. Factor the new-review volume into the alert so a tiny sample is downweighted.
3. Track a rolling history of averages rather than just two points.
4. Raise the current rating above the prior and watch the trend flip to rising.

⚠ Common Mistakes

- Comparing the raw delta to the threshold without `abs` misses a sharp drop as 'negative, ignore'.
- Printing the unrounded delta shows float noise like -0.40000000000000036.
- Inferring direction from review count instead of the rating delta answers the wrong question.

Skills gained rating trend | delta computation | threshold alert

→ Where You'll Use This: Rating-trend alerts power reputation monitoring, where an SEO is notified the moment a clients average drops enough to threaten star snippets and click-through before reviews pile up.

Mental Model

Like a smoke alarm tuned to a sensitivity: a small dip is ignored, but a real drop sets it off before the fire spreads.

Project 431 Compute a Weighted Local-Ranking Score

The Idea Behind It

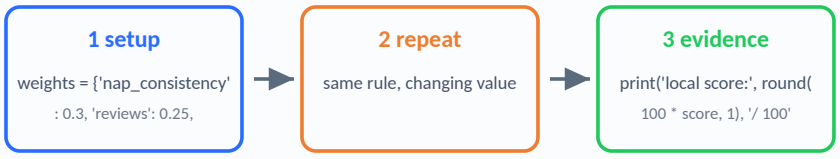
Local ranking blends several signals at different weights into one figure. This code pairs a weights dict summing to one with normalized signal strengths between zero and one, then computes a weighted sum across the shared keys. Printing each signal times its weight and scaling the total by a hundred yields a composite local score of 77 out of 100.

What You'll Build & Learn

Combine weighted, normalized local-ranking signals into a single composite score out of 100.

- Pairing weights with signal values
- Computing a weighted sum
- Scaling a normalized total to 100

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 430: track a rating trend and alert. Project 432 changes the surface problem while preserving the underlying method. *progress check*

Reading target: compute a weighted local-ranking score is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `weights = {'nap_consistency': 0.3, 'reviews': 0.25, 'proximity': 0.2,` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `print('local score:', round(100 * score, 1), '/ 100')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`weights = {'nap_consistency': 0.3, 'reviews': 0.25, 'proximity': 0.2,`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`score = sum(weights[k] * signals[k] for k in weights)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('local score:', round(100 * score, 1), '/ 100')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `score = sum(weights[k] * signals[k] for k in weights)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute a Weighted Local-Ranking Score: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: weights, nap_consistency, reviews, proximity, profile_complete. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: weights = {'nap_consistency': 0.3, 'reviews': 0.25, 'proximity': 0.2, | Core: score = sum(weights[k] *signals[k] for k in weights)* | *Evidence: print('local score:', round(100* score, 1), '/ 100')

🛠️ Reader to Writer Bridge

1. Read: explain compute a weighted local-ranking score in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 430.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 432 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('local score:', round(100 * score, 1), '/ 100')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `weights = {'nap_consistency': 0.3, 'reviews': 0.25, 'proximity': 0.2,` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute a weighted local-ranking score and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Multiplying each normalized signal by its weight and summing gives a single 0-to-1 score; scaling by 100 makes a readable composite, with sorted keys keeping the breakdown deterministic.

```
weights = {'nap_consistency': 0.3, 'reviews': 0.25, 'proximity': 0.2,
           'profile_complete': 0.15, 'categories': 0.1}
signals = {'nap_consistency': 0.8, 'reviews': 0.6, 'proximity': 0.9,
           'profile_complete': 1.0, 'categories': 0.5}
score = sum(weights[k] * signals[k] for k in weights)
for k in sorted(weights):
    print(f'{k}: {signals[k]} x {weights[k]} = {round(weights[k]*signals[k],
3)}')
print('local score:', round(100 * score, 1), '/ 100')
```

```
output
categories: 0.5 x 0.1 = 0.05
nap_consistency: 0.8 x 0.3 = 0.24
profile_complete: 1.0 x 0.15 = 0.15
proximity: 0.9 x 0.2 = 0.18
```

```
reviews: 0.6 x 0.25 = 0.15
local score: 77.0 / 100
```

How it works:

1. weights assigns each of five signals a share that sums to one.
2. signals holds each factors normalized strength between zero and one.
3. score sums weights[k] times signals[k] across the shared keys.
4. The loop prints each contribution in sorted order and the final line scales score by a hundred to 77.0.

Try it:

1. Validate that the weights sum to one and warn otherwise.
2. Add a new signal such as citation diversity with its own weight.
3. Show which low-scoring signal drags the composite down the most.
4. Bump the reviews signal to 1.0 and watch the score climb.

⚠ Common Mistakes

- Weights that do not sum to 1 silently rescale the maximum away from 100.
- Iterating the weights dict unsorted prints the breakdown in a nondeterministic order.
- Multiplying a signal above 1.0 (out of range) would push the score past 100.

Skills gained weighted scoring | signal blending | composite metric

→ Where You'll Use This: A weighted composite score lets an agency roll many local signals into one dial a client understands, and tuning the weights models how Google might prioritize proximity, reviews, and consistency.

Mental Model

Like a final grade built from weighted exams and homework: each input pushes the number by exactly its assigned share.

Project 432 Run a Full Local-SEO Health Report

The Idea Behind It

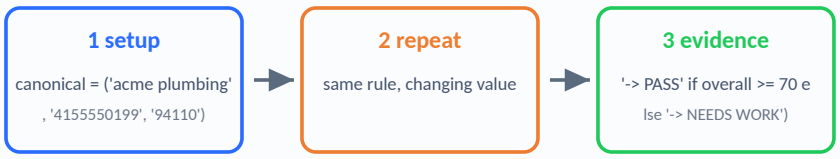
This capstone ties the chapter together into a single audit. It computes NAP consistency from citations matching a canonical tuple, scores profile completeness from a fields dict, averages the two percentages, and prints a PASS or NEEDS WORK verdict against a seventy-percent bar. The example earns 73.3 percent and passes, the skeleton of a real local audit.

What You'll Build & Learn

Combine NAP consistency and profile completeness into one local-SEO health score with a pass or needs-work verdict.

- Reusing consistency and completeness logic
- Averaging two percentages
- Producing a pass or fail verdict

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 431: compute a weighted local-ranking score. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full local-seo health report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `canonical = ('acme plumbing', '4155550199', '94110')` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check nap consistency across citations, score local signals, and audit business-profile completeness.
- Evidence: `'-> PASS' if overall >= 70 else '-> NEEDS WORK')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`canonical = ('acme plumbing', '4155550199', '94110')`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check

Move	Code to inspect	Why it matters
		nap consistency across citations, score local signals, and audit business-profile completeness.
2. Apply the rule	`consistent = sum(1 for c in citations.values() if c == canonical)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`'-> PASS' if overall >= 70 else '-> NEEDS WORK')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Local and Map SEO becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `consistent = sum(1 for c in citations.values() if c == canonical)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run a Full Local-SEO Health Report: connect the surface task to the chapter skill, check nap consistency across citations, score local signals, and audit business-profile completeness.
Names	Watch these names first: canonical, acme, plumbing, citations, Yelp. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: canonical = ('acme plumbing', '4155550199', '94110') | Core: consistent = sum(1 for c in citations.values() if c == canonical) | Evidence: '-> PASS' if overall >= 70 else '-> NEEDS WORK')

Reader to Writer Bridge

1. Read: explain run a full local-seo health report in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 431.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `'-> PASS' if overall >= 70 else '-> NEEDS WORK'`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `canonical = ('acme plumbing', '4155550199', '94110')` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full local-seo health report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Combining the NAP consistency percentage with the profile completeness percentage into one average gives a headline health number that a threshold turns into a verdict.

```
canonical = ('acme plumbing', '4155550199', '94110')
citations = {
    'Yelp': ('acme plumbing', '4155550199', '94110'),
    'Bing': ('acme plumbing', '4155550100', '94110'),
    'Apple': ('acme plumbing', '4155550199', '94110'),
}
profile = {'name': 1, 'hours': 1, 'categories': 1, 'photos': 0, 'website': 1}
consistent = sum(1 for c in citations.values() if c == canonical)
nap_pct = 100 * consistent / len(citations)
prof_pct = 100 * sum(profile.values()) / len(profile)
overall = round((nap_pct + prof_pct) / 2, 1)
print(f'NAP consistency: {round(nap_pct, 1)}% ({consistent}/{len(citations)})')
print(f'profile complete: {round(prof_pct, 1)}%')
print('local SEO health:', overall, '%',
      '-> PASS' if overall >= 70 else '-> NEEDS WORK')
```

```
output
NAP consistency: 66.7% (2/3)
profile complete: 80.0%
local SEO health: 73.3 % -> PASS
```

How it works:

1. canonical and citations drive the NAP check, counting two of three sources matching for nap_pct.
2. profile maps five fields to present flags, and prof_pct sums them over the count for 80 percent.
3. overall averages nap_pct and prof_pct to 73.3 percent.
4. The print appends PASS because overall clears the seventy-percent threshold, else NEEDS WORK.

Try it:

1. Fold in review and proximity scores so the health metric covers more signals.
2. Make the pass threshold configurable rather than fixed at seventy.
3. Print the individual subscores so the verdict is explainable.
4. Fix the Bing phone so NAP consistency hits 100%.

⚠ Common Mistakes

- Averaging two percentages weights them equally; a real audit might weight NAP higher.
- Comparing the tuple citations with `==` requires identical normalization upstream first.
- Rounding the overall before the threshold check could nudge a 69.95 over the line; round only for display.

Skills gained health report | metric combination | pass-fail verdict

→ Where You'll Use This: A combined health score is the deliverable a local-SEO audit hands over: one number plus a verdict that tells a client at a glance whether their local presence is sound or needs work.

⚡ Mental Model

Like a doctors single fit-or-unfit summary that quietly rests on blood pressure, weight, and a dozen other readings underneath.

✅ Chapter Progress Checkpoint

What this chapter added: after 30 mini-projects, Local and Map SEO should feel like a reusable Python move: check nap consistency across citations, score local signals, and audit business-profile completeness.

chapter checkpoint

1 Read
Open any project from Projects 403-432 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 13 (Log-File and Server Analysis) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

7 questions · 4 categories · graded

2 Recall · 2 Meaning · 2 Structure · 1 Transfer

12.1.Q1 Recall · MEDIUM

Turn back to Project 419 (Detect a Profile Closed All Week). Without running it, what exactly does it print?

12.1.Q2 Meaning · MEDIUM

Turn back to Project 403 (Normalize a Business Name for Matching). Without running it, what exactly does it print?

12.1.Q3 Structure · MEDIUM

Turn back to Project 405 (Normalize a Street Address). Without running it, what exactly does it print?

12.1.Q4 Transfer · EASY

What are Google's three stated local-ranking factors?

- A. Relevance, distance, prominence
- B. Title, meta, headings
- C. Crawl, index, rank
- D. Speed, links, content

12.1.Q5 Recall · MEDIUM

Two citations list a phone as "(415) 555-0199" and "+1 415-555-0199". After normalizing to bare digits and dropping a leading US country code, are they consistent?

- A. No, the formatting differs
- B. Yes — both reduce to 4155550199
- C. Only if the area codes are removed
- D. Cannot tell without the address

12.1.Q6 Meaning · MEDIUM

You audit five citations and three exactly match your canonical NAP. What is your NAP consistency, and why does it matter?

12.1.Q7 Structure MEDIUM Why is adding "Plumber" into your Google Business Profile *name* field a bad idea, even though it seems relevant?

- A It costs extra
- B It violates Google's naming rules and risks suspension
- C It slows the page down
- D It has no effect at all

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 12 – Local and Map SEO

12.1.Q1. `WARNING: business marked closed all week` then `open day count: 0`

12.1.Q2. `"Joe's Coffee House, LLC"` then `normalized: "joe's coffee house"`

12.1.Q3. `raw: 123 North Main Street, Suite 200` then `norm: 123 n main st ste 200`

12.1.Q4. A relevance (does it match), distance (how near), prominence (how trusted/known).

12.1.Q5. B strip non-digits and drop the leading "1"; both become 4155550199, so they agree.

12.1.Q6. 60% (3 of 5). It matters because conflicting citations make Google less confident the listings describe one real business, which suppresses local ranking; fixing the two offenders is the highest-leverage move.

12.1.Q7. B the name field must be the real business name; keyword-stuffing it is against the rules and can get the profile suspended.

Chapter 13 · Log-File and Server Analysis

Parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

Chapter Skill Map

What this chapter adds: In Log-File and Server Analysis, the focus is parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths. You practise it across 32 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples.

chapter arc

What it builds on: Chapter 13 assumes the reading habits from Chapter 12: Local and Map SEO. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 14, GEO, AEO and the End-to-End Technical Audit, reuses this chapter's discipline with a new kind of problem.

1 **Projects 433-442**	2 **Projects 443-452**	3 **Projects 453-464**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Your access log is the only record of what bots actually did on your site.

not what they should do — what they did

Every other SEO tool tells you what *should* happen: the sitemap lists the URLs you want crawled, robots.txt lists what you want blocked. The access log is different — it is the server's own diary of every request that arrived, written one line per hit, in the order they happened. It is ground truth. If Googlebot fetched a page you deleted, the log says so. If it never touched a page in your sitemap, the log says that too.

Most servers write the Common Log Format (CLF), a single space-separated line that packs the client IP, a timestamp, the request line, the response status, the bytes sent, and the User-Agent into one string. Learn to unpack that one line and you can read the whole file. A single regular expression with capture groups pulls every field out at once:

```
import re
line = ('66.249.66.1 - - [22/Jun/2026:10:00:00 +0000] '
        '"GET /page HTTP/1.1" 200 1234 "-" '
        '"Mozilla/5.0 (compatible; Googlebot/2.1)"')
m = re.match(
    r'(\S+) \S+ \S+ \[([^\]]+)\] "(\S+) (\S+) (\S+)" '
    r'(\d+) (\d+) "([^"]*)" "([^"]*)"', line)
ip, ts, method, path, proto, status, nbytes, ref, ua = m.groups()
print('ip:', ip)
print('path:', path)
```

```
    print('status:', status)
    print('ua:', ua)
```

```
output
ip: 66.249.66.1
path: /page
status: 200
ua: Mozilla/5.0 (compatible; Googlebot/2.1)
```

Read those nine groups and you have read a log line in full. The two fields that matter most for SEO are the `path` (which URL was asked for) and the `status` (how the server answered). The User-Agent tells you *who* asked, the timestamp tells you *when*, and the byte count tells you *how much* you served. Everything in this chapter is built from those few fields.

Why does any of this matter? Because a bot has a finite `crawl budget` — only so many fetches per visit. Spend them on pages that return 404, on redirect chains, or on a thousand parameter variants of one page, and your real pages wait days to be re-crawled. The log is where you *measure* that waste, count it, and find exactly which URLs are leaking budget.

you cannot fix what you have not counted

ACCESS LOG

The server-written record of every request received, one line per hit, in arrival order. It is the ground truth of what bots and users actually fetched.

COMMON LOG FORMAT (CLF)

The standard log line layout: `IP - - [timestamp] "METHOD path PROTOCOL" status bytes "referer" "user-agent"`. Each field is space-separated; quoted fields can contain spaces.

REQUEST PATH

The URL that was asked for, taken from the request line. The single most useful field for SEO log analysis because it names the page.

STATUS CODE

The three-digit response code (200, 301, 404, 503). Grouped by hundreds into classes: 2xx success, 3xx redirect, 4xx client error, 5xx server error.

USER-AGENT

The self-reported client string. Search bots announce themselves in it (`Googlebot`, `bingbot`), which is how you split bot traffic from human traffic.

CRAWL WASTE

Bot fetches spent on URLs that return nothing useful — a 404, a redirect, a blocked path, or a near-duplicate parameter URL. Every wasted fetch is budget stolen from a page that matters.

One line, nine fields

A CLF line looks like noise until you see its shape. The fields are positional: IP, two placeholders (`- -`), a bracketed timestamp, then the quoted request line holding method, path and protocol, then status, bytes, referer and User-Agent. You rarely need all nine. Most reports want just the `path` or just the `status`, so a focused regex that grabs only that token is faster to write and harder to break than a full parse. Here is the path, pulled from a mix of request lines:

```
import re
lines = [
    '1.2.3.4 - - [...] "GET /home HTTP/1.1" 200 512 "-" "Firefox"',
    '1.2.3.5 - - [...] "POST /api/login HTTP/1.1" 200 88 "-" "curl"',
    '1.2.3.6 - - [...] "GET /blog/post?id=7 HTTP/1.1" 200 999 "-" "Safari"',
]
for ln in lines:
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    print(path)
```

```
output
/home
/api/login
/blog/post?id=7
```

The pattern `"\S+ (\S+) HTTP` reads as: a quote, the method (non-spaces), a space, then the *captured* path (non-spaces), a space, then the protocol token. Because the path is captured, `.group(1)` returns just it. The status code lives a few fields later, and it arrives as text — parse it to `int` so you can do numeric range checks like `300 <= code < 400`:

```
import re
for raw in ['"GET /home HTTP/1.1" 200', '"GET /old HTTP/1.1" 301',
            '"GET /gone HTTP/1.1" 404']:
    status = int(re.search(r'(\d{3})$', raw).group(1))
    print(status, type(status).__name__)
```

```
output
200 int
301 int
404 int
```

Telling a real bot from a human

Search engines identify themselves in the User-Agent string. Googlebot carries `Googlebot` in it, Bing carries `bingbot`, Ahrefs carries `AhrefsBot`. So the first split — the one every later report depends on — is bot versus human, done by testing for marker substrings. Lowercase both sides so case never trips you up. A reliable way to grab the User-Agent is to split on the last two quote pairs, since it is the final quoted field:

```
lines = [
    '1.2.3.4 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
Googlebot/2.1)"',
    '1.2.3.5 - - [...] "GET /b HTTP/1.1" 200 1 "-" "Mozilla/5.0 (Windows NT 10.0)
Firefox/120"',
    '1.2.3.6 - - [...] "GET /c HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
bingbot/2.0)"',
]
bots = ('googlebot', 'bingbot')
for ln in lines:
    ua = ln.rsplit('"', 2)[1]
    is_bot = any(b in ua.lower() for b in bots)
    print('BOT ' if is_bot else 'HUMAN', ua)
```

```
output
BOT   Mozilla/5.0 (compatible; Googlebot/2.1)
HUMAN Mozilla/5.0 (Windows NT 10.0) Firefox/120
BOT   Mozilla/5.0 (compatible; bingbot/2.0)
```

`ln.rsplit('"', 2)` splits from the right at most twice, so `[1]` is the text between the last two quotes — the User-Agent — no matter how many quotes appeared earlier. Once you can label each line, the headline number is the *share* of traffic that is crawlers versus people. That one ratio frames every crawl-budget question that follows.

know the bot share before you tune anything

Counting: paths, statuses, agents

A log is thousands of repeated paths and statuses, so the workhorse is the tally. A `Counter` over a parsed field gives raw demand for each value in one pass. Count paths to see what bots and users actually want; `most_common(n)` then surfaces the top hitters. Crawl budget concentrates on a few URLs, and this is how you see which:

```
import re
from collections import Counter
lines = [
    '"GET /home HTTP/1.1" 200', '"GET /blog HTTP/1.1" 200',
    '"GET /home HTTP/1.1" 200', '"GET /shop HTTP/1.1" 200',
```

```
    '"GET /home HTTP/1.1" 200', '"GET /blog HTTP/1.1" 200',
]
paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)
for path, n in paths.most_common(2):
    print(f'{path}: {n}')
```

```
output
/home: 3
/blog: 2
```

The same move counts status codes. Individual codes are noisy, so a cleaner health check groups them into classes by integer-dividing the code by 100 — `code // 100` turns 200, 301, 404 and 503 into 2, 3, 4 and 5. A spike in the 4xx or 5xx bucket jumps out instantly:

```
import re
from collections import Counter
raws = ['" 200 1 ', '" 301 0 ', '" 404 9 ', '" 200 1 ', '" 503 9 ']
classes = Counter()
for raw in raws:
    code = int(re.search(r'(\d{3})', raw).group(1))
    classes[f'{code // 100}xx'] += 1
for cls in sorted(classes):
    print(f'{cls}: {classes[cls]}')
```

```
output
2xx: 2
3xx: 1
4xx: 1
5xx: 1
```

Measuring crawl waste and budget

Now combine the splits. Crawl waste is budget a bot spent on URLs that returned nothing useful — most simply, a bot that fetched a 404 or chased a 3xx redirect. Filter for *bot* lines whose status is 404 or in the 3xx range, count them, and you have quantified the leak. This is the single most actionable number a log produces:

```
import re
lines = [
    '"GET /a HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '"GET /b HTTP/1.1" 404 9 "-" "Googlebot/2.1"',
    '"GET /c HTTP/1.1" 301 0 "-" "Googlebot/2.1"',
    '"GET /d HTTP/1.1" 200 1 "-" "Firefox/120"',
    '"GET /e HTTP/1.1" 404 9 "-" "bingbot/2.0"',
]
bots = ('googlebot', 'bingbot')
bot_hits = waste = 0
for ln in lines:
```

```
    ua = ln.rsplit('"', 2)[1].lower()
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    if any(b in ua for b in bots):
        bot_hits += 1
        if code == 404 or 300 <= code < 400:
            waste += 1
print('bot hits:', bot_hits)
print('wasted:', waste, '(', round(100 * waste / bot_hits, 1), '%)')
```

```
output
bot hits: 4
wasted: 3 ( 60.0 % )
```

Sixty percent of this bot's fetches hit dead ends — a budget emergency. Two more leaks worth counting: bots crawling paths your robots file disallows (test `path.startswith(d)` for each disallowed prefix), and bots crawling many URL-parameter variants of one page (count hits where `'?' in path`). Both are budget you did not want spent. And to size the budget itself, count the distinct paths a bot reached — a `set` of parsed paths collapses repeats automatically:

```
import re
lines = [
    '"GET /home HTTP/1.1" 200', '"GET /blog HTTP/1.1" 200',
    '"GET /home HTTP/1.1" 200', '"GET /shop HTTP/1.1" 200',
    '"GET /blog HTTP/1.1" 200',
]
paths = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}
print('total hits:', len(lines))
print('unique paths crawled:', len(paths))
```

```
output
total hits: 5
unique paths crawled: 3
```

Five fetches, three distinct URLs — the bot re-visited pages rather than reaching new ones. Comparing the crawled set against your sitemap closes the loop: `crawled - sitemap` finds URLs the bot chased that you never listed (often junk), and `sitemap - crawled` finds listed pages the bot never reached (orphans in practice). The log turns crawl budget from a vague worry into a counted, fixable list.

Example 1

A bot made 5 fetches: /home 200, /gone 404, /old 301, /home 200, /missing 404. What is the crawl-waste percentage, and which fix matters most?

SOLUTION

1. Count the fetches that returned a dead end. A 404 or any 3xx counts as waste: `/gone (404)`, `/old (301)`, `/missing (404)` = 3 wasted.
2. Total bot fetches = 5, so waste = 3 / 5 = `60%` of this bot's budget hit nothing useful.
3. The two 404s are deleted pages the bot still has on file; the 301 is a redirect it should not need to chase. Fixing the dead links removes 2 of the 3 wasted fetches.

60% crawl waste. Prioritise the 404s — they are confirmed dead links search engines are still spending budget on. *a logged 404 is a precise repair ticket*

Example 2

You parse 6 lines: 4 carry "Googlebot" in the User-Agent, 2 carry "Firefox". Among the Googlebot lines, statuses are 200, 200, 404, 301. What two numbers do you report?

SOLUTION

1. First split bot from human by testing for the marker substring `googlebot:` `4 bot hits`, 2 human hits.
2. Within the 4 bot hits, classify each status: 200 and 200 are useful 2xx; 404 and 301 are waste (a 4xx and a 3xx).
3. Crawl waste = 2 wasted / 4 bot hits = `50%`. Report the bot share (4 of 6 ≈ 66.7%) and the waste rate (50%).

Bot share ≈ 66.7% of traffic; crawl waste = 50% of bot fetches. Half of Googlebot's visits here achieved nothing. *two ratios summarise a whole log*

Example 3

A bot fetched these paths: /p?id=1, /p?id=2, /p?id=3, /blog. Group by the path before the "?". Where is the crawl bloat?

SOLUTION

1. Strip each path at the first `?` to get its base: /p?id=1, /p?id=2, /p?id=3 all reduce to base `/p`; /blog has no query so it stays /blog.
2. Tally bases: /p appears 3 times, /blog appears once.
3. A base with many parameter variants is duplicate-ish content soaking up fetches — /p burned 3 fetches on near-duplicates while /blog took one.

/p is crawl bloat: 3 parameter variants of one page. The fix is to canonicalise or block the parameter so the bot stops re-fetching duplicates. *one page, many query strings = wasted budget*

⚡ Mental-Math Shortcut

The log is ground truth; count, then split, then divide. First *count* the raw hits per path and per status. Then *split* bot from human on the User-Agent. Then *divide* to get the two numbers that matter: bot share of traffic, and crawl waste as a percentage of bot fetches. A sitemap says what should happen; the log is the only thing that says what did.

⚠ Common Mistakes

- Trusting the User-Agent as proof of identity. The string is self-reported, so a scraper can claim to be Googlebot — verify a suspicious bot by reverse-DNS on its IP before treating its hits as real crawler traffic.
- Splitting a log line on every space. Quoted fields like the request line and the User-Agent contain spaces; use a CLF-aware regex or rsplit on the quotes, not a naive `split()`.
- Counting only 404s as crawl waste and ignoring 3xx. A bot chasing redirect chains burns budget too, and a redirect to another redirect can quietly eat several fetches per target.
- Treating raw hit counts as the whole story. Three fetches of one URL is not the same as three distinct URLs crawled — track unique paths to measure crawl breadth, not just volume.

This chapter contains 32 hands-on mini-projects (Projects 433–464). Type each one out, run it, and experiment.

Project 433 Parse One Log Line into Its Fields

💡 The Idea Behind It

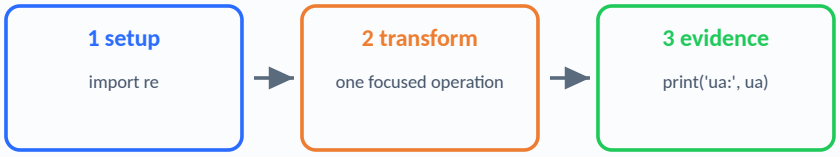
A raw access-log line is one dense string, yet every field sits in a fixed position. This project builds a single Common Log Format regex with nine capture groups and unpacks IP, timestamp, method, path, protocol, status, bytes, referrer and user-agent in one match. Understanding that anatomy is the foundation for every later analysis in the chapter.

What You'll Build & Learn

Take one server log line and split it into named, labelled fields you can read.

- Common Log Format field order
- regex capture groups
- tuple unpacking from match.groups

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 434 changes the surface problem while preserving the underlying method. *progress check*

Reading target: parse one log line into its fields is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('ua:', ua)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`line = '66.249.66.1 - - [22/Jun/2026:10:00:00 +0000] "GET /page HTTP/1.1" 200 1234 "-" "Mozilla/5.0 (compatible; Googlebot/2.1)"'`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print('ua:', ua)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
line = '66.249.66.1 - - [22/Jun/2026:10:00:00 +0000] "GET /page HTTP/1.1" 200 1234 "-" "Mozilla/5.0 (compatible; Googlebot/2.1)"'
```

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Parse One Log Line into Its Fields: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, line, Jun, page, Mozilla. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: line = '66.249.66.1 - - [22/Jun/2026:10:00:00 +0000] "GET /page HTTP/1.... | Evidence: print('ua:', ua)

Reader to Writer Bridge

1. Read: explain parse one log line into its fields in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 434 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('ua:', ua)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse one log line into its fields and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One `re.match` with parenthesised groups splits the whole line into named pieces; `\[([^\]]+)\]` grabs the bracketed timestamp and `"([^"]*)"` grabs each quoted field.

```
import re
line = '66.249.66.1 - - [22/Jun/2026:10:00:00 +0000] "GET /page HTTP/1.1" 200
1234 "-" "Mozilla/5.0 (compatible; Googlebot/2.1)"'
m = re.match(r'(\S+) \S+ \S+ \[([^\]]+)\] "(\S+) (\S+) (\S+)" (\d+) (\d+) "
([^"]*)" "([^"]*)"', line)
ip, ts, method, path, proto, status, nbytes, ref, ua = m.groups()
print('ip:', ip)
print('method:', method)
print('path:', path)
print('status:', status)
print('bytes:', nbytes)
print('ua:', ua)
```

```
output
ip: 66.249.66.1
method: GET
path: /page
status: 200
bytes: 1234
ua: Mozilla/5.0 (compatible; Googlebot/2.1)
```

How it works:

1. A sample Googlebot line is assigned to the variable line.
2. re.match runs a pattern with nine parenthesised groups against the start of that string.
3. m.groups() returns a tuple that is unpacked into ip, ts, method, path, proto, status, nbytes, ref and ua.
4. Six print statements label and show the most useful extracted fields.

Try it:

1. Add a print line that also displays the captured timestamp and referrer fields.
2. Replace re.match with re.search and test a line that has leading whitespace.
3. Wrap the parse in a try and print a warning when a malformed line fails to match.

4. Print `proto` to confirm the protocol token parsed as `HTTP/1.1`.

⚠ Common Mistakes

- Forgetting the brackets are literal in the timestamp group lets the regex skip into the wrong field.
- A missing space between the request and status groups makes the whole match fail and `m` is `None`.
- Calling `.group()` on a `None` match (a malformed line) raises AttributeError, so real parsers guard for it.

Skills gained regex | log parsing | string fields

→ Where You'll Use This: Every log-analysis tool and SEO crawl audit begins by turning unreadable log lines into structured fields you can count, filter and group.

⚡ Mental Model

The regex is a cookie cutter pressed onto a strip of dough: one stamp cleanly separates every field into its own labelled shape.

Project 434 Pull the Request Path From Each Line

💡 The Idea Behind It

Of all the log fields, the requested URL path matters most to an SEO, because it names the page a visitor or crawler actually wanted. This project loops over several lines and applies a narrow regex anchored on the quote and the HTTP token, capturing only the middle path segment from each request and printing it. It proves you can target one field without parsing the whole line.

What You'll Build & Learn

Extract only the request path from each log line and print the bare URLs.

- anchoring a regex on quotes
- single-group extraction
- iterating over log lines

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 433: parse one log line into its fields. Project 435 changes the surface problem while preserving the underlying method.

progress check

Reading target: pull the request path from each line is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(path)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`for ln in lines:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(path)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for ln in lines:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pull the Request Path From Each Line: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, Jun, home, Firefox. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: for ln in lines: | Evidence: print(path)

🛠️ Reader to Writer Bridge

1. Read: explain pull the request path from each line in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 433.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 435 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(path)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pull the request path from each line and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`'"\S+ (\S+) HTTP` anchors on the quoted request, skips the method with `\S+`, and captures the path before the protocol token.

```
import re
lines = [
    '1.2.3.4 - - [22/Jun/2026:10:00:00 +0000] "GET /home HTTP/1.1" 200 512 "-"
"Firefox"',
    '1.2.3.5 - - [22/Jun/2026:10:00:01 +0000] "POST /api/login HTTP/1.1" 200 88
"-" "curl"',
    '1.2.3.6 - - [22/Jun/2026:10:00:02 +0000] "GET /blog/post?id=7 HTTP/1.1"
200 999 "-" "Safari"',
]
for ln in lines:
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    print(path)
```

```
output
/home
/api/login
/blog/post?id=7
```

How it works:

1. A list named lines holds three request lines using GET and POST.
2. The for loop runs re.search with a pattern that matches the quote, the method token, then captures the path before HTTP.
3. group(1) pulls just the captured path out of the match.
4. Each path, including one with a query string, is printed on its own line.

Try it:

1. Add a line containing a PUT request and confirm the path still extracts correctly.
2. Strip any query string by splitting each printed path on the question mark character.
3. Collect the paths into a list instead of printing, then print the list length at the end.
4. Add a line with a query string and confirm the `?id=...` survives in the path.

⚠ Common Mistakes

- Splitting on spaces instead of regex breaks on query strings that contain encoded spaces.
- Capturing `\S+` greedily without the trailing `HTTP` anchor can swallow the protocol token too.
- A request line missing the protocol (a malformed log) makes the search return `None`.

Skills gained `regex` `path extraction` `loops`

→ **Where You'll Use This:** Pulling the clean path is the first step before tallying which URLs get hit, comparing them to a sitemap, or spotting crawl bloat.

⚡ Mental Model

Think of each log line as a sentence and the path as the one noun you underline, ignoring all the surrounding grammar.

Project 435 Read the Status Code as an Integer

💡 The Idea Behind It

Status codes in a log are stored as plain text, but their meaning is numeric: ranges like 2xx, 3xx and 4xx drive how search engines treat a URL. This project pulls the three-digit code with a regex and wraps it in int, then prints the value alongside its type name to prove the conversion. Numeric codes unlock range comparisons that string codes cannot support.

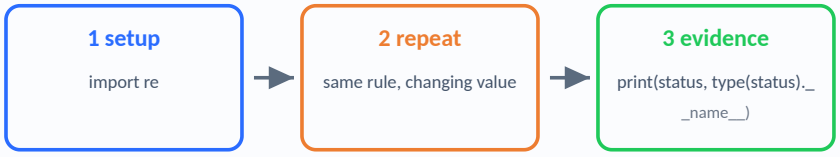
What You'll Build & Learn

Parse the HTTP status field from each line and convert it to a real integer.

- matching three digits with d{3}
- int conversion from text
- checking a value's type name

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 434: pull the request path from each line. Project 436 changes the surface problem while preserving the underlying method. *progress check*



Reading target: read the status code as an integer is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

- Evidence: `print(status, type(status).__name__)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

3. Check the evidence	`print(status, type(status).__name__)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for ln in lines:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Read the Status Code as an Integer: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, Jun, home, Firefox. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: for ln in lines: | Evidence: print(status, type(status).__name__)

🛠️ Reader to Writer Bridge

1. Read: explain read the status code as an integer in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 434.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 436 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(status, type(status).__name__)`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of read the status code as an integer and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`" (\d{3}) ` matches exactly three digits after the quoted request, and `int(...)` converts the captured text so comparisons are numeric, not lexical.

```
import re
lines = [
    '1.2.3.4 - - [22/Jun/2026:10:00:00 +0000] "GET /home HTTP/1.1" 200 512 "-"
"Firefox"',
    '1.2.3.5 - - [22/Jun/2026:10:00:01 +0000] "GET /old HTTP/1.1" 301 0 "-"
"Firefox"',
    '1.2.3.6 - - [22/Jun/2026:10:00:02 +0000] "GET /gone HTTP/1.1" 404 153 "-"
"Safari"',
]
for ln in lines:
    status = int(re.search(r'" (\d{3}) ', ln).group(1))
    print(status, type(status).__name__)
```

```
output
200 int
301 int
404 int
```

How it works:

1. Three log lines carry the codes 200, 301 and 404.
2. Inside the loop re.search finds the quoted code surrounded by spaces and group(1) returns it as text.
3. int() converts that text into a number stored in status.
4. Each line prints the integer and type(status).__name__, confirming the value is now an int.

Try it:

1. Add a test that prints whether each code falls in the redirect range 300 to 399.
2. Append a 500 server-error line and confirm it parses and prints as an int.
3. Sum the parsed codes into a total just to see arithmetic now works on them.
4. Add a 502 line and confirm it parses as the integer 502.

⚠ Common Mistakes

- Leaving the code as a string makes `code < 400` compare characters, not numbers.
- Matching `\d+` instead of `\d{3}` could grab the byte count on an oddly spaced line.
- Forgetting the surrounding spaces lets the regex match three digits inside a longer number.

Skills gained regex | type conversion | status codes

→ Where You'll Use This: Numeric status codes let you write range tests for redirects and errors, the basis for crawl-health histograms and error reports later in this chapter.

⚡ Mental Model

Reading the code as text is like seeing a price tag as a sticker; calling int turns it into money you can actually add up.

Project 436 Flag Bot Hits by User-Agent

💡 The Idea Behind It

Search engines identify themselves inside the User-Agent string, so the first move in separating crawlers from people is spotting marker words. This project grabs the user-agent with rsplit on the quote character, lowercases it, and uses any() against a tuple of bot markers to label each hit BOT or HUMAN. It shows pattern matching on substrings rather than exact equality.

What You'll Build & Learn

Read each line's user-agent and label it as a bot or a human visitor.

- rsplit to grab the last quoted field
- case-insensitive substring matching
- any over a marker tuple

🧭 Skill Roadmap

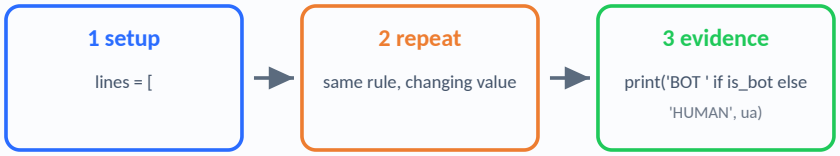
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 435: read the status code as an integer. Project 437 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag bot hits by user-agent is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens



- Setup: `lines = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('BOT ' if is_bot else 'HUMAN', ua)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`lines = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`print('BOT ' if is_bot else 'HUMAN', ua)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('BOT ' if is_bot else 'HUMAN', ua)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('BOT ' if is_bot else 'HUMAN', ua)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Bot Hits by User-Agent: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: lines, Mozilla, compatible, Googlebot, Windows. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: lines = [| Core: print('BOT ' if is_bot else 'HUMAN', ua) | Evidence: print('BOT ' if is_bot else 'HUMAN', ua)

🛠️ Reader to Writer Bridge

1. Read: explain flag bot hits by user-agent in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 435.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 437 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('BOT ' if is_bot else 'HUMAN', ua)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `lines = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag bot hits by user-agent and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The user-agent is the last quoted field, so `rsplit('"', 2)[1]` lifts it out; lowercasing then testing membership against a marker tuple classifies the hit.

```
lines = [
    '1.2.3.4 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
Googlebot/2.1)"',
    '1.2.3.5 - - [...] "GET /b HTTP/1.1" 200 1 "-" "Mozilla/5.0 (Windows NT
10.0) Firefox/120"',
    '1.2.3.6 - - [...] "GET /c HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
bingbot/2.0)"',
```

```
    '1.2.3.7 - - [...] "GET /d HTTP/1.1" 200 1 "-" "Mozilla/5.0 (Macintosh)
Safari/605"',
]
bots = ('googlebot', 'bingbot')
for ln in lines:
    ua = ln.rsplit('"', 2)[1]
    is_bot = any(b in ua.lower() for b in bots)
    print('BOT ' if is_bot else 'HUMAN', ua)
```

```
output
BOT   Mozilla/5.0 (compatible; Googlebot/2.1)
HUMAN Mozilla/5.0 (Windows NT 10.0) Firefox/120
BOT   Mozilla/5.0 (compatible; bingbot/2.0)
HUMAN Mozilla/5.0 (Macintosh) Safari/605
```

How it works:

1. A list of four lines mixes Googlebot, bingbot, Firefox and Safari agents.
2. bots holds the lowercase markers googlebot and bingbot.
3. Each loop pass uses ln.rsplit on the quote, index 1, to isolate the user-agent string.
4. any() tests whether a marker appears in the lowercased agent, and the result prints as BOT or HUMAN beside the agent.

Try it:

1. Add AhrefsBot and DuckDuckBot to the markers tuple and retest the lines.
2. Print a running count of how many lines were tagged as bots.
3. Handle a line with no quotes by guarding the rsplit with a length check.
4. Add an `AhrefsBot` line and extend the markers tuple to catch it.

⚠ Common Mistakes

- Matching case-sensitively misses `Googlebot` if you only test `googlebot` without lowercasing.
- Using `split('"')` from the left grabs the wrong quoted field when a referrer is present.
- A browser whose product token contains 'bot' would be a false positive worth noting.

Skills gained substring match | user-agent | rsplit

→ Where You'll Use This: Bot detection underpins crawl-budget analysis: nearly every later report splits traffic by whether a known search engine made the request.

Mental Model

It is like reading name tags at a conference door: a glance at the badge tells you whether someone is staff or a guest.

Project 437 Split Bot and Human Traffic

The Idea Behind It

Once a single hit can be classified, the natural summary is the overall split between crawler and human traffic. This project counts bot lines with a generator inside sum, where any() scans each lowercased line for a marker, then derives the human total by subtraction. The two printed numbers frame how much of your server's work is spent serving search engines versus actual people.

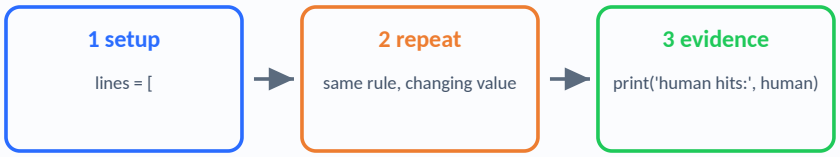
What You'll Build & Learn

Count how many log hits came from bots versus humans and print both totals.

- summing a boolean generator
- deriving the complement by subtraction
- marker tuples

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 436: flag bot hits by user-agent. Project 438 changes the surface problem while preserving the underlying method.



progress check

Reading target: split bot and human traffic is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `lines = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('human hits:', human)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`lines = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`bot = sum(1 for ln in lines if any(b in ln.lower() for b in bots))`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('human hits:', human)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `bot = sum(1 for ln in lines if any(b in ln.lower() for b in bots))`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 436.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 438 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('human hits:', human)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `lines = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split bot and human traffic and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Summing a generator of bot matches counts bot hits in one pass, and the human count is just the remainder of the total.

```
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 1 "-" "Firefox/120"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 1 "-" "Safari/605"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 200 1 "-" "Chrome/119"',
]
```

```
bots = ('googlebot', 'bingbot')
bot = sum(1 for ln in lines if any(b in ln.lower() for b in bots))
human = len(lines) - bot
print('bot hits:', bot)
print('human hits:', human)
```

```
output
bot hits: 2
human hits: 3
```

How it works:

1. Five lines mix two bot agents with three human browser agents.
2. sum with a generator adds 1 for every line where any() finds a bot marker, giving bot.
3. human is computed as len(lines) minus bot rather than scanning again.
4. Both bot hits and human hits are printed.

Try it:

1. Print the bot share as a percentage of total hits using rounding.
2. Scan the full line versus only the user-agent field and compare the counts.
3. Add an unknown-agent line and decide which bucket it falls into.
4. Print the bot share as `round(100 * bot / len(lines), 1)` percent.

⚠ Common Mistakes

- Testing the marker against the whole line risks matching a path that happens to contain 'bot'.
- Recomputing `len(lines)` after filtering would double-count if you reuse the variable.
- Counting humans by re-scanning instead of subtracting can drift if the two passes disagree.

Skills gained counting generators traffic split

→ Where You'll Use This: The bot-versus-human ratio is a top-line metric in any log audit; a surprisingly high bot share is often the first sign of crawl-budget trouble.

⚡ Mental Model

Like a turnstile counter at a museum that separates ticketed visitors from staff, giving you the day's split at a glance.

Project 438 Count Requests per Path

💡 The Idea Behind It

To learn what users and crawlers actually want, you tally requests per URL. This project feeds the path extracted from each line into a Counter, which builds a tidy map of path to hit count in one expression. Printing the counts in sorted path order gives the raw demand profile for the site, the basis for understanding where attention concentrates.

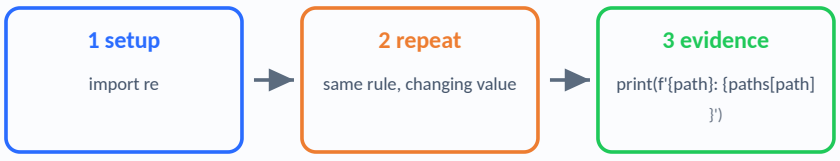
What You'll Build & Learn

Count how many times each URL path appears across the log and print the tally.

- Counter from a generator
- regex path extraction
- sorted iteration of keys

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 437: split bot and human traffic. Project 439 changes the surface problem while preserving the underlying method.



progress check

Reading target: count requests per path is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{path}: {paths[path]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {paths[path]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Requests per Path: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, home. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: import re | Core: paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in li... | Evidence: print(f'{path}: {paths[path]}')

🛠️ Reader to Writer Bridge

1. Read: explain count requests per path in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 437.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 439 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {paths[path]}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count requests per path and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Feeding a generator of parsed paths straight into `Counter` tallies hits per URL; sorting the keys before printing keeps the report deterministic.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.2 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.3 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.4 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.5 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Bot"',
]
paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)
for path in sorted(paths):
    print(f'{path}: {paths[path]}')
```

```
output
```

```
/blog: 2
/home: 3
```

How it works:

1. Five lines repeat the paths /home and /blog in varying amounts.
2. A Counter is built directly from a generator that runs re.search on each line and pulls group(1).
3. Counter records how many times each distinct path occurred.
4. The loop walks sorted(paths) and prints each path with its count using an f-string.

Try it:

1. Switch the output to print paths ordered by descending count instead of alphabetically.
2. Add several more lines and confirm the totals still add up correctly.
3. Print the single most-hit path along with its count.
4. Add another `/blog` hit and watch its count rise.

⚠ Common Mistakes

- Printing the Counter directly emits insertion order, which is not sorted or stable across runs.
- Counting full request lines instead of just the path treats identical paths as distinct.
- Forgetting to sort the keys makes the output order depend on hit order.

Skills gained Counter regex aggregation

→ **Where You'll Use This:** Per-URL hit counts feed crawl-frequency reports, top-page rankings and the parameter-bloat checks that appear later in the chapter.

⚡ Mental Model

The Counter is a tally clerk with a clipboard, adding a tick mark beside a URL every time someone asks for it.

Project 439 Surface the Most-Crawled Paths

💡 The Idea Behind It

Crawl budget concentrates on a handful of URLs, so ranking pages by hits answers where bots and users spend the most fetches. This project reuses the Counter-over-paths idea but calls most_common(2) to surface only the top two paths in descending order. It demonstrates that Counter does the sorting for you when you want a leaderboard rather than a full table.

What You'll Build & Learn

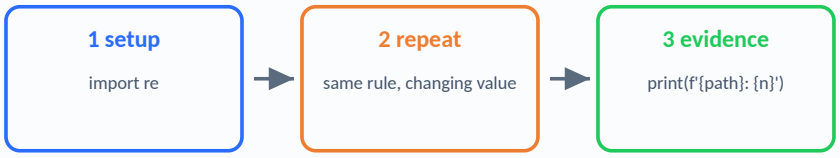
Rank URL paths by hit count and print only the two most-crawled pages.

- Counter.most_common with a limit

- ranking by frequency
- tuple unpacking in a loop

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 438: count requests per path. Project 440 changes the surface problem while preserving the underlying method.



progress check

Reading target: surface the most-crawled paths is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{path}: {n}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Reader to Writer Bridge

1. Read: explain surface the most-crawled paths in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 438.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 440 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {n}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of surface the most-crawled paths and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`Counter.most_common(N)` returns the top-N paths already sorted by descending count, so the busiest URLs surface without a manual sort.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.2 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.3 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.4 - - [...] "GET /shop HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.5 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Bot"',
    '1.1.1.6 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Bot"',
]
paths = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)
for path, n in paths.most_common(2):
    print(f'{path}: {n}')
```

```
output
/home: 3
/blog: 2
```

How it works:

1. Six lines give /home three hits, /blog two and /shop one.
2. A Counter tallies the path extracted from each line.
3. most_common(2) returns the top two path-count pairs already sorted high to low.
4. The loop unpacks each pair into path and n and prints them.

Try it:

1. Change the argument to most_common(3) and observe the extra row appear.
2. Call most_common with no argument to print every path in ranked order.
3. Add a tie between two paths and note how the order resolves.
4. Raise the top-N to 3 and see the full ranking.

⚠ Common Mistakes

- `most_common` breaks ties by insertion order, so equal counts are not alphabetical.
- Passing no argument to `most_common()` returns everything, not the top N.
- Counting request lines instead of paths splits one URL across many counts.

Skills gained most_common ranking Counter

→ Where You'll Use This: A top-pages leaderboard tells you which URLs deserve the freshest content and the tightest internal linking to keep crawlers returning.

⚡ Mental Model

It is a music chart: out of all the tracks played, you only print this week's top two singles.

Project 440 Tally Status Codes Across Log Lines

💡 The Idea Behind It

A frequency table of status codes is the quickest pulse check on a log, because a spike of 404s or 5xx leaps off the page. This project parses each three-digit code to an int and counts the values with a Counter, then prints them in sorted numeric order. The result is a compact histogram that summarises the health of every response the server returned.

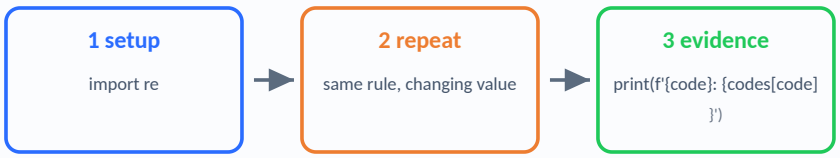
What You'll Build & Learn

Build a frequency table of HTTP status codes across the log and print it sorted.

- counting integer keys
- regex plus int conversion
- sorted numeric output

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 439: surface the most-crawled paths. Project 441 changes the surface problem while preserving the underlying method.



progress check

Reading target: tally status codes across log lines is the surface task; the transferable Python move is to mark setup, rule, and output before running. setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{code}: {codes[code]}')` exposes the result; match it against the output before changing the program. output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`codes = Counter(int(re.search(r'" (\d{3}) ', ln).group(1)) for ln in lines)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{code}: {codes[code]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `codes = Counter(int(re.search(r'" (\d{3}) ', ln).group(1)) for ln in lines)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Tally Status Codes Across Log Lines: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, codes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: codes = Counter(int(re.search(r'" (\d{3}) ', ln).group(1)) for ln in li... | Evidence: print(f'{code}: {codes[code]}')

Reader to Writer Bridge

1. Read: explain tally status codes across log lines in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 439.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 441 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: {codes[code]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of tally status codes across log lines and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Parsing each code to `int` and feeding it to a `Counter` builds the histogram; sorting the codes prints them in numeric order.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 301 0 "-" "B"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 404 9 "-" "B"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.6 - - [...] "GET /f HTTP/1.1" 500 9 "-" "B"',
]
codes = Counter(int(re.search(r'" (\d{3}) ', ln).group(1)) for ln in lines)
for code in sorted(codes):
    print(f'{code}: {codes[code]}')
```

```
output
200: 3
301: 1
404: 1
500: 1
```

How it works:

1. Six lines carry the codes 200, 301, 404 and 500.
2. A Counter is built from a generator that converts each matched three-digit code with int.
3. Counter records how often each numeric code appeared.
4. Iterating sorted(codes) prints each code beside its count.

Try it:

1. Add several 404 lines and watch that bucket grow in the output.
2. Print only codes whose count exceeds one to highlight the common ones.
3. Compute the percentage each code represents of all hits.

4. Add a bar of `'#' * codes[code]` to draw the histogram.

⚠ Common Mistakes

- Counting codes as strings sorts '404' before '50' lexically, scrambling the histogram.
- Matching `\d+` could capture the byte field on a malformed line.
- Iterating `codes` unsorted gives a different order each run.

Skills gained Counter | status codes | histogram

→ Where You'll Use This: Status-code histograms are the standard at-a-glance log health check, flagging error surges that hurt crawlability before users complain.

Mental Model

Like a hospital chart of vital signs: one quick scan of the numbers tells you whether the server is healthy or feverish.

Project 441 Total the Bytes Served

The Idea Behind It

Bandwidth is a genuine cost and crawlers can consume a surprising slice of it, so totalling bytes served matters. This project extracts the byte field with a regex that skips past the status code, converts each value to int, and sums them inside a generator. It then prints the raw total and a kilobyte figure, showing how to aggregate a numeric column straight from text.

What You'll Build & Learn

Sum the bytes-served field across the log and report the total transfer.

- regex that skips the status to reach bytes
- summing converted integers
- rounding to kilobytes

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 440: tally status codes across log lines. Project 442 changes the surface problem while preserving the underlying method.

progress check

Reading target: total the bytes served is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('total KB:', round(total / 1024, 2))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`total = sum(int(re.search(r'" \d{3} (\d+) ', ln).group(1)) for ln in lines)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('total KB:', round(total / 1024, 2))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Total the Bytes Served: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, total, sum, search. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: total = sum(int(re.search(r'" \d{3} (\d+) ', ln).group(1)) for ln in li... | Evidence: print('total KB:', round(total / 1024, 2))

🛠️ Reader to Writer Bridge

1. Read: explain total the bytes served in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 440.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 442 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total KB:', round(total / 1024, 2))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of total the bytes served and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`" \d{3} (\d+) ` captures the byte count after the status code; summing the parsed integers totals bytes, and dividing by 1024 reports KB.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1200 "-" "B"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 3400 "-" "B"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 304 0 "-" "B"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 560 "-" "B"',
]
total = sum(int(re.search(r'" \d{3} (\d+) ', ln).group(1)) for ln in lines)
print('total bytes served:', total)
print('total KB:', round(total / 1024, 2))
```

```
output
total bytes served: 5160
total KB: 5.04
```

How it works:

1. Four lines carry byte sizes including a 304 response with zero bytes.
2. sum runs a generator that matches the status then captures the byte count and applies int.
3. The accumulated total is printed as raw bytes.
4. Dividing by 1024 and rounding to two places prints the size in KB.

Try it:

1. Add a megabyte line such as 5000000 bytes and reprint the KB total.
2. Also print the total in megabytes rounded to two decimals.
3. Skip lines whose byte field is zero before summing and compare totals.
4. Report the average bytes per request with `total / len(lines)`.

⚠ Common Mistakes

- A '-' byte field (some servers log it for 304s) would break `int(...)`; this fixture uses 0 instead.
- Capturing the status code by mistake inflates the total with response codes.
- Printing the raw float for KB without `round` gives a noisy long decimal.

Skills gained summing regex bandwidth

→ Where You'll Use This: Total transfer figures support bandwidth budgeting and later let you compare how much data bots pull versus humans on a busy site.

Mental Model

It is reading the odometer of data leaving your server: every response adds a few more miles to the trip total.

Project 442 Rank the Top User-Agents

The Idea Behind It

Knowing which clients hit a site most reveals whether crawlers, scrapers or real browsers dominate. This project counts the exact user-agent string, grabbed with rsplit on the quote, using a Counter, then prints every agent ranked by frequency via most_common. It treats the whole agent string as the key, so identical agents group together while distinct ones stay separate.

What You'll Build & Learn

Rank the user-agent strings in the log by how often each one appears.

- Counter over full user-agent strings
- rsplit field extraction
- most_common ranking

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 441: total the bytes served. Project 443 changes the surface problem while preserving the underlying method.

progress check

Reading target: rank the top user-agents is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

- Evidence: `print(f'{n} {ua}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`agents = Counter(ln.rsplit('"', 2)[1] for ln in lines)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Code Reading Stack

Layer	What to read
Intent	Rank the Top User-Agents: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: collections, Counter, lines, Googlebot, Firefox. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: agents = Counter(ln.rsplit('"', 2)[1] for ln in lines) | Evidence: print(f'{n} {ua}')

🛠️ Reader to Writer Bridge

1. Read: explain rank the top user-agents in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 441.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 443 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{n} {ua}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank the top user-agents and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The user-agent is the last quoted field via `rsplit('"', 2)[1]`; a `Counter` tallies them and `most_common()` prints the ranking.

```python
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 200 1 "-" "Firefox/120"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
]
agents = Counter(ln.rsplit('"', 2)[1] for ln in lines)
for ua, n in agents.most_common():
    print(f'{n}  {ua}')
```

```
output
3  Googlebot/2.1
1  Firefox/120
1  bingbot/2.0
```

How it works:

1. Five lines repeat Googlebot three times alongside one Firefox and one bingbot.
2. A Counter is built from each line's rsplit on the quote at index 1, the user-agent.
3. most_common with no argument returns every agent-count pair sorted by frequency.
4. The loop prints the count followed by the agent string.

Try it:

1. Normalise agents to a family name before counting so Googlebot versions merge.
2. Print only agents seen more than once.
3. Add an empty user-agent line and see how it ranks.
4. Limit the ranking with `most_common(2)`.

⚠ Common Mistakes

- Splitting from the left grabs the referrer field instead of the user-agent.
- Treating slightly different version strings as the same agent needs normalising first.
- `most_common()` ties break by first-seen order, not alphabetically.

Skills gained Counter | user-agent | ranking

→ Where You'll Use This: A top-agents table quickly exposes aggressive scrapers or unexpected bots that may be eating crawl budget or skewing your analytics.

⚡ Mental Model

Like a bouncer's headcount of who came through the door most often, by face rather than by category.

Project 443 Tally Requests by Status Class

💡 The Idea Behind It

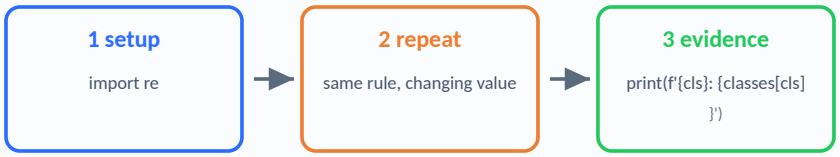
Individual status codes are noisy, so grouping them into 2xx, 3xx, 4xx and 5xx classes gives a cleaner read on crawl health. This project parses each code, computes its class label with integer division by 100 plus the xx suffix, and increments a Counter under that label. Printing the classes in sorted order collapses dozens of codes into four meaningful buckets.

What You'll Build & Learn

Roll individual status codes up into their hundreds class and count each class.

- integer division to find a class
- f-string class labels
- Counter accumulation in a loop

🧭 Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 442: rank the top user-agents. Project 444 changes the surface problem while preserving the underlying method. *progress check*

Reading target: tally requests by status class is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{cls}: {classes[cls]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Code Reading Stack

Layer	What to read
Intent	Tally Requests by Status Class: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, classes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: for ln in lines: | Evidence: print(f'{cls}: {classes[cls]}')

🛠️ Reader to Writer Bridge

1. Read: explain tally requests by status class in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 442.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 444 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{cls}: {classes[cls]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of tally requests by status class and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Integer-dividing the code by 100 yields its class digit, and an f-string like `f'{code // 100}xx'` labels each bucket for the Counter.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 301 0 "-" "B"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 404 9 "-" "B"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 503 9 "-" "B"',
```

```
]
classes = Counter()
for ln in lines:
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    classes[f'{code // 100}xx'] += 1
for cls in sorted(classes):
    print(f'{cls}: {classes[cls]}')
```

```
output
2xx: 2
3xx: 1
4xx: 1
5xx: 1
```

How it works:

1. Five lines span 200, 301, 404 and 503 codes.
2. An empty Counter named classes is created up front.
3. For each line the code is parsed to int, then code // 100 plus 'xx' builds labels like 2xx.
4. The matching class label is incremented, and sorted classes print with their counts.

Try it:

1. Print each class as a percentage of all hits.
2. Add a 1xx informational line and confirm a new 1xx bucket appears.
3. Flag the run as unhealthy when the 5xx class exceeds a threshold.
4. Add a 503 line and watch the 5xx bucket grow.

⚠ Common Mistakes

- Using string slicing `str(code)[0]` instead of `// 100` breaks on any non-three-digit code.
- Forgetting the `xx` label makes the buckets look like raw codes.
- Not sorting the class keys reorders the buckets between runs.

Skills gained integer division | Counter | status classes

→ Where You'll Use This: Status-class summaries are how dashboards report site health at a glance, separating successful responses from redirects, client errors and server faults.

Mental Model

Like sorting mail into four pigeonholes by floor number instead of reading every individual apartment address.

Project 444 Measure Crawl Waste From Bot Errors

The Idea Behind It

Crawl waste is budget spent on URLs that return nothing useful, such as a bot fetching a 404 or chasing a redirect. This project isolates bot lines, parses each status, and counts a line as wasted when a crawler hit a 404 or any 3xx code. It prints both total bot hits and wasted hits, putting a hard number on a leak that quietly drains crawl budget.

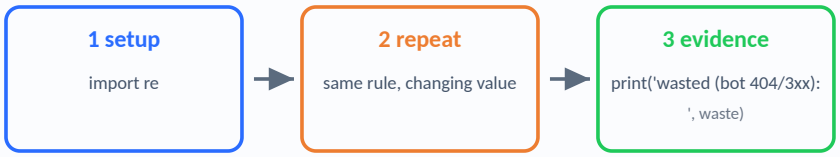
What You'll Build & Learn

Count how many bot requests landed on 404s or redirects, quantifying wasted crawl.

- combining bot and status filters
- redirect range test 300 to 400
- counting under two conditions

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 443: tally requests by status class. Project 445 changes the surface problem while preserving the underlying method.



progress check

Reading target: measure crawl waste from bot errors is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('wasted (bot 404/3xx):', waste)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if any(b in ua for b in bots) and (code == 404 or 300 <= code < 400):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('wasted (bot 404/3xx):', waste)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(b in ua for b in bots) and (code == 404 or 300 <= code < 400):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Crawl Waste From Bot Errors: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, Googlebot, Firefox, bingbot. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if any(b in ua for b in bots) and (code == 404 or 300 <= code < 400): | Evidence: print('wasted (bot 404/3xx):', waste)

🛠️ Reader to Writer Bridge

1. Read: explain measure crawl waste from bot errors in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 443.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 445 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('wasted (bot 404/3xx):', waste)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure crawl waste from bot errors and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A hit counts as waste when the user-agent is a bot and the status is 404 or in the 3xx range, combining the bot test with a status-class check.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 404 9 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 301 0 "-" "Googlebot/2.1"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 1 "-" "Firefox/120"',
```

```
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 404 9 "-" "bingbot/2.0"',
]
bots = ('googlebot', 'bingbot')
waste = 0
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    if any(b in ua for b in bots) and (code == 404 or 300 <= code < 400):
        waste += 1
print('bot hits:', sum(1 for ln in lines if any(b in ln.lower() for b in
bots)))
print('wasted (bot 404/3xx):', waste)
```

```
output
bot hits: 4
wasted (bot 404/3xx): 3
```

How it works:

1. Five lines mix Googlebot, bingbot and Firefox hits with 200, 404 and 301 codes.
2. Each loop pass extracts the lowercased user-agent and parses the status to int.
3. A hit counts as waste when any() finds a bot marker and the code is 404 or sits in the 3xx range.
4. Total bot hits and the wasted count are both printed.

Try it:

1. Treat 5xx server errors as waste too and recount.
2. Print the waste figure as a percentage of bot hits.
3. Collect the wasted paths into a list so you know which URLs to fix.
4. Print the waste as a percentage of bot hits.

⚠ Common Mistakes

- Counting 3xx as waste is debatable: a single redirect is normal, chains are the real smell.
- Testing `code == 300` misses 301 and 302; the range `300 <= code < 400` is required.
- Including human 404s in the waste count answers a different question than crawl budget.

Skills gained filtering | crawl waste | conditions

→ Where You'll Use This: Quantifying wasted crawl makes the case for fixing dead links and redirect chains, the single biggest lever on how efficiently bots index your real pages.

Mental Model

It is like tracking how many delivery trips ended at a wrong or empty address: every one is fuel burned for no parcel delivered.

Project 445 Catch Bot Hits to Disallowed Paths

The Idea Behind It

When a bot crawls a path your robots file disallows, like /admin or /cart, either the rule is being ignored or the crawler is impolite, and either way it wastes budget. This project filters lines down to bot hits whose extracted path begins with a disallowed prefix, then prints each offending crawl. It combines user-agent detection with prefix matching against a disallow tuple.

What You'll Build & Learn

Flag bot requests that hit paths your robots rules are supposed to block.

- str.startswith for prefix rules
- combining bot and path filters
- tuple of disallowed prefixes

Skill Roadmap

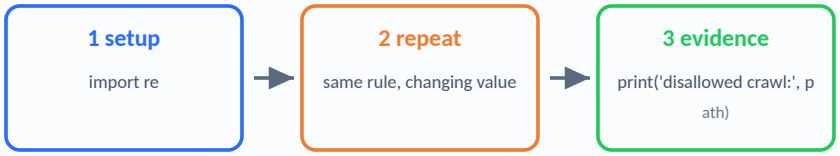
Skill step: moves you from recognition toward independent tracing. It builds on Project 444: measure crawl waste from bot errors. Project 446 changes the surface problem while preserving the underlying method.

progress check

Reading target: catch bot hits to disallowed paths is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('disallowed crawl:', path)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if any(b in ua for b in bots) and any(path.startswith(d) for d in disallow):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('disallowed crawl:', path)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(b in ua for b in bots) and any(path.startswith(d) for d in disallow):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Catch Bot Hits to Disallowed Paths: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, Googlebot, admin. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if any(b in ua for b in bots) and any(path.startswith(d) for d in disal... | Evidence: print('disallowed crawl:', path)

🛠️ Reader to Writer Bridge

1. Read: explain catch bot hits to disallowed paths in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 444.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 446 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('disallowed crawl:', path)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of catch bot hits to disallowed paths and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each bot hit, `path.startswith(prefix)` against a tuple of disallowed prefixes flags any crawl that should have been blocked.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /admin/x HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /cart HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.4 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
]
```

```
disallow = ('/admin', '/cart')
bots = ('googlebot', 'bingbot')
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if any(b in ua for b in bots) and any(path.startswith(d) for d in
disallow):
        print('disallowed crawl:', path)
```

```
output
disallowed crawl: /admin/x
disallowed crawl: /cart
```

How it works:

1. Four lines include Googlebot and bingbot hits to /home, /admin/x, /cart and /blog.
2. disallow lists the prefixes /admin and /cart, and bots lists the crawler markers.
3. Each pass extracts the lowercased agent and the request path.
4. When any() confirms a bot and any path.startswith matches a disallowed prefix, the path prints as a disallowed crawl.

Try it:

1. Add /checkout to the disallowed prefixes and retest.
2. Print the offending bot's user-agent alongside each path.
3. Count the disallowed crawls instead of printing each one.
4. Add `/private` to the disallow tuple and a matching hit.

⚠ Common Mistakes

- Using `==` instead of `startswith` misses sub-paths like /admin/login under a /admin rule.
- Not lowercasing the user-agent misses `Googlebot` when matching against `googlebot`.
- A disallow prefix without a leading slash matches unintended substrings of the path.

Skills gained startswith robots rules filtering

→ Where You'll Use This: Catching bots inside disallowed areas validates your robots.txt and reveals sensitive sections leaking into crawl paths, a recurring technical-SEO audit task.

Mental Model

Like a security guard noticing a visitor wandering into rooms marked staff-only despite the sign on the door.

Project 446 List the 404s Googlebot Hit

The Idea Behind It

A 404 that Googlebot fetched is a known dead link search engines already have on file, so listing those paths yields a precise repair queue. This project filters lines to those where the user-agent contains googlebot and the parsed status equals 404, appending each path to a list. Sorting and printing the collected paths gives an actionable, deduplicatable record of broken URLs Google has seen.

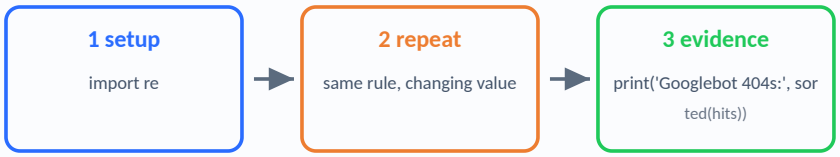
What You'll Build & Learn

Collect and list every path where Googlebot received a 404 response.

- combining agent and exact-code filters
- appending matches to a list
- sorting collected paths

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 445: catch bot hits to disallowed paths. Project 447 changes the surface problem while preserving the underlying method.



progress check

Reading target: list the 404s googlebot hit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('Googlebot 404s:', sorted(hits))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if 'googlebot' in ua and code == 404:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('Googlebot 404s:', sorted(hits))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if 'googlebot' in ua and code == 404:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	List the 404s Googlebot Hit: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, Googlebot, gone. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if 'googlebot' in ua and code == 404: | Evidence: print('Googlebot 404s:', sorted(hits))

🛠️ Reader to Writer Bridge

1. Read: explain list the 404s googlebot hit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 445.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 447 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('Googlebot 404s:', sorted(hits))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of list the 404s googlebot hit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering hits where the user-agent contains 'googlebot' and the status equals 404 isolates the dead URLs Google still tries to crawl.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /gone HTTP/1.1" 404 9 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /missing HTTP/1.1" 404 9 "-" "bingbot/2.0"',
    '1.1.1.4 - - [...] "GET /old HTTP/1.1" 404 9 "-" "Googlebot/2.1"',
]
```

```
hits = []
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if 'googlebot' in ua and code == 404:
        hits.append(path)
print('Googlebot 404s:', sorted(hits))
```

```
output
Googlebot 404s: ['/gone', '/old']
```

How it works:

1. Four lines include Googlebot and bingbot hits with both 200 and 404 codes.
2. An empty list named hits is created.
3. Each pass extracts the lowercased agent, the integer status and the path.
4. When the agent contains googlebot and the code is exactly 404, the path is appended, and sorted hits prints at the end.

Try it:

1. Include bingbot 404s and label which crawler hit each path.
2. Deduplicate the list with a set before printing.
3. Also capture 410 Gone responses in the same pass.
4. Include bingbot by widening the user-agent test.

⚠ Common Mistakes

- Sorting the result is needed for stable output; a raw list follows log order.
- Matching status as a string `== '404'` works only if you never converted to int elsewhere.
- Counting every 404 ignores the question, which is specifically Googlebot's 404s.

Skills gained filtering lists 404 audit

→ **Where You'll Use This:** A Googlebot 404 list is a direct to-do for the SEO team: each path either needs a redirect, a restored page, or removal from internal links.

Mental Model

It is a list of addresses where the postman keeps finding the house demolished, handed straight to the maintenance crew.

Project 447 Count the Unique Paths Crawled

The Idea Behind It

The count of distinct URLs in a log measures crawl breadth, how widely bots and users roam the site. This project collects every parsed path into a set comprehension, which discards repeats automatically, then prints the set size and the sorted unique paths. It contrasts with earlier Counter work by caring about presence rather than frequency.

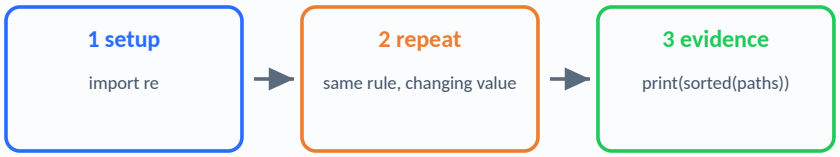
What You'll Build & Learn

Count the distinct URL paths that appear in the log and list them.

- set comprehension for uniqueness
- len of a set
- sorting a set for display

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 446: list the 404s googlebot hit. Project 448 changes the surface problem while preserving the underlying method.



progress check

Reading target: count the unique paths crawled is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(sorted(paths))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`paths = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(sorted(paths))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `paths = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count the Unique Paths Crawled: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, blog, shop. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: paths = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines} | Evidence: print(sorted(paths))

🛠️ Reader to Writer Bridge

1. Read: explain count the unique paths crawled in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 446.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 448 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(sorted(paths))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count the unique paths crawled and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A set comprehension over the parsed paths drops duplicates, so its length is the count of unique URLs touched.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.3 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [...] "GET /shop HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "B"',
```

```
]
paths = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}
print('unique paths:', len(paths))
print(sorted(paths))
```

```
output
unique paths: 3
['/blog', '/home', '/shop']
```

How it works:

1. Five lines repeat /home, /blog and /shop with duplicates.
2. A set comprehension runs re.search on each line and keeps only group(1), automatically dropping repeats.
3. len(paths) gives the number of unique paths.
4. sorted(paths) prints the distinct URLs in order.

Try it:

1. Compare the unique count to the total line count to gauge repetition.
2. Strip query strings before adding paths so variants collapse.
3. Print which paths appear only once versus many times.
4. Add a duplicate `/home` hit and confirm the unique count does not change.

⚠ Common Mistakes

- Using a list keeps duplicates, so `len` overstates the unique count.
- Printing the set directly is nondeterministic; sort it first.
- Counting request lines instead of paths treats two methods on one URL as two URLs.

Skills gained sets uniqueness regex

→ Where You'll Use This: Crawl breadth tells you how much of a large site bots actually reach; a low unique-path count on a big site signals discoverability problems.

Mental Model

Like counting how many different rooms a tour group visited, no matter how many times anyone walked back through the same door.

Project 448 Report Crawl Frequency per URL

The Idea Behind It

Beyond raw counts, the share of total hits each URL receives shows where crawl attention truly concentrates. This project tallies paths with a Counter, sums the values to get a grand total, then prints each path's hit count

alongside its percentage of all hits. Converting counts to percentages turns a frequency table into a clear per-URL slice of the crawl pie.

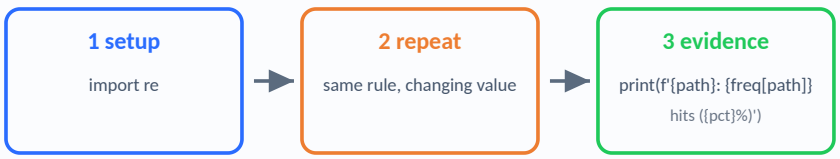
What You'll Build & Learn

Report each URL's hit count and its percentage share of total crawl activity.

- summing Counter values for a total
- percentage of a part to a whole
- formatted percentage output

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 447: count the unique paths crawled. Project 449 changes the surface problem while preserving the underlying method.



progress check

Reading target: report crawl frequency per url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{path}: {freq[path]} hits ({pct}%)')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`freq = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {freq[path]} hits ({pct}%)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `freq = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Report Crawl Frequency per URL: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, home. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: freq = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lin... | Evidence: print(f'{path}: {freq[path]} hits ({pct}%)')

Reader to Writer Bridge

1. Read: explain report crawl frequency per url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 447.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 449 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {freq[path]} hits ({pct}%)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of report crawl frequency per url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

From Concept to Code (Python)

Dividing each path's count by the summed total and multiplying by 100 gives its percentage share, rounded for clean output.

```python
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.3 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [...] "GET /shop HTTP/1.1" 200 1 "-" "B"',
]
freq = Counter(re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines)
total = sum(freq.values())
for path in sorted(freq):
    pct = round(100 * freq[path] / total, 1)
    print(f'{path}: {freq[path]} hits ({pct}%)')
```

```
output
/blog: 1 hits (20.0%)
/home: 3 hits (60.0%)
/shop: 1 hits (20.0%)
```

How it works:

1. Five lines give /home three hits and /blog and /shop one each.
2. A Counter named freq tallies the extracted paths.
3. sum(freq.values()) computes the grand total of hits.
4. For each sorted path, the share is computed as 100 times count over total, rounded, and printed with the count.

Try it:

1. Sort the output by descending percentage instead of by path.
2. Add a cumulative percentage column to see how few URLs cover most hits.
3. Round the percentages to two decimal places for precision.
4. Sort the report by share descending.

⚠ Common Mistakes

- Dividing by `len(freq)` (number of URLs) instead of total hits gives the wrong denominator.
- Integer division would floor every percentage to 0; the counts must be floats here.
- Not rounding prints long repeating decimals like 33.33333.

Skills gained `percentages` `Counter` `reporting`

→ **Where You'll Use This:** Percentage shares make crawl reports comparable across sites of different sizes and reveal when one page hogs a disproportionate slice of attention.

Mental Model

It turns a stack of tally marks into pie slices, so you can see at a glance which page eats the biggest wedge.

Project 449 Find Crawled URLs Off the Sitemap

The Idea Behind It

A bot crawling URLs absent from your sitemap may be chasing junk: faceted parameters, old links, or pages you forgot to list. This project builds a set of crawled paths and a set of sitemap URLs, then uses set subtraction to find paths that were crawled but never declared. The off-sitemap result points straight at URLs that may be wasting crawl or hint at gaps in your sitemap.

What You'll Build & Learn

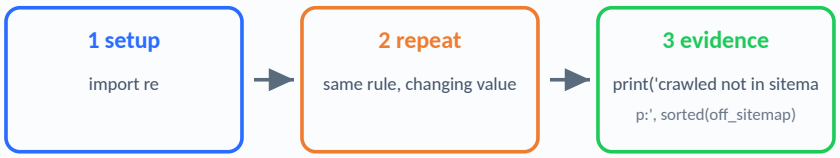
Find crawled URLs that do not appear in your sitemap using set subtraction.

- set difference with the minus operator
- building a crawled-path set

- comparing log to sitemap

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 448: report crawl frequency per url. Project 450 changes the surface problem while preserving the underlying method.



progress check

Reading target: find crawled urls off the sitemap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('crawled not in sitemap:', sorted(off_sitemap))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Crawled URLs Off the Sitemap: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, Googlebot, ghost. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines} | Evidence: print('crawled not in sitemap:', sorted(off_sitemap))

Reader to Writer Bridge

1. Read: explain find crawled urls off the sitemap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 448.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 450 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('crawled not in sitemap:', sorted(off_sitemap))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find crawled urls off the sitemap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting the sitemap set from the set of crawled paths leaves exactly the URLs that were fetched but never declared in the sitemap.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /ghost HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.4 - - [...] "GET /stale HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
]
sitemap = {'/home', '/blog', '/shop'}
crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}
off_sitemap = crawled - sitemap
print('crawled not in sitemap:', sorted(off_sitemap))
```

```
output
crawled not in sitemap: ['/ghost', '/stale']
```

How it works:

1. Four lines include Googlebot and bingbot hits to /home, /ghost, /blog and /stale.
2. sitemap is a literal set of declared URLs.
3. crawled is a set comprehension of every parsed path from the log.
4. crawled minus sitemap yields off_sitemap, which prints sorted as the URLs crawled but not listed.

Try it:

1. Swap the operands to instead list sitemap URLs never crawled.
2. Restrict the crawled set to only bot hits before comparing.

3. Print how many off-sitemap URLs were found, not just the list.
4. Add `/ghost` to the sitemap and watch it drop off the list.

⚠ Common Mistakes

- Subtracting in the wrong order returns sitemap-only URLs, a different report.
- Comparing lists instead of sets makes the `-` operator fail.
- Not sorting the difference makes the output order vary.

Skills gained set difference | sitemap | crawl audit

→ Where You'll Use This: Comparing crawl logs against the sitemap surfaces orphaned or stray URLs that dilute crawl budget and may not belong in the index at all.

Mental Model

It is checking the guest list against who actually walked in: the difference is the gatecrashers nobody invited.

Project 450 Break Down the HTTP Method Mix

The Idea Behind It

GET dominates crawl traffic, but a flood of POST or HEAD requests can signal forms being probed or uptime monitors at work. This project captures the HTTP method, the first token after the opening quote, with a tight regex and feeds it into a Counter. Printing the methods in sorted order reveals the request mix and any unusual verb activity worth investigating.

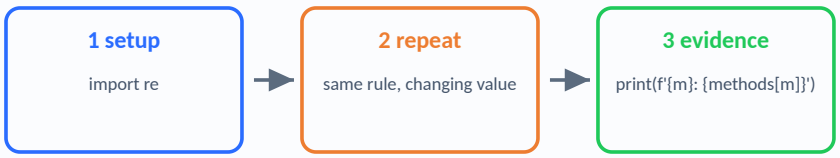
What You'll Build & Learn

Break down the log by HTTP method and count how often each verb is used.

- capturing the leading method token
- Counter over methods
- sorted method output

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 449: find crawled urls off the sitemap. Project 451 changes the surface problem while preserving the underlying method.



progress check

Reading target: break down the http method mix is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{m}: {methods[m]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

Evidence	Entry: import re | Core: methods = Counter(re.search(r'"(\S+) ', ln).group(1) for ln in lines) | Evidence: print(f'{m}: {methods[m]}')

🛠️ Reader to Writer Bridge

1. Read: explain break down the http method mix in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 449.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 451 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{m}: {methods[m]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of break down the http method mix and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`'"(\S+) ` captures the leading method token inside the quoted request, and a `Counter` tallies how often each verb appears.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "POST /login HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.3 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [...] "HEAD /ping HTTP/1.1" 200 0 "-" "B"',
    '1.1.1.5 - - [...] "GET /shop HTTP/1.1" 200 1 "-" "B"',
]
methods = Counter(re.search(r'"(\S+) ', ln).group(1) for ln in lines)
for m in sorted(methods):
    print(f'{m}: {methods[m]}')
```

```
output
GET: 3
HEAD: 1
POST: 1
```

How it works:

1. Five lines use GET three times plus one POST and one HEAD.
2. A Counter is built from a generator that matches the opening quote and captures the method token.
3. Counter tallies each distinct verb.
4. Iterating sorted(methods) prints each method with its count.

Try it:

1. Flag a warning when POST requests exceed a chosen share of traffic.
2. Add a DELETE line and confirm it gets its own bucket.
3. Print methods ranked by count rather than alphabetically.
4. Add a DELETE line and watch a new bucket appear.

⚠ Common Mistakes

- Capturing the path by mistake counts URLs, not methods.
- Lowercase methods would split GET from get; logs normally keep them uppercase.
- Not sorting the method keys reorders the breakdown between runs.

Skills gained `regex` `Counter` `HTTP methods`

→ **Where You'll Use This:** Method breakdowns help spot scraping, form abuse or monitoring traffic that inflates request volume without representing genuine page demand.

⚡ Mental Model

Like sorting incoming requests by the kind of action they ask for, GET to read, POST to submit, HEAD to peek at the headers.

Project 451 Detect a Crawl Spike by the Minute

💡 The Idea Behind It

A sudden burst of requests in one minute can mean a crawler went rogue or a page got hammered. This project parses each timestamp with strptime, buckets hits by the HH:MM minute via strftime, and counts them in a Counter. Each minute prints with a SPIKE flag when its count exceeds a threshold, turning raw timestamps into a simple anomaly detector.

What You'll Build & Learn

Bucket log hits by the minute and flag any minute that exceeds a request threshold.

- strptime to parse log timestamps
- bucketing by minute with strftime
- threshold flagging

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 450: break down the http method mix. Project 452 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a crawl spike by the minute is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from datetime import datetime` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

- Evidence: `print(f'{minute}: {per_min[minute]}{flag}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from datetime import datetime`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`flag = ' SPIKE' if per_min[minute] > threshold else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{minute}: {per_min[minute]}{flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = ' SPIKE' if per_min[minute] > threshold else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Crawl Spike by the Minute: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: datetime, collections, Counter, lines, Jun. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from datetime import datetime | Core: flag = ' SPIKE' if per_min[minute] > threshold else '' | Evidence: print(f'{minute}: {per_min[minute]}{flag}')

🛠️ Reader to Writer Bridge

1. Read: explain detect a crawl spike by the minute in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 450.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 452 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{minute}: {per_min[minute]}{flag}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `from datetime import datetime` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a crawl spike by the minute and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`datetime.strptime` parses the bracketed timestamp, `strftime('%H:%M')` buckets each hit by minute, and a count over the threshold is flagged a spike.

```
from datetime import datetime
from collections import Counter
lines = [
    '1.1.1.1 - - [22/Jun/2026:10:00:01 +0000] "GET /a HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [22/Jun/2026:10:00:30 +0000] "GET /b HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.3 - - [22/Jun/2026:10:00:45 +0000] "GET /c HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [22/Jun/2026:10:00:55 +0000] "GET /d HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [22/Jun/2026:10:01:10 +0000] "GET /e HTTP/1.1" 200 1 "-" "B"',
]
per_min = Counter()
for ln in lines:
    raw = ln.split('[')[1].split()[0]
    t = datetime.strptime(raw, '%d/%b/%Y:%H:%M:%S')
    per_min[t.strftime('%H:%M')] += 1
threshold = 3
for minute in sorted(per_min):
    flag = ' SPIKE' if per_min[minute] > threshold else ''
    print(f'{minute}: {per_min[minute]}{flag}')
```

```
output
10:00: 4 SPIKE
10:01: 1
```

How it works:

1. Five lines fall mostly in 10:00 with one at 10:01.
2. The timestamp is sliced out between the bracket and the space, then parsed by strptime with the log format string.
3. strftime formats it to HH:MM and that minute key is incremented in per_min.
4. Each sorted minute prints its count, appending SPIKE when the count tops the threshold of three.

Try it:

1. Lower the threshold to two and watch more minutes flag.
2. Bucket by ten-second windows to catch sharper bursts.
3. Only count bot hits when deciding whether a minute spikes.
4. Lower the threshold to 2 and watch more buckets flag.

⚠ Common Mistakes

- Using `datetime.now` is forbidden and wrong here; the timestamps come from the log itself.
- Bucketing by `%H` (hour) instead of `%H:%M` hides minute-level bursts.
- Comparing `>=` instead of `>` flags a bucket exactly at the threshold.

Skills gained `datetime` `bucketing` `anomaly flag`

→ **Where You'll Use This:** Per-minute spike detection catches runaway crawlers and traffic floods early, before they exhaust crawl budget or knock the server over.

⚡ Mental Model

Like a seismograph for traffic: most minutes draw a flat line, and a spike is the tremor that makes you look.

Project 452 Count Requests per Bot Type

💡 The Idea Behind It

Different crawlers have different appetites, so attributing each hit to a named bot shows whether Googlebot, bingbot or a scraper does the work. This project loops over a tuple of known bot names and, for each line, increments a Counter under whichever name appears in the lowercased user-agent. Printing the per-bot counts gives a clear breakdown of who is crawling and how hard.

What You'll Build & Learn

Attribute each bot hit to a specific named crawler and count them per bot.

- matching against a list of bot names
- nested loop over known bots
- Counter keyed by bot name

🧭 Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 451: detect a crawl spike by the minute. Project 453 changes the surface problem while preserving the underlying method.

progress check

`Reading target:` count requests per bot type is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` A nested loop means `outer choice` plus `inner repeated work`. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- `Writing move:` this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

- Evidence: `print(f'{bot}: {counts[bot]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if bot.lower() in ua.lower():`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{bot}: {counts[bot]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if bot.lower() in ua.lower():`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Requests per Bot Type: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: collections, Counter, lines, Mozilla, compatible. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: if bot.lower() in ua.lower(): | Evidence: print(f'{bot}: {counts[bot]}')

🛠️ Reader to Writer Bridge

1. Read: explain count requests per bot type in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 451.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 453 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{bot}: {counts[bot]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count requests per bot type and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each line the user-agent is tested against a tuple of known bot names, and the first matching name increments its Counter bucket.

```
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
Googlebot/2.1)"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
bingbot/2.0)"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
Googlebot/2.1)"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
AhrefsBot/7.0)"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 200 1 "-" "Mozilla/5.0 (compatible;
Googlebot/2.1)"',
]
known = ('Googlebot', 'bingbot', 'AhrefsBot')
counts = Counter()
for ln in lines:
    ua = ln.rsplit('"', 2)[1]
    for bot in known:
        if bot.lower() in ua.lower():
            counts[bot] += 1
for bot in sorted(counts):
    print(f'{bot}: {counts[bot]}')
```

```
output
AhrefsBot: 1
Googlebot: 3
bingbot: 1
```

How it works:

1. Five lines feature Googlebot, bingbot and AhrefsBot agents.
2. known holds the three bot names and an empty Counter is created.
3. For each line the user-agent is isolated, then an inner loop checks each known bot name in lowercase.
4. The matching bot name is incremented, and sorted counts print per bot.

Try it:

1. Add a bucket for unknown agents that match none of the known bots.
2. Extend the known list with YandexBot and DuckDuckBot.
3. Print each bot's share of total bot hits as a percentage.
4. Add a `YandexBot` line and extend the known tuple.

⚠ Common Mistakes

- A user-agent matching two names (rare) would be counted twice without a break.
- Case-sensitive matching misses `Googlebot` when the known list is lowercase.

- Not sorting the bot keys reorders the per-bot report.

Skills gained `Counter` `bot attribution` `nested loops`

→ Where You'll Use This: Naming each crawler tells you which search engines value your site and which third-party scrapers are quietly consuming resources you may want to throttle.

Mental Model

It is a visitor log at reception that records not just that a courier came, but which delivery company they worked for.

Project 453 Average Response Size by Status

The Idea Behind It

A 200 should carry a real payload while a 404 should be tiny, so averaging bytes per status code surfaces bloated error pages or empty success responses. This project captures both code and bytes in one regex, groups byte sizes into a defaultdict of lists keyed by status, then prints the mean size for each code. Grouping numeric values by a category and averaging is a core analysis pattern.

What You'll Build & Learn

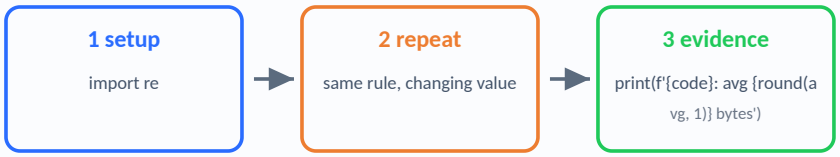
Group response sizes by status code and report the average bytes for each code.

- defaultdict of lists for grouping
- capturing two fields in one regex
- computing a mean per group

Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 452: count requests per bot type. Project 454 changes the surface problem while preserving the underlying method.

progress check



`Reading target:` average response size by status is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- `Setup:` `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated library calls.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{code}: avg {round(avg, 1)} bytes')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`for ln in lines:`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print(f'{code}: avg {round(avg, 1)} bytes')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for ln in lines:`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Average Response Size by Status: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, defaultdict, lines, sizes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: for ln in lines: | Evidence: print(f'{code}: avg {round(avg, 1)} bytes')

🛠️ Reader to Writer Bridge

1. Read: explain average response size by status in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 452.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 454 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: avg {round(avg, 1)} bytes')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of average response size by status and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Grouping byte counts into a `defaultdict(list)` keyed by status code lets you average each group, exposing how heavy each response class is.

```
import re
from collections import defaultdict
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1000 "-" "B"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 2000 "-" "B"',
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 404 150 "-" "B"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 3000 "-" "B"',
    '1.1.1.5 - - [...] "GET /e HTTP/1.1" 404 250 "-" "B"',
]
sizes = defaultdict(list)
for ln in lines:
    code, nbytes = re.search(r'" (\d{3}) (\d+) ', ln).groups()
    sizes[int(code)].append(int(nbytes))
for code in sorted(sizes):
    avg = sum(sizes[code]) / len(sizes[code])
    print(f'{code}: avg {round(avg, 1)} bytes')
```

```
output
200: avg 2000.0 bytes
404: avg 200.0 bytes
```

How it works:

1. Five lines pair 200 and 404 codes with various byte sizes.
2. A defaultdict(list) named sizes is created.
3. One regex captures the status and byte fields together, and each byte value is appended to the list under its integer code.
4. For each sorted code, the average of its list prints rounded as bytes.

Try it:

1. Also print the maximum byte size seen for each status code.
2. Add a 200 line with zero bytes and watch the average shift.
3. Group by status class such as 2xx instead of exact code.
4. Print the max byte size per status alongside the average.

⚠ Common Mistakes

- Dividing by `len(lines)` instead of the per-code count gives the wrong average.
- Capturing only the status and not the bytes leaves nothing to average.
- Printing the raw float without `round` yields noisy decimals.

Skills gained `defaultdict` `averaging` `grouping`

→ **Where You'll Use This:** Average size by status flags error pages that are surprisingly heavy or success pages returning almost nothing, both worth investigating for performance and SEO.

Mental Model

Like weighing every parcel and then reporting the average weight per shipping label, so an oddly heavy category stands out.

Project 454 Find the Busiest Hour

The Idea Behind It

Knowing your peak traffic hour helps schedule deploys away from it and spot crawler activity windows. This project parses each timestamp, buckets hits by the integer hour into a Counter, then picks the busiest hour with max using the count as the key. It prints that hour formatted with leading zeros and its hit total, demonstrating how to find an argmax over a frequency table.

What You'll Build & Learn

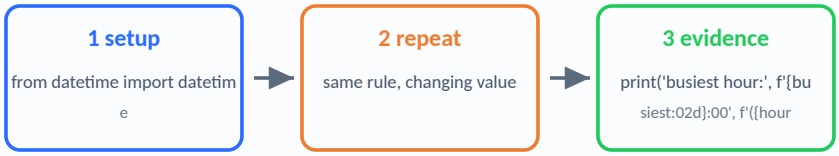
Find the hour of day with the most log hits and print it with its count.

- bucketing by the hour attribute
- max with a key function
- zero-padded hour formatting

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 453: average response size by status. Project 455 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find the busiest hour is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `from datetime import datetime` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('busiest hour:', f'{busiest:02d}:00', f'({hours[busiest]} hits)')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from datetime import datetime`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`for ln in lines:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('busiest hour:', f'{busiest:02d}:00', f'({hours[busiest]} hits)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for ln in lines:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find the Busiest Hour: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: datetime, collections, Counter, lines, Jun. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from datetime import datetime | Core: for ln in lines: | Evidence: print('busiest hour:', f'{busiest:02d}:00', f'({hours[busiest]} hits)')

🛠️ Reader to Writer Bridge

1. Read: explain find the busiest hour in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 453.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 455 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('busiest hour:', f'{busiest:02d}:00', f'({hours[busiest]} hits)')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `from datetime import datetime` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find the busiest hour and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`strptime(...).hour` extracts the hour from each parsed timestamp; `max` over the sorted hours with a count key returns the busiest one deterministically.

```
from datetime import datetime
from collections import Counter
lines = [
    '1.1.1.1 - - [22/Jun/2026:09:14:00 +0000] "GET /a HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [22/Jun/2026:10:01:00 +0000] "GET /b HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.3 - - [22/Jun/2026:10:30:00 +0000] "GET /c HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [22/Jun/2026:10:55:00 +0000] "GET /d HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [22/Jun/2026:11:02:00 +0000] "GET /e HTTP/1.1" 200 1 "-" "B"',
]
hours = Counter()
for ln in lines:
    raw = ln.split('[')[1].split()[0]
    hours[datetime.strptime(raw, '%d/%b/%Y:%H:%M:%S').hour] += 1
busiest = max(sorted(hours), key=lambda h: hours[h])
print('busiest hour:', f'{busiest:02d}:00', f'({hours[busiest]} hits)')
```

```
output
busiest hour: 10:00 (3 hits)
```

How it works:

1. Five lines span the 09, 10 and 11 hours, with three in the 10 hour.
2. Each timestamp is sliced out and parsed by strptime, and its .hour attribute increments the hours Counter.
3. max over sorted(hours) with a key of hours[h] returns the hour with the highest count.
4. That busiest hour prints zero-padded as HH:00 with its hit total.

Try it:

1. Print the three busiest hours instead of only the top one.
2. Restrict the count to bot hits to find the peak crawl hour.
3. Bucket by day and hour together for a multi-day log.
4. Print every hour with its hit count, not just the peak.

⚠ Common Mistakes

- Calling `max` over the unsorted Counter makes ties resolve unpredictably.
- Taking `max` of the counts loses which hour they belong to.
- Parsing with the wrong format string raises ValueError on the bracketed timestamp.

Skills gained `datetime` `argmax` `Counter`

→ Where You'll Use This: Peak-hour analysis guides maintenance windows and reveals when search engines crawl most, helping you ensure servers respond fast during critical times.

⚡ Mental Model

Like asking a shop when its busiest hour is so you avoid restocking the shelves while customers are crowding the aisles.

Project 455 Track First and Last Seen per Path

💡 The Idea Behind It

When a URL first and last appeared in the log bounds its activity window, telling you whether a page is freshly crawled or has gone quiet. This project keeps a dict mapping each path to a (first, last) tuple, updating it per line with min and max against the parsed timestamp. Printing the window per path shows each URL's span of activity in a compact form.

What You'll Build & Learn

Track the first and last time each URL path was seen in the log.

- dict.get with a default tuple
- min and max to widen a window
- per-key state updates in a loop

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 454: find the busiest hour. Project 456 changes the surface problem while preserving the underlying method. *progress check*

Reading target: track first and last seen per path is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{path}: {f.strftime("%H:%M")} -> {l.strftime("%H:%M")}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`for ln in lines:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {f.strftime("%H:%M")} -> {l.strftime("%H:%M")}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for ln in lines:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Track First and Last Seen per Path: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, datetime, lines, Jun, home. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: for ln in lines: | Evidence: print(f'{path}: {f.strftime("%H:%M")} -> {l.strftime("%H:%M")}')

🛠️ Reader to Writer Bridge

1. Read: explain track first and last seen per path in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 454.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 456 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {f.strftime("%H:%M")} -> {l.strftime("%H:%M")}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of track first and last seen per path and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each path the running min and max of its parsed timestamps are kept in a dict, so the final pair is the page's first and last appearance.

```
import re
from datetime import datetime
lines = [
    '1.1.1.1 - - [22/Jun/2026:10:00:00 +0000] "GET /home HTTP/1.1" 200 1 "-"
"B"',
    '1.1.1.2 - - [22/Jun/2026:10:05:00 +0000] "GET /blog HTTP/1.1" 200 1 "-"
"B"',
    '1.1.1.3 - - [22/Jun/2026:10:09:00 +0000] "GET /home HTTP/1.1" 200 1 "-"
"B"',
    '1.1.1.4 - - [22/Jun/2026:10:12:00 +0000] "GET /home HTTP/1.1" 200 1 "-"
"B"',
]
seen = {}
for ln in lines:
    raw = ln.split('[')[1].split()[0]
    t = datetime.strptime(raw, '%d/%b/%Y:%H:%M:%S')
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    first, last = seen.get(path, (t, t))
    seen[path] = (min(first, t), max(last, t))
for path in sorted(seen):
    f, l = seen[path]
    print(f'{path}: {f.strftime("%H:%M")} -> {l.strftime("%H:%M")}')
```

```
output
/blog: 10:05 -> 10:05
/home: 10:00 -> 10:12
```

How it works:

1. Four lines hit /home three times and /blog once at different minutes.
2. An empty dict named seen is created.
3. Each line parses its timestamp and path, reads the existing window with seen.get defaulting to (t, t), then stores the min and max against the new time.
4. For each sorted path, the window prints as a start to end time range.

Try it:

1. Also record how many times each path was seen inside its window.

2. Compute and print the duration of each window in minutes.
3. Flag paths whose last-seen time is far behind the others.
4. Print the active span in minutes for each path.

⚠ Common Mistakes

- Initialising the pair to `(t, t)` on first sight is essential; an empty default breaks `min`/`max`.
- Comparing timestamp strings instead of `datetime` objects sorts wrong across hour boundaries.
- Overwriting instead of taking min/max loses the earlier or later time.

Skills gained dict state | datetime | min max

→ Where You'll Use This: First and last seen windows reveal which pages crawlers have stopped revisiting, an early warning that content is going stale in the index.

Mental Model

Like a guestbook that records each room's first and last visitor of the day, bracketing when it was in use.

Project 456 Detect Orphan Sitemap URLs

The Idea Behind It

A sitemap URL that never appears in the log is one search engines may not have crawled yet, an orphan in practice. This project builds a set of crawled paths from the log and subtracts it from the sitemap set, leaving the URLs that were declared but never fetched. The result is the mirror image of the off-sitemap check, pointing at pages that need help getting discovered.

What You'll Build & Learn

Find sitemap URLs that never appear in the crawl log using set subtraction.

- sitemap minus crawled for orphans
- set comprehension from the log
- interpreting an empty intersection

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 455: track first and last seen per path. Project 457 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect orphan sitemap urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('sitemap URLs never crawled:', sorted(orphans))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('sitemap URLs never crawled:', sorted(orphans))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the

behaviour.

CORE LINE `crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Orphan Sitemap URLs: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, Googlebot, blog. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines} | Evidence: print('sitemap URLs never crawled:', sorted(orphans))

🛠️ Reader to Writer Bridge

1. Read: explain detect orphan sitemap urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 455.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 457 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('sitemap URLs never crawled:', sorted(orphans))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect orphan sitemap urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting the set of crawled paths from the sitemap set leaves URLs that were declared but never fetched in this log window.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /home HTTP/1.1" 200 1 "-" "bingbot/2.0"',
]
sitemap = {'/home', '/blog', '/shop', '/about'}
crawled = {re.search(r'"\S+ (\S+) HTTP', ln).group(1) for ln in lines}
orphans = sitemap - crawled
print('sitemap URLs never crawled:', sorted(orphans))
```

```
output
sitemap URLs never crawled: ['/about', '/shop']
```

How it works:

1. Three lines crawl only /home and /blog.
2. sitemap is a literal set of four declared URLs.
3. crawled is a set comprehension of every parsed path.
4. sitemap minus crawled yields orphans, which prints sorted as the sitemap URLs never crawled.

Try it:

1. Count and print how many orphans were found.
2. Restrict the crawled set to Googlebot hits only.
3. Run both directions to print orphans and off-sitemap URLs together.
4. Add a `/shop` hit and watch it leave the orphan list.

⚠ Common Mistakes

- Subtracting the sitemap from the crawled set answers the opposite question.

- A URL crawled with a query string will not match its clean sitemap entry without normalising.
- Not sorting the gap set makes the output order vary.

Skills gained set difference | orphan detection | sitemap

→ Where You'll Use This: Orphan detection highlights pages search engines are ignoring, prompting fixes like better internal linking or resubmitting the sitemap to speed discovery.

⚡ Mental Model

It is checking which invited guests never showed up: the empty chairs are the pages bots have not reached.

Project 457 Pull Redirect Hits From the Log

💡 The Idea Behind It

Redirects in a log, the 301, 302 and 308 codes, show where URLs send visitors and bots elsewhere. This project parses each status and path, then filters to the 3xx class with a range test, printing the redirect code and the path it was served on. Listing every redirect hit makes redirect behaviour visible so you can audit chains and outdated rules.

What You'll Build & Learn

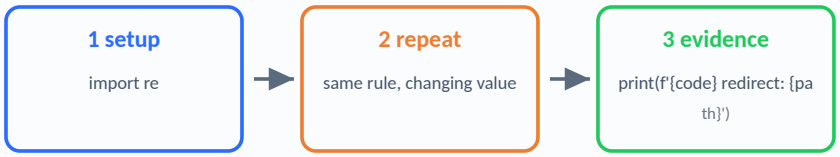
Filter the log to redirect responses and list each redirecting path with its code.

- redirect range test 300 to 400
- extracting code and path together
- filtering inside a loop

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 456: detect orphan sitemap urls. Project 458 changes the surface problem while preserving the underlying method.

progress check



Reading target: pull redirect hits from the log is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{code} redirect: {path}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if 300 <= code < 400:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{code} redirect: {path}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if 300 <= code < 400:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pull Redirect Hits From the Log: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, home, old, www. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if 300 <= code < 400: | Evidence: print(f'{code} redirect: {path}')

🛠️ Reader to Writer Bridge

1. Read: explain pull redirect hits from the log in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 456.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 458 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code} redirect: {path}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of pull redirect hits from the log and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Testing `300 <= code < 400` selects the redirect class, and the captured path names the URL that issued each redirect.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /old HTTP/1.1" 301 0 "-" "B"',
    '1.1.1.3 - - [...] "GET /www HTTP/1.1" 302 0 "-" "B"',
    '1.1.1.4 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.5 - - [...] "GET /moved HTTP/1.1" 308 0 "-" "B"',
]
for ln in lines:
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if 300 <= code < 400:
        print(f'{code} redirect: {path}')
```

```
output
301 redirect: /old
302 redirect: /www
308 redirect: /moved
```

How it works:

1. Five lines mix 200 responses with 301, 302 and 308 redirects.
2. Each pass parses the status to int and extracts the request path.
3. An if test keeps only codes where 300 is at most the code and the code is below 400.
4. Each qualifying line prints its redirect code and path.

Try it:

1. Separate permanent 301 and 308 from temporary 302 in the output.
2. Count how many redirects each path received.
3. Add a 307 line and confirm it is captured by the range.
4. Separate permanent (301/308) from temporary (302/307) redirects.

⚠ Common Mistakes

- Testing `code == 301` alone misses 302, 307 and 308 redirects.
- Treating 304 Not Modified as a redirect is wrong; it is a cache validator even though it is in the 3xx range.

- Matching status as a string skips the numeric range check entirely.

Skills gained `range filter` `redirects` `regex`

→ **Where You'll Use This:** A redirect inventory helps you find chains, loops and leftover temporary 302s that should be permanent, all of which dilute link signals and slow crawling.

Mental Model

Like reading the forwarding stickers on returned mail: each one tells you the old address and that the resident moved on.

Project 458 Spot Oversized Responses

The Idea Behind It

A multi-megabyte image or unminified asset wastes bandwidth and slows crawls, so flagging responses above a byte threshold finds the heavy hitters. This project parses the byte field and path from each line and prints any response larger than a set limit, converting the size to megabytes for readability. It is a simple but powerful filter for performance triage.

What You'll Build & Learn

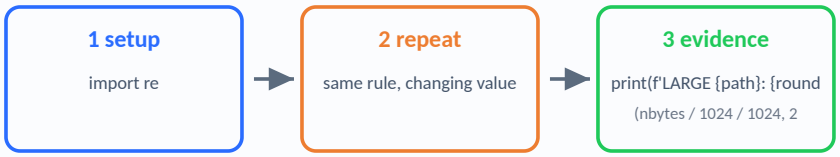
Flag log responses whose size exceeds a byte limit and report them in megabytes.

- thresholding a numeric field
- bytes to megabytes conversion
- extracting bytes and path together

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 457: pull redirect hits from the log. Project 459 changes the surface problem while preserving the underlying method. *progress check*

Reading target: spot oversized responses is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the

most-crawled paths.

- Evidence: `print(f'LARGE {path}: {round(nbytes / 1024 / 1024, 2)} MB')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if nbytes > limit:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'LARGE {path}: {round(nbytes / 1024 / 1024, 2)} MB')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nbytes > limit:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Spot Oversized Responses: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, css, hero, jpg. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if nbytes > limit: | Evidence: print(f'LARGE {path}: {round(nbytes / 1024 / 1024, 2)} MB')

🛠️ Reader to Writer Bridge

1. Read: explain spot oversized responses in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 457.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 459 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'LARGE {path}: {round(nbytes / 1024 / 1024, 2)} MB')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spot oversized responses and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing the parsed byte count to a fixed limit flags large transfers, and dividing by 1024 twice reports the size in megabytes.

```python
import re
lines = [
    '1.1.1.1 - - [...] "GET /a.css HTTP/1.1" 200 4000 "-" "B"',
    '1.1.1.2 - - [...] "GET /hero.jpg HTTP/1.1" 200 920000 "-" "B"',
    '1.1.1.3 - - [...] "GET /b.js HTTP/1.1" 200 30000 "-" "B"',
    '1.1.1.4 - - [...] "GET /video.mp4 HTTP/1.1" 200 5500000 "-" "B"',
]
limit = 500000
for ln in lines:
    nbytes = int(re.search(r'" \d{3} (\d+) ', ln).group(1))
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if nbytes > limit:
        print(f'LARGE {path}: {round(nbytes / 1024 / 1024, 2)} MB')
```

```
output
LARGE /hero.jpg: 0.88 MB
LARGE /video.mp4: 5.25 MB
```

How it works:

1. Four lines list a CSS file, a hero image, a JS file and a video with varying sizes.
2. limit is set to 500000 bytes.
3. Each pass parses the byte count and the path.
4. When the byte count exceeds the limit, the path prints with its size converted to megabytes and rounded.

Try it:

1. Sort the flagged responses from largest to smallest before printing.
2. Lower the limit to 100000 and see more assets flagged.
3. Group oversized hits by file extension to find the worst asset type.
4. Lower the limit to 100 KB and watch more assets flag.

⚠ Common Mistakes

- Using a threshold in bytes but reporting MB without converting confuses the reader.
- Capturing the status instead of the byte field compares the wrong number.
- An integer MB conversion would floor 0.88 MB to 0; keep it a float and round.

Skills gained thresholds | byte conversion | performance

→ Where You'll Use This: Spotting oversized assets drives image compression and minification work, directly improving page speed, a confirmed ranking and crawl-efficiency factor.

Mental Model

Like an airport scale beeping only when a bag tips over the weight limit, so you focus on the few that are too heavy.

Project 459 Compute the Error Rate per Path

The Idea Behind It

Some URLs fail more than others, so dividing error hits by total hits per path ranks pages by how often they break. This project keeps two defaultdicts, one counting all hits and one counting hits with a status of 400 or higher, per path. It then prints each path's error rate as a percentage with the supporting fraction, turning raw counts into a reliability score per URL.

What You'll Build & Learn

Compute and report the percentage of requests that errored for each URL path.

- two parallel defaultdicts
- error test code at least 400
- rate as errors over total

Skill Roadmap

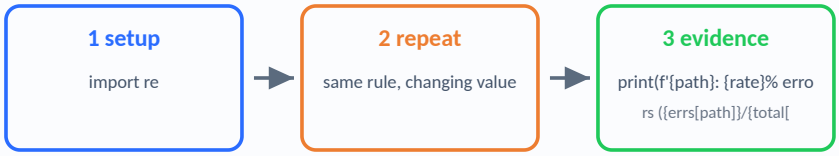
Skill step: pushes the same idea into a less automatic situation. It builds on Project 458: spot oversized responses. Project 460 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute the error rate per path is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print(f'{path}: {rate}% errors ({errs[path]}/{total[path]})')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if code >= 400:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{path}: {rate}% errors ({errs[path]}/{total[path]})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

1. Predict: before running, write the exact output you expect from `print(f'{path}: {rate}% errors ({errs[path]}/{total[path]})')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute the error rate per path and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Two `defaultdict(int)` counters track total and error (status >= 400) hits per path, and their ratio is the per-URL error rate.

```
import re
from collections import defaultdict
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.2 - - [...] "GET /a HTTP/1.1" 500 9 "-" "B"',
    '1.1.1.3 - - [...] "GET /b HTTP/1.1" 200 1 "-" "B"',
    '1.1.1.4 - - [...] "GET /a HTTP/1.1" 200 1 "-" "B"',
```

```
    '1.1.1.5 - - [...] "GET /b HTTP/1.1" 404 9 "-" "B"',
]
total = defaultdict(int)
errs = defaultdict(int)
for ln in lines:
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    total[path] += 1
    if code >= 400:
        errs[path] += 1
for path in sorted(total):
    rate = round(100 * errs[path] / total[path], 1)
    print(f'{path}: {rate}% errors ({errs[path]}/{total[path]})')
```

```
output
/a: 33.3% errors (1/3)
/b: 50.0% errors (1/2)
```

How it works:

1. Five lines hit /a and /b with a mix of 200, 404 and 500 codes.
2. total and errs are both defaultdict(int).
3. Each pass parses the status and path, always increments total, and increments errs only when the code is 400 or above.
4. For each sorted path the rate is errors over total times 100, printed with the underlying fraction.

Try it:

1. Sort the output by descending error rate to surface the worst pages.
2. Count only 5xx server errors rather than all 4xx and 5xx.
3. Skip paths with fewer than a minimum number of hits to reduce noise.
4. Flag any path over a 50% error rate.

⚠ Common Mistakes

- Counting 3xx redirects as errors inflates the rate; errors start at 400.
- Dividing by the global total instead of the per-path total mixes pages together.
- A path with zero hits would divide by zero, but every path here has at least one.

Skills gained defaultdict | error rate | percentages

→ Where You'll Use This: Per-path error rates pinpoint the specific URLs costing you crawl trust and user goodwill, prioritising which broken pages to repair first.

Mental Model

Like a batting average per player: it is not the raw misses that matter but how often each one fails out of all their attempts.

Project 460 Measure Crawl Budget Spent on Parameters

The Idea Behind It

Bots that crawl many URL-parameter variants of one page burn budget on near-duplicates, so measuring the parametered share quantifies the waste. This project counts bot hits whose path contains a question mark separately from clean bot hits, then prints both counts and the percentage of bot budget spent on parametered URLs. It frames query-string crawling as a measurable efficiency loss.

What You'll Build & Learn

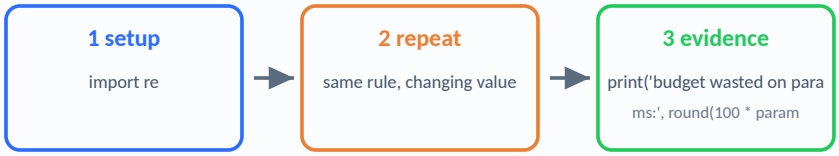
Measure what share of a bot's requests target parametered URLs versus clean ones.

- detecting a query string with in
- splitting counts by a condition
- percentage of parametered hits

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 459: compute the error rate per path. Project 461 changes the surface problem while preserving the underlying method.

progress check



Reading target: measure crawl budget spent on parameters is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('budget wasted on params:', round(100 * param / (param + clean), 1), '%')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if any(b in ua for b in bots):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('budget wasted on params:', round(100 * param / (param + clean), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(b in ua for b in bots):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Crawl Budget Spent on Parameters: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, lines, utm, ad, Googlebot. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if any(b in ua for b in bots): | Evidence: print('budget wasted on params:', round(100 * param / (param + clean),...

🛠️ Reader to Writer Bridge

1. Read: explain measure crawl budget spent on parameters in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 459.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 461 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('budget wasted on params:', round(100 * param / (param + clean), 1), '%')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure crawl budget spent on parameters and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Among bot hits, a `?` in the path marks a parametered URL; the share of parametered hits estimates budget lost to query-string variants.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /p?utm=ad HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /p HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /p?sort=asc HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
```

```
    '1.1.1.4 - - [...] "GET /q HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.5 - - [...] "GET /p?utm=x&sort=z HTTP/1.1" 200 1 "-"
"Googlebot/2.1"',
]
bots = ('googlebot', 'bingbot')
param = clean = 0
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if any(b in ua for b in bots):
        if '?' in path:
            param += 1
        else:
            clean += 1
print('bot hits with params:', param)
print('bot hits clean:', clean)
print('budget wasted on params:', round(100 * param / (param + clean), 1), '%')
```

```
output
bot hits with params: 3
bot hits clean: 2
budget wasted on params: 60.0 %
```

How it works:

1. Five lines mix Googlebot and bingbot hits to clean paths and several with utm and sort parameters.
2. param and clean counters start at zero.
3. For each bot hit, the path is checked for a question mark; if present param increments, otherwise clean does.
4. Both counts print, followed by the percentage of bot budget spent on parametered URLs.

Try it:

1. List the distinct parameter keys bots crawled most.
2. Include human hits and compare their parameter share to bots.
3. Treat only tracking parameters like utm as waste, not functional ones.
4. List the distinct base paths behind the parametered hits.

⚠ Common Mistakes

- Treating the fragment `#` like a query parameter is wrong; only `?` starts the query string.
- Counting human param hits dilutes the crawl-budget question, which is about bots.
- Dividing by only the param count instead of the bot total overstates the percentage.

Skills gained `query strings` `counting` `crawl budget`

→ **Where You'll Use This:** Quantifying parameter crawl makes the case for canonical tags, parameter handling and robots rules that stop bots wasting fetches on infinite filter combinations.

Mental Model

Like noticing a courier keeps delivering to the same house with slightly different apartment numbers scribbled on, wasting trips on duplicates.

Project 461 Find URL-Parameter Crawl Bloat

The Idea Behind It

When one base path explodes into many parameter variants, crawlers waste fetches on duplicates. This project strips each path at the first question mark to get its base, counts the variants per base in a Counter, then prints each base with a crawl-bloat note when it has more than one variant. Grouping by the part before the query string exposes which pages spawn too many URLs.

What You'll Build & Learn

Group crawled URLs by their base path and flag bases with many parameter variants.

- splitting a path on the question mark
- Counter of base paths
- conditional inline note

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 460: measure crawl budget spent on parameters. Project 462 changes the surface problem while preserving the underlying method.

progress check

Reading target: find url-parameter crawl bloat is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

- Evidence: `print(f'{base}: {keys[base]} variants{note}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`note = ' <- crawl bloat' if keys[base] > 1 else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{base}: {keys[base]} variants{note}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `note = ' <- crawl bloat' if keys[base] > 1 else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find URL-Parameter Crawl Bloat: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, id. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: note = ' <- crawl bloat' if keys[base] > 1 else '' | Evidence: print(f'{base}: {keys[base]} variants{note}')

🛠️ Reader to Writer Bridge

1. Read: explain find url-parameter crawl bloat in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 460.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 462 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{base}: {keys[base]} variants{note}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find url-parameter crawl bloat and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Splitting each path on `?` and counting the base URL reveals which clean URLs spawned multiple parametered variants in the log.

```python
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /p?id=1 HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /p?id=2 HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /p?id=3 HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.4 - - [...] "GET /blog HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
]
keys = Counter()
for ln in lines:
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    base = path.split('?', 1)[0]
    keys[base] += 1
for base in sorted(keys):
    note = '  <- crawl bloat' if keys[base] > 1 else ''
    print(f'{base}: {keys[base]} variants{note}')
```

```
output
/blog: 1 variants
/p: 3 variants  <- crawl bloat
```

How it works:

1. Four lines crawl /p with three different id parameters plus a clean /blog.
2. An empty Counter named keys is created.
3. Each path is split on the question mark with maxsplit one, and the base before it increments the counter.
4. For each sorted base, a crawl-bloat note is appended when its variant count exceeds one before printing.

Try it:

1. Sort the output by variant count to surface the worst offender first.
2. Print the actual variant URLs under each bloated base.
3. Raise the bloat threshold so only bases with many variants are flagged.
4. Raise the bloat threshold to 3 variants.

⚠ Common Mistakes

- Splitting on `=` instead of `?` mangles paths that contain equals signs.
- Counting full parametered paths instead of bases hides that they share one page.
- Flagging bloat at one variant is too aggressive; the threshold here is more than one.

Skills gained string split | Counter | crawl bloat

→ Where You'll Use This: Finding bloated base paths reveals where faceted navigation or session parameters generate near-infinite URLs, a classic source of wasted crawl on ecommerce sites.

Mental Model

Like spotting one product that ships in fifty barely different SKUs, cluttering the catalogue with duplicates of essentially the same thing.

Project 462 Split Bandwidth Between Bots and Humans

The Idea Behind It

Bots can quietly consume a large share of bandwidth, so summing bytes separately for bot and human hits shows who is really using the pipe. This project classifies each line by its user-agent, adds its byte count to either bot_bytes or human_bytes, and prints both totals plus the bot share as a percentage. It combines the bot-detection and byte-summing patterns into a bandwidth split.

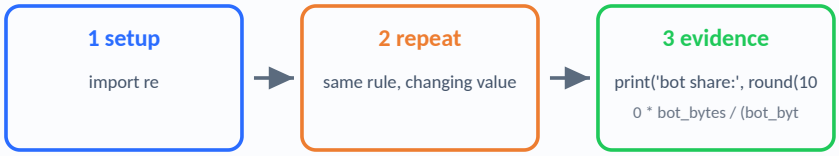
What You'll Build & Learn

Sum bytes served to bots versus humans and report the bot share of bandwidth.

- accumulating bytes by category
- bot versus human classification
- bandwidth share percentage

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 461: find url-parameter crawl bloat. Project 463 changes the surface problem while preserving the underlying method.



progress check

Reading target: split bandwidth between bots and humans is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split bandwidth between bots and humans and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each hit's byte count is added to a bot or human running total based on the user-agent test, and the bot share is its fraction of the combined bytes.

```
import re
lines = [
    '1.1.1.1 - - [...] "GET /a HTTP/1.1" 200 5000 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /b HTTP/1.1" 200 2000 "-" "Firefox/120"',
```

```
    '1.1.1.3 - - [...] "GET /c HTTP/1.1" 200 3000 "-" "Googlebot/2.1"',
    '1.1.1.4 - - [...] "GET /d HTTP/1.1" 200 4000 "-" "Safari/605"',
]
bots = ('googlebot', 'bingbot')
bot_bytes = human_bytes = 0
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    nbytes = int(re.search(r'" \d{3} (\d+) ', ln).group(1))
    if any(b in ua for b in bots):
        bot_bytes += nbytes
    else:
        human_bytes += nbytes
print('bot bytes:', bot_bytes)
print('human bytes:', human_bytes)
print('bot share:', round(100 * bot_bytes / (bot_bytes + human_bytes), 1), '%')
```

```
output
bot bytes: 8000
human bytes: 6000
bot share: 57.1 %
```

How it works:

1. Four lines mix Googlebot hits with Firefox and Safari hits, each with a byte size.
2. bot_bytes and human_bytes both start at zero.
3. Each pass isolates the lowercased agent and parses the bytes, then adds them to the bot or human total based on any() matching a marker.
4. Both byte totals print, followed by the bot share as a percentage.

Try it:

1. Break bot bytes down further by individual crawler name.
2. Print the totals in megabytes for readability.
3. Add the human share so both percentages display together.
4. Report the totals in KB instead of raw bytes.

⚠ Common Mistakes

- Counting hits instead of bytes answers a different question than bandwidth.
- Adding bytes to the wrong bucket on a missed bot match skews the share.
- Dividing by only the bot bytes instead of the combined total gives a nonsensical percentage.

Skills gained bandwidth | classification | percentages

→ Where You'll Use This: A bot-versus-human bandwidth split justifies rate-limiting aggressive crawlers and reveals when serving bots costs more than serving paying customers.

Mental Model

Like metering two taps off the same water main to see whether the garden hose or the kitchen is draining the supply.

Project 463 Measure a Bot's Crawl Pacing

The Idea Behind It

A polite crawler spaces its requests while a hammering one fires them seconds apart, so averaging the gaps between consecutive timestamps measures pacing. This project parses all timestamps into a list, computes the second differences between neighbours, averages them, and prints the gaps plus a polite-or-hammering verdict against a five-second cutoff. It turns a sequence of times into a rate-of-crawl signal.

What You'll Build & Learn

Measure how fast a bot crawls by averaging the seconds between its consecutive hits.

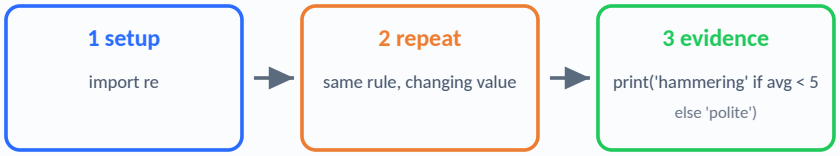
- parsing timestamps into a list
- differences between neighbours
- total_seconds for a timedelta

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 462: split bandwidth between bots and humans. Project 464 changes the surface problem while preserving the underlying method.

progress check

Reading target: measure a bot's crawl pacing is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('hammering' if avg < 5 else 'polite')` exposes the result; match it against the output before changing the program.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure a Bot's Crawl Pacing: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, datetime, lines, Jun, Googlebot. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('hammering' if avg < 5 else 'polite') | Evidence: print('hammering' if avg < 5 else 'polite')

🛠️ Reader to Writer Bridge

1. Read: explain measure a bot's crawl pacing in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 462.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 464 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('hammering' if avg < 5 else 'polite')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure a bot's crawl pacing and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Subtracting consecutive parsed timestamps yields inter-hit gaps in seconds via `total_seconds`, and the average gap classifies the crawler as polite or hammering.

```
import re
from datetime import datetime
lines = [
    '1.1.1.1 - - [22/Jun/2026:10:00:00 +0000] "GET /a HTTP/1.1" 200 1 "-"
"Googlebot/2.1"',
    '1.1.1.1 - - [22/Jun/2026:10:00:02 +0000] "GET /b HTTP/1.1" 200 1 "-"
"Googlebot/2.1"',
```

```
    '1.1.1.1 - - [22/Jun/2026:10:00:03 +0000] "GET /c HTTP/1.1" 200 1 "-"
"Googlebot/2.1"',
    '1.1.1.1 - - [22/Jun/2026:10:00:20 +0000] "GET /d HTTP/1.1" 200 1 "-"
"Googlebot/2.1"',
]
times = []
for ln in lines:
    raw = ln.split('[')[1].split()[0]
    times.append(datetime.strptime(raw, '%d/%b/%Y:%H:%M:%S'))
gaps = [(times[i] - times[i - 1]).total_seconds() for i in range(1,
len(times))]
avg = sum(gaps) / len(gaps)
print('inter-hit gaps (s):', [int(g) for g in gaps])
print('avg gap:', round(avg, 1), 's')
print('hammering' if avg < 5 else 'polite')
```

```
output
inter-hit gaps (s): [2, 1, 17]
avg gap: 6.7 s
polite
```

How it works:

1. Four Googlebot lines from one IP arrive at 10:00:00, 02, 03 and 20.
2. Each timestamp is sliced out and parsed by strptime into the times list.
3. A comprehension computes total_seconds for each adjacent pair, giving the gaps list.
4. The average gap prints with the gap list, then 'hammering' or 'polite' depending on whether the average is below five seconds.

Try it:

1. Print the smallest gap to catch the fastest burst, not just the average.
2. Group lines by IP first so each crawler's pacing is measured separately.
3. Lower the cutoff to three seconds and see how the verdict changes.
4. Print the smallest gap to find the tightest burst.

⚠ Common Mistakes

- Assuming the log is time-sorted; if not, the gaps can go negative and need sorting first.
- Using `datetime.now` is both forbidden and meaningless; the times come from the log.
- Dividing by `len(times)` instead of `len(gaps)` (one fewer) skews the average.

Skills gained datetime deltas crawl pacing

→ Where You'll Use This: Crawl pacing analysis catches bots overloading the server and informs crawl-delay settings, protecting site stability without blocking legitimate indexing.

Mental Model

Like timing the seconds between a woodpecker's taps: steady spacing is polite, a rapid drumroll means it is hammering.

Project 464 Run a Full Crawl-Waste Audit

The Idea Behind It

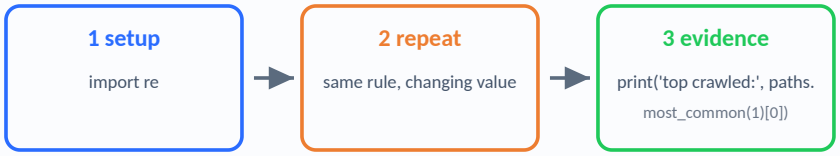
This capstone ties the chapter together by running every key measure in one pass over the log. It counts total hits, isolates bot traffic, tallies bot paths in a Counter, and marks each bot hit on a 404 or 3xx as wasted. It then prints total and bot hits, the wasted-crawl percentage, and the single most-crawled path, producing a compact crawl-waste audit report.

What You'll Build & Learn

Run a combined audit that reports total hits, bot hits, wasted crawl and the top path.

- combining several metrics in one loop
- wasted-crawl percentage
- most_common for the top path

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 463: measure a bot's crawl pacing. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full crawl-waste audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
- Evidence: `print('top crawled:', paths.most_common(1)[0])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
2. Apply the rule	`if any(b in ua for b in bots):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('top crawled:', paths.most_common(1)[0])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Log-File and Server Analysis becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(b in ua for b in bots):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run a Full Crawl-Waste Audit: connect the surface task to the chapter skill, parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.
Names	Watch these names first: re, collections, Counter, lines, home. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if any(b in ua for b in bots): | Evidence: print('top crawled:', paths.most_common(1)[0])

🛠️ Reader to Writer Bridge

1. Read: explain run a full crawl-waste audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 463.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('top crawled:', paths.most_common(1)[0])`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full crawl-waste audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A single loop classifies each hit, counts bot paths, and tallies waste (bot 404s and redirects); the closing report combines coverage, waste and the top URL.

```
import re
from collections import Counter
lines = [
    '1.1.1.1 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Googlebot/2.1"',
    '1.1.1.2 - - [...] "GET /gone HTTP/1.1" 404 9 "-" "Googlebot/2.1"',
    '1.1.1.3 - - [...] "GET /old HTTP/1.1" 301 0 "-" "Googlebot/2.1"',
```

```
    '1.1.1.4 - - [...] "GET /home HTTP/1.1" 200 1 "-" "Firefox/120"',
    '1.1.1.5 - - [...] "GET /home HTTP/1.1" 200 1 "-" "bingbot/2.0"',
    '1.1.1.6 - - [...] "GET /missing HTTP/1.1" 404 9 "-" "bingbot/2.0"',
]
bots = ('googlebot', 'bingbot')
bot_hits = waste = 0
paths = Counter()
for ln in lines:
    ua = ln.rsplit('"', 2)[1].lower()
    code = int(re.search(r'" (\d{3}) ', ln).group(1))
    path = re.search(r'"\S+ (\S+) HTTP', ln).group(1)
    if any(b in ua for b in bots):
        bot_hits += 1
        paths[path] += 1
        if code == 404 or 300 <= code < 400:
            waste += 1
print('total hits:', len(lines))
print('bot hits:', bot_hits)
print('wasted crawl:', waste, '(', round(100 * waste / bot_hits, 1), '%)')
print('top crawled:', paths.most_common(1)[0])
```

```
output
total hits: 6
bot hits: 5
wasted crawl: 3 ( 60.0 %)
top crawled: ('/home', 2)
```

How it works:

1. Six lines mix Googlebot, bingbot and Firefox hits with 200, 404 and 301 codes.
2. bot_hits and waste start at zero and a Counter named paths is created.
3. For each bot hit, bot_hits and the path counter increment, and waste increments when the code is 404 or in the 3xx range.
4. It prints total hits, bot hits, the wasted percentage of bot hits, and the top path from most_common.

Try it:

1. Add total bytes served to the report for a bandwidth figure.
2. Break the wasted count into 404s versus redirects separately.
3. List the top three crawled paths instead of just the single top one.
4. Add the human-hit count to the report for completeness.

⚠ Common Mistakes

- Computing the waste percentage against total hits instead of bot hits understates it.
- Calling `most_common(1)[0]` on an empty Counter would raise; the fixture guarantees bot hits.

- Counting human 404s as crawl waste mixes user errors into the crawl-budget metric.

Skills gained audit | Counter | crawl waste

→ Where You'll Use This: A one-pass crawl-waste audit is the deliverable an SEO hands to engineering: a single report quantifying how efficiently search engines spend their budget on the site.

Mental Model

Like a single-page health summary at the end of a checkup: one sheet rolls up every test into the numbers that matter.

✅ Chapter Progress Checkpoint

What this chapter added: after 32 mini-projects, Log-File and Server Analysis should feel like a reusable Python move: parse server log lines, separate bot hits, measure crawl waste and find the most-crawled paths.

chapter checkpoint

1 Read
Open any project from Projects 433-464 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 14 (GEO, AEO and the End-to-End Technical Audit) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall | 3 Meaning | 2 Structure | 1 Transfer

13.1.Q1 Recall MEDIUM — Turn back to Project 441 (Total the Bytes Served). Without running it, what exactly does it print?

13.1.Q2 Meaning MEDIUM — Turn back to Project 447 (Count the Unique Paths Crawled). Without running it, what exactly does it print?

13.1.Q3 Structure MEDIUM — Turn back to Project 438 (Count Requests per Path). Without running it, what exactly does it print?

13.1.Q4 Transfer MEDIUM — Turn back to Project 437 (Split Bot and Human Traffic). Without running it, what exactly does it print?

13.1.Q5 Recall EASY In a Common Log Format line, which two fields are most useful for SEO analysis?

- A IP and referer
- B Request path and status code
- C Timestamp and bytes
- D Protocol and method

13.1.Q6 Meaning EASY A line shows status 301 fetched by Googlebot. Does it count toward crawl waste?

- A No, only 404s count
- B No, 3xx is a success
- C Yes — a 3xx redirect is a fetch that returned no content, so a bot chasing it is wasted budget
- D Only if the path is in robots.txt

13.1.Q7 Structure EASY Why is splitting a log line with a plain space-based split unreliable?

- A Spaces are not allowed in logs
- B The request line and User-Agent are quoted fields that themselves contain spaces, so a naive split mis-counts the fields
- C It is too slow
- D It only works on bot lines

13.1.Q8 Meaning MEDIUM A bot made 10 fetches but only touched 4 distinct paths. What does the gap tell you, and how do you measure it in code?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 13 – Log-File and Server Analysis

13.1.Q1. `total bytes served: 5160` then `total KB: 5.04`

13.1.Q2. `unique paths: 3` then `['/blog', '/home', '/shop']`

13.1.Q3. `/blog: 2` then `/home: 3`

13.1.Q4. `bot hits: 2` then `human hits: 3`

13.1.Q5. B the path names which URL was asked for and the status says how the server answered; together they reveal crawl behaviour.

13.1.Q6. C crawl waste includes any bot fetch that returned nothing useful, and the 3xx redirect class qualifies along with 404s.

13.1.Q7. B quoted fields hold internal spaces, so positional splitting breaks; a CLF-aware regex or an rsplit on the quotes is needed.

13.1.Q8. It re-crawled pages rather than reaching new ones, so crawl breadth is low. Measure distinct paths by collecting parsed paths into a set and comparing len(set) to the total number of lines.

Chapter 14 · GEO, AEO and the End-to-End Technical Audit

Score answer-extractability and E-E-A-T signals, AI-mode readiness, and run a 32-point technical audit.

Chapter Skill Map

What this chapter adds: In GEO, AEO and the End-to-End Technical Audit, the focus is score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit. You practise it across 36 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 14 assumes the reading habits from Chapter 13: Log-File and Server Analysis. You should carry forward the habit of predicting output before trusting the page.

Where it leads: This final chapter asks you to combine earlier habits: trace, explain, modify, and test without being handed the exact next step.

1 **Projects 465-476** Recognise the pattern and read the code slowly. *name it first*	2 **Projects 477-488** Trace similar programs with less prompting and explain what changed.	3 **Projects 489-500** Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Two questions decide whether you win the search box now: **can a machine *extract* your answer, and can it *trust* you enough to cite it? ***extraction + trust = a citation***

For twenty years SEO meant *earn a blue link and hope for a click*. Answer engines changed the game. Google's AI Overviews, Bing Copilot and chat assistants no longer just list pages — they read several pages, synthesise an answer, and cite a handful of sources. GEO (generative engine optimization) and AEO (answer engine optimization) are the craft of being one of those cited sources. The blue link still exists, but the prize moved: you now compete to be *the sentence the machine lifts*, not just the tenth result.

An answer engine does two things with your page. First it extracts — it looks for a tight, self-contained chunk that resolves the query: a 30-word lead paragraph, a clean `X is a ...` definition, a numbered list, a comparison table. Second it judges trust — is there a named author with credentials, recent dates, outbound citations, schema it can parse? A page can be perfectly extractable and still be skipped because nothing signals it is worth quoting. So GEO/AEO reduces to two measurable axes: *extractability* and *trust*.

The lovely thing is that both axes are computable. You do not have to guess whether a page is answer-ready — you can measure it. The simplest GEO signal of all is the lead paragraph: answer engines reward a first paragraph that resolves the query in one tight bite, roughly 20-60 words. Too short and it is not an answer; too long and it is an essay. Here is that signal as code:

```
import re
html = ('<h1>What Is Schema Markup?</h1>'
        '<p>Schema markup is structured data added to a page that '
```

```
        'helps search engines understand its content. It uses a '
        'shared vocabulary so machines can extract facts reliably.</p>')
first = re.search(r'<p>(.*?)</p>', html).group(1)
words = len(first.split())
ok = 20 <= words <= 60
print(f'lead answer words: {words}')
print('extractable lead:', 'YES' if ok else 'NO')
```

```
output
lead answer words: 27
extractable lead: YES
```

That is the whole field in miniature. Every GEO check is a small function over the HTML that returns a score, and every audit is just a pile of such functions run together. This chapter is the capstone: it teaches the new extraction-and-trust signals, then folds them in with crawlability, indexability, status codes, on-page, canonicals, speed, structured data and hreflang from every prior chapter into one 32-point audit that grades a site end to end. *measure, score, grade, fix*

Keep one frame in mind throughout: a citation is *extraction × trust*. A page that is extractable but untrusted is quotable but unquoted; a page that is trusted but not extractable has nothing clean to lift. You need both, and the audit measures both.

GEO (GENERATIVE ENGINE OPTIMIZATION)

Optimising a page so generative AI engines (AI Overviews, Copilot, chat assistants) select, synthesise and cite its content when composing an answer — not just rank it as a link.

AEO (ANSWER ENGINE OPTIMIZATION)

The narrower discipline of structuring content so answer engines and featured snippets can extract a direct answer: question-style headings, concise lead answers, FAQ/HowTo schema.

ANSWER-EXTRACTABILITY

How easily a machine can lift a self-contained answer from a page: a concise lead paragraph, a clean definition, a list, or a table that resolves the query without further reading.

E-E-A-T

Experience, Expertise, Authoritativeness and Trust — a quality framework inferred from concrete page signals such as a named author bio, credentials, outbound citations, and an about/contact page.

CONTENT FRESHNESS

How recently a page was published or updated. Answer engines and rankers prefer recent pages for many queries; comparing an updated date to an audit date flags stale content.

TECHNICAL AUDIT

A repeatable pass that runs many independent checks (crawl, robots, sitemap, status, canonical, speed, schema, hreflang, on-page, AEO, E-E-A-T) over a site, scores them, grades the total, and lists what to fix.

Extraction: the four shapes a machine can lift

Answer engines do not paraphrase a whole article — they look for a chunk in a *shape* they can quote. There are four shapes worth engineering for: a concise lead paragraph (the direct answer up top), a definition sentence (X `is a ...`), a list (steps or bullets), and a table (a comparison). Classifying each block by its shape predicts how it can be reused. If a block is none of these — just prose — it is far less likely to be extracted.

```
import re
blocks = {
    'definition': '<p>Crawl budget is the number of pages Googlebot fetches.</p>',
    'steps':      '<ol><li>Open Search Console</li><li>Submit sitemap</li></ol>',
    'comparison': '<table><tr><th>301</th><th>302</th></tr></table>',
    'plain':      '<p>We think SEO is great and you should try it sometime.</p>',
}
for name, block in blocks.items():
    if re.search(r'<ol>|<ul>', block):
        fmt = 'list/steps'
    elif '<table' in block:
        fmt = 'table/comparison'
    elif re.match(r'<p>\w+( \w+)? (is|are) (a |an |the )', block):
        fmt = 'definition'
    else:
        fmt = 'prose'
    print(f'{name}: {fmt}')
```

```
output
definition: definition
steps: list/steps
comparison: table/comparison
plain: prose
```

Pair an extractable shape with a *question-style heading* and you have the recipe for a featured snippet or an answer box. An interrogative H1 like "How Long Should A Title Tag Be?" tells the engine exactly which query the page

resolves; a substantial first paragraph then supplies the answer. That heading-plus-answer pattern is the single highest-leverage AEO move.

Passage ranking: the engine quotes one sentence, not the page

When an engine answers a query it often pulls a *single passage* — the one sentence on the page that best resolves the question. A crude but faithful model of how it chooses is `term overlap`: tokenise the question, tokenise each candidate passage, and pick the passage that shares the most terms. Write content as self-contained sentences and you give the engine clean passages to choose from; bury the answer mid-paragraph and it has nothing to lift.

```
import re
question = 'what is canonical url'
passages = [
    'A canonical URL is the single preferred address you tell '
    'search engines to index for duplicate pages.',
    'Sitemaps list the URLs you want crawled.',
    'Redirects send users from an old URL to a new one.',
]
qterms = set(re.findall(r'[a-z]+', question.lower()))
best, score = None, -1
for p in passages:
    overlap = len(qterms & set(re.findall(r'[a-z]+', p.lower())))
    if overlap > score:
        best, score = p, overlap
print('best passage:', best)
print('term overlap:', score)
```

```
output
best passage: A canonical URL is the single preferred address you tell search engines to
index for duplicate pages.
term overlap: 3
```

The same overlap idea, run the other way, audits *coverage*: map every question your audience asks to the heading that best covers it, and any question with no matching heading is a `content gap` — a query you cannot win because you never wrote the answer.

Trust: turning E-E-A-T from a vibe into a number

Experience, Expertise, Authoritativeness, Trust sounds unmeasurable, but engines infer it from concrete page signals, so you can too. Sum a checklist: is there an author bio? author credentials? at least a couple of outbound citations? published and updated dates? an about page and a contact page? Each present signal is a point. A fuzzy quality concept becomes a score out of seven.

```
signals = {
    'author_bio': True, 'author_credentials': True,
    'outbound_citations': 4, 'published_date': True,
    'updated_date': False, 'about_page': True, 'contact_page': False,
```

```
}
score = 0
score += 1 if signals['author_bio'] else 0
score += 1 if signals['author_credentials'] else 0
score += 1 if signals['outbound_citations'] >= 2 else 0
score += 1 if signals['published_date'] else 0
score += 1 if signals['updated_date'] else 0
score += 1 if signals['about_page'] else 0
score += 1 if signals['contact_page'] else 0
print(f'E-E-A-T score: {score}/7')
print('grade:', 'strong' if score >= 6 else 'moderate' if score >= 4 else 'weak')
```

```
output
E-E-A-T score: 5/7
grade: moderate
```

Two of those signals deserve their own checks. Freshness: compare each page's updated date to a fixed audit date and flag anything older than a year — answer engines distrust stale pages. Citations: count the outbound links to authoritative `https://` domains, because linking out to real sources is itself a trust cue. Here is the freshness flag:

```
from datetime import datetime
AS_OF = '2026-06-22'
pages = {'/guide-a': '2026-05-01', '/guide-b': '2024-11-15', '/guide-c': '2026-06-10'}
asof = datetime.strptime(AS_OF, '%Y-%m-%d')
for path in sorted(pages):
    updated = datetime.strptime(pages[path], '%Y-%m-%d')
    age_days = (asof - updated).days
    state = 'STALE' if age_days > 365 else 'fresh'
    print(f'{path}: {age_days}d old -> {state}')
```

```
output
/guide-a: 52d old -> fresh
/guide-b: 584d old -> STALE
/guide-c: 12d old -> fresh
```

AEO schema: handing the engine ready-made Q&A

The cleanest extractable shape of all is structured data that *is* a question and answer. `FAQPage`, `HowTo` and `QAPage` JSON-LD give an answer engine machine-readable question/answer pairs — no extraction guesswork required. Scanning a page's `@type` values for those tells you whether it is AEO-equipped. (Validity matters too — the schema must parse and declare a `@type`, which is the structured-data check we reuse in the audit.)

```
import re
html = ('<script type="application/ld+json">{"@type":"FAQPage"}</script>'
```

```
        '<script type="application/ld+json">{"@type":"Article"}</script>'
        '<script type="application/ld+json">{"@type":"HowTo"}</script>')
types = re.findall(r'"@type"\s*:\s*"(\w+)"', html)
aeo_types = {'FAQPage', 'HowTo', 'QAPage'}
present = sorted(set(types) & aeo_types)
print('schema types:', sorted(set(types)))
print('AEO-relevant:', present)
print('AEO-ready:', 'YES' if present else 'NO')
```

```
output
schema types: ['Article', 'FAQPage', 'HowTo']
AEO-relevant: ['FAQPage', 'HowTo']
AEO-ready: YES
```

The end-to-end audit: every chapter, one score

Now the capstone move. Every prior chapter contributed an independent check — robots reachable, sitemap valid, canonical self-referencing, key pages return 200, Core Web Vitals in the green, hreflang reciprocal with an x-default, schema parses, title and meta lengths sane. Add this chapter's GEO/AEO signals — concise lead answer, AEO schema, author bio, freshness — and you have `32 checks in four groups of eight`: crawlability, indexability+status, performance, and content+AEO+E-E-A-T. Run them all over one site, count the passes, and map the percentage to a letter grade.

```
s = {
    # crawlability (8)
    'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True,
    'sitemap_present': True, 'sitemap_size_ok': True, 'sitemap_valid': True,
    'no_orphans': False, 'internal_links_ok': True,
    # indexability + status (8)
    'canonical_self': True, 'no_noindex_key': True, 'https': True, 'all_200': True,
    'redirects_short': True, 'hreflang_reciprocal': True, 'x_default': False,
'no_broken': True,
    # performance (8)
    'lcp_ok': True, 'inp_ok': True, 'cls_ok': False, 'mobile_ok': True,
    'compressed': True, 'render_block_ok': True, 'weight_ok': True, 'ttfb_ok':
True,
    # content + AEO + E-E-A-T (8)
    'title_ok': True, 'meta_ok': True, 'h1_ok': True, 'schema_valid': True,
    'lead_answer_ok': True, 'aeo_schema': True, 'author_bio': True, 'fresh': False,
}
failed = [c for c in s if not s[c]]
score = len(s) - len(failed)
pct = round(100 * score / 32)
grade = 'A' if pct >= 90 else 'B' if pct >= 80 else 'C' if pct >= 70 else 'D' if
pct >= 60 else 'F'
print('=== 32-POINT TECHNICAL SEO AUDIT ===')
```

```
print(f'score: {score}/32 ({pct}%)  grade: {grade}')
print('failures:', failed)
```

```
output
=== 32-POINT TECHNICAL SEO AUDIT ===
score: 28/32 (88%)  grade: B
failures: ['no_orphans', 'x_default', 'cls_ok', 'fresh']
```

A score and a list of failing names is not yet useful — a stakeholder cannot act on `cls_ok: False`. The last step maps each failure to a fix, turning the audit into a remediation plan; and run over time, diffing today's audit against a baseline surfaces regressions (checks that broke) and wins (checks you fixed). That loop — measure, grade, fix, re-measure — is what makes an audit a tool rather than a one-off report.

an audit you cannot act on and re-run is just a screenshot

Example 1

A page has a question H1 "What Is A 301 Redirect?", a 24-word lead paragraph answering it, a bulleted list of redirect types, supporting detail below, but no QAPage schema. Score its answer-box readiness on the 5-point checklist, and say whether it can win a featured snippet.

SOLUTION

1. Walk the five checks: question-style heading yes; concise answer up top yes (24 words, under 60); answer under 60 words yes; supporting detail below yes; QAPage schema no.
2. Four of five pass, so readiness is 4/5 — strong but not perfect.
3. Featured snippets are drawn from a 40-60 word paragraph, a list, or a table. The page has a list, so it is snippet-eligible even without the schema; the missing QAPage only costs the cleaner answer-box treatment.

Answer-box readiness 4/5; yes, it can win a snippet because the bulleted list is an extractable structure.

a list or table alone is enough to be snippet-eligible — schema is the bonus, not the gate

Example 2

Run a weighted AI-mode readiness score for a page with clear_headings=yes, schema=yes, concise_answers=yes, fresh=no, cited_sources=yes, using weights headings 2, schema 2, concise 3, fresh 1, citations 2. Is it ready, and what is the top gap?

SOLUTION

1. Sum the weights of the *passing* signals: headings 2 + schema 2 + concise 3 + citations 2 = `9`. The only failing signal is freshness (weight 1).
2. Total possible weight is 2+2+3+1+2 = 10, so the score is 9/10 = `90%`.
3. A common readiness bar is 70%; 90% clears it comfortably, so the verdict is *ready*. The single missing signal — freshness — is the top gap to fix.

AI-mode readiness 9/10 (90%), verdict ready; the top gap is freshness.

weighting matters: a concise answer is worth 3, freshness only 1, so fix the heavy signals first

Example 3

A site scores 28/32 on the technical audit with failures no_orphans, x_default, cls_ok and fresh, plus a GEO/AEO sub-score of 4/5 (missing: fresh). Combine them into one scorecard and give the letter grade and the highest-priority fix.

SOLUTION

1. Combine the two scores: technical 28 + GEO/AEO 4 = `32` out of (32 + 5) = 37 total.
2. Percentage is 32/37 = 86%, which lands in the 80-89 band → grade `B`.
3. Freshness fails in *both* halves (it is one of the four technical failures and the one GEO gap), so it is the single fix that lifts two scores at once — the highest-priority remediation.

Combined 32/37 (86%), grade B; refresh the stale content and bump its lastmod date first, because freshness is the failure that appears on both scorecards.

fix the failure that shows up in more than one group first — it has the best score-per-effort

⚡ Mental-Math Shortcut

A citation is extraction times trust — and an audit is just a pile of small checks. To be cited, a page must offer a *clean shape to lift* (a concise lead, a definition, a list, a table) and *reasons to be trusted* (named author, recent date, real sources, parseable schema); missing either factor zeroes the product. And whenever a quality idea feels unmeasurable — E-E-A-T, "answer-readiness", site health — turn it into a checklist, sum the passes, grade the percentage, and map each failure to a fix. Measure, score, grade, remediate, repeat.

⚠ Common Mistakes

- Treating GEO/AEO as new keyword stuffing — packing question phrases everywhere instead of writing one clean, self-contained answer in an extractable shape near the top.
- Burying the answer. A correct answer in paragraph six loses to a worse answer in the first sentence, because the engine extracts the passage it can lift, not the best one it could find with effort.
- Adding FAQPage/HowTo schema but never validating it — invalid JSON-LD or a missing `@type` means the engine ignores the markup entirely, so the AEO check should require the schema to parse.
- Auditing once and filing the report. The value is in re-running it: diffing against a baseline catches regressions, and mapping failures to fixes is what makes the score actionable rather than decorative.
- Optimising extraction while ignoring trust (or vice versa). A perfectly structured page with no author, no dates and no citations is quotable but rarely quoted; a trusted page with no clean passage has nothing to lift.

This chapter contains 36 hands-on mini-projects (Projects 465–500). Type each one out, run it, and experiment.

Project 465 Score a Page's Answer-Extractability Lead

The Idea Behind It

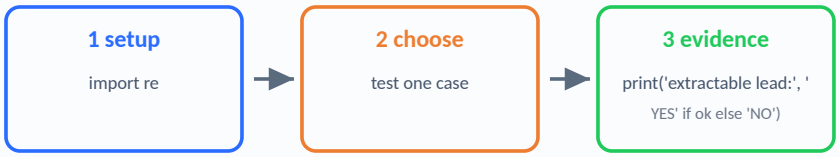
Generative engines reward a page whose opening paragraph resolves the query in one tight pass. This project pulls the first paragraph out of raw HTML with a regular expression, counts its words after splitting on whitespace, and treats a lead between twenty and sixty words as the sweet spot for extraction. The single boolean comparison turns a vague editorial instinct about a good intro into a hard, reproducible answer-extractability signal you can run over any page.

What You'll Build & Learn

Measure whether a page's first paragraph is a concise, on-topic answer that an AI engine can lift verbatim.

- Extract the lead paragraph with a regex
- Word-count a string after splitting
- Range checks express editorial rules

Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 466 changes the surface problem while preserving the underlying method. *progress check*

Reading target: score a page's answer-extractability lead is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('extractable lead:', 'YES' if ok else 'NO')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('extractable lead:', 'YES' if ok else 'NO')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('extractable lead:', 'YES' if ok else 'NO')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('extractable lead:', 'YES' if ok else 'NO')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Score a Page's Answer-Extractability Lead: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, h1, What, Is. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: print('extractable lead:', 'YES' if ok else 'NO') | Evidence: print('extractable lead:', 'YES' if ok else 'NO')

🛠️ Reader to Writer Bridge

1. Read: explain score a page's answer-extractability lead in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 466 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('extractable lead:', 'YES' if ok else 'NO')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of score a page's answer-extractability lead and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Pulling the first `<p>` and checking its word count against a 20-60 band approximates whether the lead is a snippet-sized answer rather than a vague intro.

```
import re
html = '<h1>What Is Schema Markup?</h1><p>Schema markup is structured data
added to a page that helps search engines understand its content. It uses a
shared vocabulary so machines can extract facts reliably.</p><p>More details
follow below.</p>'
first = re.search(r'<p>(.*?)</p>', html).group(1)
words = len(first.split())
ok = 20 <= words <= 60
print(f'lead answer words: {words}')
print('extractable lead:', 'YES' if ok else 'NO')
```

```
output
lead answer words: 27
extractable lead: YES
```

How it works:

1. An HTML string holds a heading plus two paragraphs of definition-style copy about schema markup.
2. re.search with a non-greedy pattern captures the text inside the first opening and closing paragraph tag.
3. Splitting that captured text on whitespace and taking its length yields the lead word count.
4. The boolean ok holds True only when the count sits between twenty and sixty inclusive.
5. Two print lines report the raw word count and a plain YES or NO verdict on extractability.

Try it:

1. Loop over every paragraph and report the position of the first one that lands in the twenty-to-sixty window.
2. Strip nested inline tags like anchors before counting so markup does not inflate the word total.
3. Make the lower and upper bounds parameters so different engines can use their own thresholds.
4. Lower the upper bound to 40 words and see this lead still pass.

⚠ Common Mistakes

- A greedy `<p>(.*)</p>` would span multiple paragraphs; the lazy `.*?` stops at the first close tag.
- Counting characters instead of words makes the 20-60 band meaningless for answer length.

- If the page opens with a hero image or nav `<p>`, the first paragraph may not be the real lead.

Skills gained regex extraction | word counting | range validation | GEO signals

→ Where You'll Use This: Auditing whether blog posts and FAQ answers open with a quotable lead is now table stakes for AI Overviews and featured-snippet work, and this check scales across a whole content library.

Mental Model

Like a newspaper lede: the first sentence has to deliver the story before the reader, or the engine, decides whether to keep reading.

Project 466 Detect a Direct Answer Near the Top

The Idea Behind It

AI Overviews and featured snippets favour pages that pair an interrogative heading with an immediate, substantial answer. The code reads an H1 and the body paragraphs, ignoring a sponsored ad block, and checks two things independently: whether the heading ends with a question mark, and whether the first real paragraph carries at least eight words. Separating the heading test from the answer test lets you see exactly which half of the question-and-answer contract a page is honouring.

What You'll Build & Learn

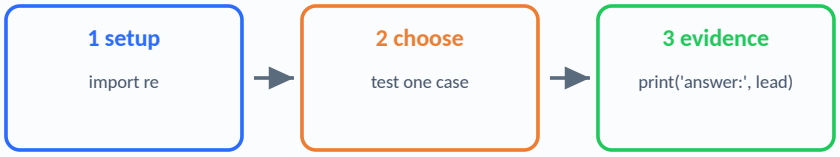
Confirm a page poses a question in its heading and resolves it with a meaningful paragraph right below.

- Detect question headings via a suffix test
- Find the first substantial body paragraph
- Combine two independent boolean signals

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 465: score a page's answer-extractability lead. Project 467 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect a direct answer near the top is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated

library calls.

- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('answer:', lead)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`lead = paras[0] if paras else ''`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('answer:', lead)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `lead = paras[0] if paras else ''`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Direct Answer Near the Top: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, h1, How, Long. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; classes/records group responsibilities; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: lead = paras[0] if paras else '' | Evidence: print('answer:', lead)

🛠️ Reader to Writer Bridge

1. Read: explain detect a direct answer near the top in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 465.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 467 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('answer:', lead)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a direct answer near the top and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A heading ending in `?` plus a non-trivial first paragraph (>= 8 words) is a strong cue that the page leads with a direct answer.

```
import re
html = '<h1>How Long Should A Title Tag Be?</h1><div class="ad">Sponsored</div>
<p>A title tag should be about 50 to 60 characters so it does not get truncated
in search results.</p>'
# strip tags, find first substantial paragraph text near the top
paras = re.findall(r'<p>(.*?)</p>', html)
lead = paras[0] if paras else ''
heading = re.search(r'<h1>(.*?)</h1>', html).group(1)
is_q = heading.strip().endswith('?')
direct = bool(lead) and len(lead.split()) >= 8
print('heading is a question:', is_q)
print('direct answer present:', direct)
print('answer:', lead)
```

```
output
heading is a question: True
direct answer present: True
answer: A title tag should be about 50 to 60 characters so it does not get truncated
in search results.
```

How it works:

1. re.findall gathers every paragraph, and the first one becomes the candidate lead while an ad div is skipped.
2. A separate re.search captures the H1 text so the heading can be examined on its own.
3. endswith on the stripped heading sets is_q True when the title is phrased as a question.
4. The direct flag requires a non-empty lead whose split length is at least eight words.
5. Three prints expose the question verdict, the direct-answer verdict, and the actual answer text.

Try it:

1. Accept headings ending in other interrogatives by also matching leading words like how, what, or why.
2. Raise the answer threshold and require the lead to repeat a keyword from the heading.
3. Walk all headings and pair each with the nearest following paragraph instead of only the H1.
4. Strip the trailing `?` from the heading and watch `is a question` go False.

⚠ Common Mistakes

- An ad or banner `<div>` between the heading and the answer is skipped because only `<p>` text is collected.
- Requiring exactly one `<p>` would miss pages with a short lead followed by detail.

- A heading phrased as a statement, not a question, fails `endswith('?')` even if the page answers well.

Skills gained heading detection | paragraph parsing | boolean logic | AEO

→ Where You'll Use This: When optimising help-centre and how-to pages for answer boxes, this verifies the basic structural pattern engines look for before deciding a page deserves a direct-answer treatment.

Mental Model

Think of a quiz card: the question on the front is useless unless the answer on the back is right there and complete.

Project 467 Detect FAQ and HowTo Schema for AEO

The Idea Behind It

Answer engines love structured data that hands them ready-made question-and-answer pairs, so FAQPage, HowTo and QAPage markup is worth detecting directly. This snippet scans concatenated JSON-LD scripts with a regex that captures every @type value, then intersects the discovered set with a known set of AEO-relevant types. Set intersection is the elegant trick here: it cleanly keeps only the markup that matters for answer optimisation and ignores ordinary Article or other types.

What You'll Build & Learn

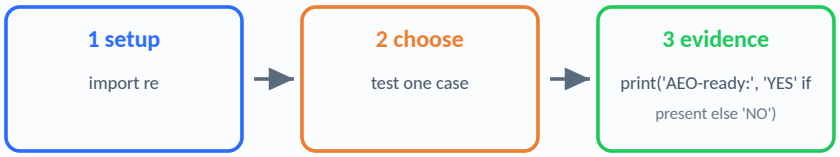
Scan a page's JSON-LD for the schema types that feed answer engines and flag whether any are present.

- Capture schema @type values with regex
- Use set intersection to filter
- Distinguish AEO-relevant markup from generic

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 466: detect a direct answer near the top. Project 468 changes the surface problem while preserving the underlying method.

progress check



Reading target: detect faq and howto schema for aeo is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

Code Reading Stack

Layer	What to read
Intent	Detect FAQ and HowTo Schema for AEO: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, script, type, application. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('AEO-ready:', 'YES' if present else 'NO') | Evidence: print('AEO-ready:', 'YES' if present else 'NO')

🛠️ Reader to Writer Bridge

1. Read: explain detect faq and howto schema for aeo in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 466.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 468 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('AEO-ready:', 'YES' if present else 'NO')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect faq and howto schema for aeo and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Extracting every `@type` with a regex and intersecting with the AEO-relevant set tells you whether the page exposes answer-friendly schema.

```
import re
html = '''<script type="application/ld+json">{"@type":"FAQPage"}</script>
<script type="application/ld+json">{"@type":"Article"}</script>
<script type="application/ld+json">{"@type":"HowTo"}</script>'''
types = re.findall(r'"@type"\s*:\s*"(\w+)"', html)
aeo_types = {'FAQPage', 'HowTo', 'QAPage'}
present = sorted(set(types) & aeo_types)
print('schema types:', sorted(set(types)))
print('AEO-relevant:', present)
print('AEO-ready:', 'YES' if present else 'NO')
```

```
output
schema types: ['Article', 'FAQPage', 'HowTo']
AEO-relevant: ['FAQPage', 'HowTo']
AEO-ready: YES
```

How it works:

1. A triple-quoted string holds three JSON-LD script blocks declaring FAQPage, Article and HowTo types.
2. re.findall pulls every quoted value that follows an @type key into a list of type names.
3. The found types are deduplicated into a set and intersected with the aeo_types reference set.
4. Sorting that intersection produces a stable, alphabetised list of the AEO-relevant types present.
5. A final print reports YES when any AEO type was matched and NO otherwise.

Try it:

1. Parse each script block with json.loads instead of regex so nested and array-valued @type entries are handled.
2. Report a count of how many distinct AEO types appear rather than a single yes-or-no.
3. Add Recipe and QAPage variants and warn when an Article page is missing any answer schema entirely.
4. Add a `"Recipe"` type and confirm it is not counted as AEO-relevant.

⚠ Common Mistakes

- A regex over raw text ignores JSON nesting; a `@type` inside an unrelated object still matches.
- Sorting is required because a set's print order is otherwise nondeterministic.
- Matching `"FAQ"` as a substring would wrongly catch `FAQPage` and vice versa; match the whole token.

Skills gained JSON-LD parsing | set operations | schema detection | AEO

→ Where You'll Use This: Verifying that priority pages actually emit FAQ or HowTo markup is a recurring audit task, since this schema is what wins expandable answer results and AI citations.

⚡ Mental Model

Schema is a label printed in a language only machines read; this check makes sure the most useful labels are actually on the box.

Project 468 Find the Passage That Answers a Question

💡 The Idea Behind It

Passage ranking lets an engine surface the single best sentence on a page rather than the whole document, and this project models that selection with a term-overlap score. It tokenises the question into a set of lowercase words, then for each candidate passage counts how many question terms reappear, keeping a running best. The loop is a tiny argmax: it never sorts, it simply remembers the highest overlap seen so far, which mirrors how a retriever picks one answer span from many.

What You'll Build & Learn

Pick the passage on a page that best answers a question by scoring shared terms against each candidate.

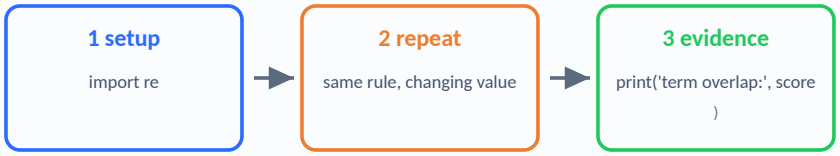
- Tokenise text into word sets
- Score relevance by term overlap
- Track a running maximum in a loop

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 467: detect faq and howto schema for aeo. Project 469 changes the surface problem while preserving the underlying method.

progress check

Reading target: find the passage that answers a question is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('term overlap:', score)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if overlap > score:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('term overlap:', score)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if overlap > score:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find the Passage That Answers a Question: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, question, what, is, canonical. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if overlap > score: | Evidence: print('term overlap:', score)

🛠️ Reader to Writer Bridge

1. Read: explain find the passage that answers a question in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 467.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 469 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('term overlap:', score)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find the passage that answers a question and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Tokenising both the question and each passage and counting shared words gives a crude relevance score; the highest-overlap passage is the likely answer.

```
import re
question = 'what is canonical url'
passages = [
    'A canonical URL is the single preferred address you tell search engines to
index for duplicate pages.',
    'Sitemaps list the URLs you want crawled.',
    'Redirects send users from an old URL to a new one.',
```

```
]
qterms = set(re.findall(r'[a-z]+', question.lower()))
best, score = None, -1
for p in passages:
    pterms = set(re.findall(r'[a-z]+', p.lower()))
    overlap = len(qterms & pterms)
    if overlap > score:
        best, score = p, overlap
print('best passage:', best)
print('term overlap:', score)
```

```
output
best passage: A canonical URL is the single preferred address you tell search
engines to index for duplicate pages.
term overlap: 3
```

How it works:

1. A question string and a list of three candidate passages about SEO concepts are defined upfront.
2. re.findall extracts lowercase alphabetic tokens from the question into a set called qterms.
3. Each passage is tokenised the same way, and the intersection size becomes its overlap score.
4. When a passage beats the current best score, best and score are updated to that passage.
5. The code prints the winning passage text and its term-overlap count.

Try it:

1. Weight rarer question terms more heavily so common words do not dominate the overlap score.
2. Break ties by preferring the shorter passage, which is usually the more quotable one.
3. Return the top three passages with their scores instead of only the single winner.
4. Add a stop-word filter so only content words contribute to overlap.

⚠ Common Mistakes

- Without lowercasing, `URL` and `url` count as different terms and miss the match.
- Stop words like `is` inflate overlap; a real ranker would remove them first.
- Ties are broken by whichever passage is seen first, which depends on list order.

Skills gained tokenisation | overlap scoring | argmax loop | passage ranking

→ Where You'll Use This: When diagnosing why a page is not cited for a query, scoring its passages against the target question shows whether any single sentence is a strong enough answer to be lifted.

Mental Model

It is a spotlight operator scanning a stage: whichever performer shares the most cues with the script gets the light.

Project 469 Match Questions to the Best Heading

The Idea Behind It

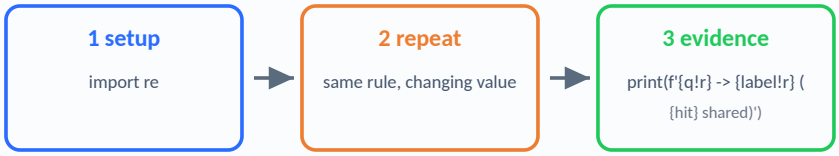
Mapping the questions people ask to the headings a page actually offers reveals how well content is organised around real intent. The code defines a keyword helper that tokenises a string and drops common stop words, then for each question uses max with a key function to pick the heading sharing the most meaningful words. Filtering stop words first is what makes the match honest, because it stops glue words like the or your from creating false overlaps between unrelated phrases.

What You'll Build & Learn

Match each user question to the page heading that best covers it and flag questions with no good match.

- Strip stop words before matching
- Use max with a key function
- Surface content gaps from zero matches

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 468: find the passage that answers a question. Project 470 changes the surface problem while preserving the underlying method. *progress check*

Reading target: match questions to the best heading is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{q!r} -> {label!r} ({hit} shared)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return {w for w in re.findall(r'[a-z]+', s.lower()) if w not in stop}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{q!r} -> {label!r} ({hit} shared)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return {w for w in re.findall(r'[a-z]+', s.lower()) if w not in stop}`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Match Questions to the Best Heading: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, questions, How, submit, sitemap. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: return {w for w in re.findall(r'[a-z]+', s.lower()) if w not in stop} | Evidence: print(f'{q!r} -> {label!r} ({hit} shared)')

🛠️ Reader to Writer Bridge

1. Read: explain match questions to the best heading in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 468.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 470 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{q!r} -> {label!r} ({hit} shared)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of match questions to the best heading and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

After stripping question words, the heading with the most shared content terms is the best topical match; zero shared terms means no heading covers that question.

```
import re
questions = ['How do I submit a sitemap?', 'What is crawl budget?', 'When does
Google recrawl?']
headings = ['Submitting Your Sitemap to Search Console', 'Understanding Crawl
```

```
Budget', 'How Often Google Recrawls Pages']
def keywords(s):
    stop =
{'how','do','i','a','what','is','when','does','the','to','your','and','often'}
    return {w for w in re.findall(r'[a-z]+', s.lower()) if w not in stop}
for q in questions:
    qk = keywords(q)
    best = max(headings, key=lambda h: len(qk & keywords(h)))
    hit = len(qk & keywords(best))
    label = best if hit else 'NO MATCH'
    print(f'{q!r} -> {label!r} ({hit} shared)')
```

```
output
'How do I submit a sitemap?' -> 'Submitting Your Sitemap to Search Console' (1
shared)
'What is crawl budget?' -> 'Understanding Crawl Budget' (2 shared)
'When does Google recrawl?' -> 'How Often Google Recrawls Pages' (1 shared)
```

How it works:

1. Parallel lists hold three user questions and three section headings drawn from a hypothetical guide.
2. The keywords helper lowercases, extracts alphabetic tokens, and removes a small stop-word set.
3. For each question, max scans the headings and returns the one with the largest keyword intersection.
4. If the best heading shares zero keywords, the label becomes the literal string NO MATCH.
5. Each line prints the question, its chosen heading or the gap marker, and the shared-word count.

Try it:

1. Expand the stop-word list or load it from a file so the matcher generalises across topics.
2. Add a minimum-overlap threshold so a weak single-word match is also reported as a gap.
3. Stem words like recrawl and recrawls to the same root so morphological variants still match.
4. Add a question with no matching heading and watch it report NO MATCH.

⚠ Common Mistakes

- A weak stop-word list leaves words like `often` to skew the overlap counts.
- `recrawl` and `recrawls` differ as tokens, so the match here rides on the shared word `google`.
- `max` over headings returns the first on a tie, so heading order can decide close calls.

Skills gained stop-word filtering | keyword matching | gap analysis | content mapping

→ Where You'll Use This: Content teams use this kind of question-to-heading mapping to audit whether a page structures its sections around the actual queries it is meant to rank for, exposing missing sections.

Mental Model

Like checking a book's chapter titles against a reader's questions: a question with no matching chapter is a hole in the table of contents.

Project 470 Test Featured-Snippet Eligibility

The Idea Behind It

Featured snippets are extracted from one of three shapes, a forty-to-sixty word paragraph, a list, or a table, so eligibility is really a question of format presence. The code measures the first paragraph's word count for the paragraph rule, then checks the markup for list and table tags, and declares the page eligible if any one of those conditions holds. The logical OR is the key idea: a page does not need every format, just one extractable structure, to qualify for a snippet.

What You'll Build & Learn

Estimate whether a page can win a featured snippet by checking for a tight paragraph, a list, or a table.

- Test multiple eligibility paths with OR
- Detect list and table markup
- Apply a paragraph word-count band

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 469: match questions to the best heading. Project 471 changes the surface problem while preserving the underlying method. *progress check*

Reading target: test featured-snippet eligibility is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated library calls.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.

- Evidence: `print('snippet-eligible:', 'YES' if eligible else 'NO')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('snippet-eligible:', 'YES' if eligible else 'NO')`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('snippet-eligible:', 'YES' if eligible else 'NO')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('snippet-eligible:', 'YES' if eligible else 'NO')`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Test Featured-Snippet Eligibility: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, redirect, is, permanent. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: print('snippet-eligible:', 'YES' if eligible else 'NO') | Evidence: print('snippet-eligible:', 'YES' if eligible else 'NO')

🛠️ Reader to Writer Bridge

1. Read: explain test featured-snippet eligibility in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 469.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 471 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('snippet-eligible:', 'YES' if eligible else 'NO')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of test featured-snippet eligibility and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A page qualifies if it has a paragraph in the snippet word band OR a list OR a table; any one extractable format is enough.

```
import re
html = '<p>A 301 redirect is a permanent server instruction that points one URL
to another and passes ranking signals to the new address for good.</p><ul>
<li>301 permanent</li><li>302 temporary</li></ul>'
para = re.search(r'<p>(.*?)</p>', html).group(1)
wc = len(para.split())
has_list = '<ul>' in html or '<ol>' in html
has_table = '<table' in html
para_ok = 40 <= wc <= 60
eligible = para_ok or has_list or has_table
print(f'paragraph words: {wc} (40–60 ok: {para_ok})')
print(f'has list: {has_list} | has table: {has_table}')
print('snippet-eligible:', 'YES' if eligible else 'NO')
```

```
output
paragraph words: 24 (40–60 ok: False)
has list: True | has table: False
snippet-eligible: YES
```

How it works:

1. An HTML string pairs a redirect definition paragraph with a short two-item unordered list.
2. re.search captures the first paragraph and its split length gives the word count wc.
3. para_ok is True only inside the forty-to-sixty band, while has_list and has_table test for tags.
4. eligible becomes True if the paragraph rule passes or either structural format is present.
5. Prints report the paragraph stats, the list and table flags, and the final eligibility verdict.

Try it:

1. Distinguish ordered from unordered lists and report which snippet type each format would feed.
2. Count how many qualifying structures exist so a richer page scores higher than a bare one.
3. Add a heading-plus-paragraph rule so definition snippets near an H2 also count as eligible.
4. Lengthen the paragraph into the 40-60 band and watch both routes qualify.

⚠ Common Mistakes

- The paragraph here is too short, so eligibility rides entirely on the list being present.
- Checking only `<ol>` misses unordered `<ul>` lists that snippets also use.
- An inline `<table>` used purely for layout would be a false positive for a data table.

Skills gained format detection | boolean OR | snippet eligibility | HTML parsing

→ Where You'll Use This: Before chasing a featured snippet for a target query, this quickly confirms the page even offers an extractable format, saving effort on pages that present only loose prose.

Mental Model

Snippets are like vending-machine slots shaped for paragraphs, lists, or tables; your content only needs to fit one slot to drop into the tray.

Project 471 Score E-E-A-T Signals From a Dict

The Idea Behind It

Experience, expertise, authoritativeness and trust feel abstract until you reduce them to concrete page signals you can count. This project stores seven such signals in a dictionary, then adds one point for each that passes its own rule, including a threshold check that outbound citations must reach at least two. Turning a fuzzy quality concept into a seven-point integer, then bucketing that integer into strong, moderate or weak, is exactly how an auditor makes E-E-A-T discussable with stakeholders.

What You'll Build & Learn

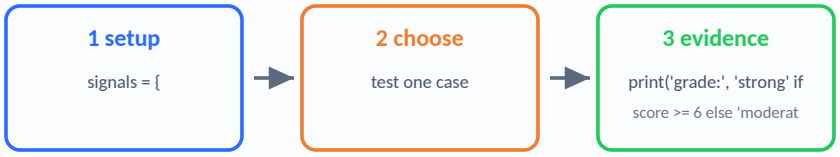
Convert a checklist of concrete trust signals into a single E-E-A-T score and a plain quality grade.

- Model qualitative signals as a dict
- Score with conditional point additions
- Bucket a score into named grades

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 470: test featured-snippet eligibility. Project 472 changes the surface problem while preserving the underlying method.

progress check



Reading target: score e-e-a-t signals from a dict is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `signals = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('grade:', 'strong' if score >= 6 else 'moderate' if score >= 4 else 'weak')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`signals = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`score += 1 if signals['author_bio'] else 0`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. slow line
3. Check the evidence	`print('grade:', 'strong' if score >= 6 else 'moderate' if score >= 4 else 'weak')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `score += 1 if signals['author_bio'] else 0`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Score E-E-A-T Signals From a Dict: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 472 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('grade:', 'strong' if score >= 6 else 'moderate' if score >= 4 else 'weak')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `signals = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score e-e-a-t signals from a dict and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each present trust signal (author bio, credentials, enough citations, dates, about/contact pages) adds a point; the total maps to a strong/moderate/weak grade.

```
signals = {
    'author_bio': True,
    'author_credentials': True,
    'outbound_citations': 4,
```

```
    'published_date': True,
    'updated_date': False,
    'about_page': True,
    'contact_page': False,
}
score = 0
score += 1 if signals['author_bio'] else 0
score += 1 if signals['author_credentials'] else 0
score += 1 if signals['outbound_citations'] >= 2 else 0
score += 1 if signals['published_date'] else 0
score += 1 if signals['updated_date'] else 0
score += 1 if signals['about_page'] else 0
score += 1 if signals['contact_page'] else 0
print(f'E-E-A-T score: {score}/7')
print('grade:', 'strong' if score >= 6 else 'moderate' if score >= 4 else
'weak')
```

```
output
E-E-A-T score: 5/7
grade: moderate
```

How it works:

1. A signals dictionary records seven boolean or numeric trust cues for a single page.
2. Each line adds one to score when its signal is truthy, using a threshold for outbound citations.
3. The citation rule awards a point only when the count is at least two, not for any single link.
4. The total is printed as a fraction out of seven so the ceiling is always visible.
5. A chained conditional maps the score to strong, moderate or weak using six-and-four cutoffs.

Try it:

1. Weight credentials and citations more heavily than the about and contact page signals.
2. Replace the manual additions with a loop that sums booleans for cleaner, shorter code.
3. Add an HTTPS and a reviewed-by-expert signal to extend the checklist beyond seven points.
4. Raise the citation threshold to 3 and watch the score drop.

⚠ Common Mistakes

- Treating `outbound_citations` as a boolean ignores that 1 citation is weak; a `>= 2` threshold is used here.
- A missing dict key would raise `KeyError`; every signal must be present in the fixture.
- Counting raw `True` values without thresholds would over-credit a single citation.

Skills gained dict scoring | threshold checks | grade bucketing | E-E-A-T

→ Where You'll Use This: Quantifying trust signals lets agencies show clients a before-and-after E-E-A-T number, which is increasingly tied to whether AI engines will cite a page as a reliable source.

Mental Model

Like a credit score for a page: many small verifiable facts roll up into one number lenders, or engines, trust at a glance.

Project 472 Flag Stale Content Against an As-Of Date

The Idea Behind It

Freshness is both a ranking and a trust signal, and answer engines lean toward pages that were updated recently. The code parses a fixed audit date and each page's last-updated date with strptime, subtracts them to get an age in days, and flags any page older than a year as stale. Anchoring everything to one explicit AS_OF constant rather than today's clock makes the audit deterministic, so re-running it next month never silently changes which pages were considered stale at audit time.

What You'll Build & Learn

Flag pages whose last-updated date is more than a year before a fixed audit date as stale content.

- Parse dates with strptime
- Compute an age via date subtraction
- Anchor audits to a fixed as-of date

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 471: score e-e-a-t signals from a dict. Project 473 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag stale content against an as-of date is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `from datetime import datetime` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from datetime import datetime`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Stale Content Against an As-Of Date: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: datetime, pages, guide, asof, strptime. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from datetime import datetime | Core: print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}') | Evidence: print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')

🛠️ Reader to Writer Bridge

1. Read: explain flag stale content against an as-of date in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 471.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 473 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from datetime import datetime` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag stale content against an as-of date and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`datetime.strptime` parses the embedded date strings (no clock call), and subtracting from a fixed as-of date gives an age in days that a 365-day threshold judges.

```
from datetime import datetime
AS_OF = '2026-06-22'
pages = {'/guide-a': '2026-05-01', '/guide-b': '2024-11-15', '/guide-c': '2026-06-10'}
asof = datetime.strptime(AS_OF, '%Y-%m-%d')
for path in sorted(pages):
    updated = datetime.strptime(pages[path], '%Y-%m-%d')
    age_days = (asof - updated).days
    stale = age_days > 365
    print(f'{path}: {age_days}d old -> {"STALE" if stale else "fresh"}')
```

```
output
/guide-a: 52d old -> fresh
/guide-b: 584d old -> STALE
/guide-c: 12d old -> fresh
```

How it works:

1. A constant AS_OF string and a dictionary of three page paths with update dates are defined.
2. strptime turns the as-of string into a datetime object the page dates can be compared against.
3. Iterating sorted paths, each page date is parsed and subtracted to yield an integer day age.
4. The stale flag is True whenever that age exceeds three hundred sixty-five days.
5. Each line prints the path, its age in days, and a STALE or fresh label.

Try it:

1. Make the staleness window configurable so news pages use ninety days and evergreen pages use a year.
2. Sort the output by age so the stalest pages surface at the top of the report.
3. Read the page dates and as-of value from a CSV file rather than a hard-coded dictionary.
4. Move `AS_OF` forward a year and watch more pages turn STALE.

⚠ Common Mistakes

- Using `datetime.now()` would be nondeterministic; a fixed `AS_OF` constant keeps the audit reproducible.
- Comparing date strings lexically works for ISO dates but breaks the day-count maths.
- An off-by-one in the threshold (`>=` vs `>`) reclassifies a page exactly one year old.

Skills gained date parsing | datetime math | freshness audit | deterministic runs

→ Where You'll Use This: Editorial and content-decay audits use exactly this logic to build refresh queues, prioritising the oldest evergreen pages that have drifted past a freshness threshold.

Mental Model

Treat content like food in a fridge: each page carries a date, and anything past its window gets pulled and refreshed before it spoils trust.

Project 473 Count Outbound Citations to Sources

The Idea Behind It

Linking out to authoritative sources is a trust signal both reviewers and answer engines weigh, so it pays to separate genuine citations from internal navigation. The code extracts every href with a regex, then partitions them into outbound links that start with https and internal links that start with a slash. Pulling the host out of each outbound URL with a split on the third path segment also reports which domains the page actually cites, turning a raw link count into a meaningful sourcing profile.

What You'll Build & Learn

Count a page's outbound citations versus internal links and list the external domains it references.

- Extract all hrefs with one regex
- Partition links by URL prefix
- Derive a host from a URL split

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 472: flag stale content against an as-of date. Project 474 changes the surface problem while preserving the underlying method. *progress check*

Reading target: count outbound citations to sources is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('cited domains:', sorted({h.split('/')[2] for h in outbound}))` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`outbound = [h for h in hrefs if h.startswith('https://')]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('cited domains:', sorted({h.split('/')[2] for h in outbound}))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `outbound = [h for h in hrefs if h.startswith('https://')]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Outbound Citations to Sources: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, Per, the, href. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: outbound = [h for h in hrefs if h.startswith('https://')] | Evidence: print('cited domains:', sorted({h.split('/')[2] for h in outbound}))

🛠️ Reader to Writer Bridge

1. Read: explain count outbound citations to sources in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 472.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 474 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('cited domains:', sorted({h.split('/')[2] for h in outbound}))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count outbound citations to sources and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Splitting hrefs by whether they start with `https://` (external) or `/` (internal) counts citations, and the host slice gives the distinct domains cited.

```
import re
html = '''<p>Per the <a href="https://standards.org/spec">spec</a>, see also
<a href="https://web.dev/lcp">web.dev</a> and <a href="/internal/page">our
guide</a>.</p>'''
hrefs = re.findall(r'href="([^"]+)"', html)
outbound = [h for h in hrefs if h.startswith('https://')]
internal = [h for h in hrefs if h.startswith('/')]
print('outbound citations:', len(outbound))
print('internal links:', len(internal))
print('cited domains:', sorted({h.split('/')[2] for h in outbound}))
```

```
output
outbound citations: 2
internal links: 1
cited domains: ['standards.org', 'web.dev']
```

How it works:

1. A multi-line HTML string contains two external https links and one internal slash-prefixed link.
2. re.findall captures every value inside an href attribute into a flat list of URLs.
3. A comprehension keeps links starting with https as outbound and slash-prefixed ones as internal.
4. Splitting each outbound URL on slashes and taking index two extracts the bare domain name.
5. Prints report the outbound count, the internal count, and the sorted set of cited domains.

Try it:

1. Use urllib.parse to extract hosts robustly instead of splitting on the third slash.
2. Flag nofollow links separately so sculpted and editorial citations are distinguished.
3. Treat links to the page's own domain as internal even when they use a full https URL.
4. Add another external link to the same domain and watch the citation count rise but domains stay.

⚠ Common Mistakes

- A relative link without a leading slash slips past the `/`-prefix internal test.
- Protocol-relative or uppercase-scheme URLs would not start with `https://` and be miscounted.
- `h.split('/')[2]` assumes a well-formed absolute URL; a malformed href would index out of range.

Skills gained href extraction | link partitioning | domain parsing | citation audit

→ Where You'll Use This: Assessing how well-sourced a page is, and which authorities it leans on, supports both E-E-A-T audits and competitive analysis of why rival pages earn more trust.

Mental Model

Citations are an academic paper's bibliography: a page that names credible sources reads as researched, while a sourceless one reads as opinion.

Project 474 Detect a Substantive Author Bio

The Idea Behind It

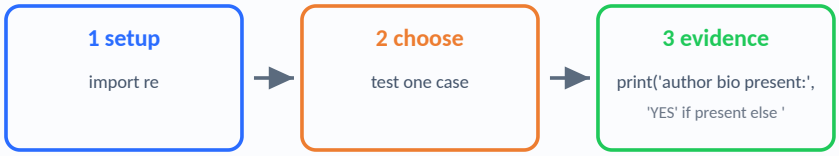
A named author with a real biography is a core trust cue, but a byline that is just a name proves little. This code confirms three things together: that an author-bio block exists in the markup, that a name can be captured from it, and that the bio paragraph carries at least ten words of substance. Requiring all three with a single combined boolean stops a decorative byline from passing, which is what separates genuine authorship signals from cosmetic ones.

What You'll Build & Learn

Verify a page has a real author block, a captured name, and a bio of meaningful length, not just a byline.

- Detect a block by class substring
- Capture nested text with re.S
- Gate on a minimum bio length

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 473: count outbound citations to sources. Project 475 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect a substantive author bio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is about responsibility: data and behaviour are grouped under a name, so read methods as actions that belong to that object.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('author bio present:', 'YES' if present else 'NO')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`bio_words = len(bio_m.group(1).split()) if bio_m else 0`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. slow line
3. Check the evidence	`print('author bio present:', 'YES' if present else 'NO')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `bio_words = len(bio_m.group(1).split()) if bio_m else 0`

Construction pattern

The construction groups state and behavior under names. Read the class/record/interface header, then ask what each method is responsible for.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

List the fields or attributes first, then read methods as behavior attached to that stored state.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Substantive Author Bio: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, article, Body, text. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; classes/records group responsibilities; conditions choose a route.
Data shape	Object data: state is bundled with the methods that operate on it.
Evidence	Entry: import re | Core: bio_words = len(bio_m.group(1).split()) if bio_m else 0 | Evidence: print('author bio present:', 'YES' if present else 'NO')

🛠️ Reader to Writer Bridge

1. Read: explain detect a substantive author bio in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 473.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 475 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('author bio present:', 'YES' if present else 'NO')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a substantive author bio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Requiring an `author-bio` block, a captured name, and a bio of at least 10 words rejects empty or token bylines while accepting a genuine one.

```
import re
html = '''<article><p>Body text here.</p>
<div class="author-bio"><span class="author-name">Dana Lee</span>
<p>Dana is a senior SEO engineer with 10 years auditing technical sites.</p>
</div></article>'''
```

```
has_block = 'author-bio' in html
name_m = re.search(r'author-name">([^<]+)<', html)
bio_m = re.search(r'author-bio".*?<p>([^<]+)</p>', html, re.S)
bio_words = len(bio_m.group(1).split()) if bio_m else 0
present = has_block and name_m and bio_words >= 10
print('author block:', has_block)
print('author name:', name_m.group(1) if name_m else None)
print('bio words:', bio_words)
print('author bio present:', 'YES' if present else 'NO')
```

```
output
author block: True
author name: Dana Lee
bio words: 12
author bio present: YES
```

How it works:

1. An article string nests an author-bio div containing an author-name span and a biography paragraph.
2. A simple substring test sets has_block True when author-bio appears in the markup.
3. One regex captures the author name and another, using re.S, captures the bio paragraph across newlines.
4. The bio word count comes from splitting that captured paragraph, defaulting to zero if absent.
5. present is True only when the block, a name, and a ten-word bio all hold, and a YES prints.

Try it:

1. Also require a link to an author page or a sameAs profile to strengthen the signal.
2. Detect multiple author blocks on a page and report each name and bio length.
3. Raise the bio threshold and check that the bio mentions a relevant credential keyword.
4. Shorten the bio under 10 words and watch the verdict flip to NO.

⚠ Common Mistakes

- The bio regex uses `re.S` so `.*?` can cross newlines between the block and its `<p>`.
- A byline with a name but no descriptive bio passes the name test yet should fail on word count.
- Hard-coding the `author-bio` class name misses sites that mark up bios differently.

Skills gained substring detection | multiline regex | length gating | authorship signals

→ Where You'll Use This: Confirming bylines are backed by substantive author bios is central to E-E-A-T audits, especially for your-money-your-life pages where Google scrutinises authorship hardest.

⚡ Mental Model

A byline without a bio is a signature on a blank cheque: the name means nothing until something behind it vouches for the person.

Project 475 Count Distinct Entity Mentions

💡 The Idea Behind It

Knowledge-graph-aware engines read topical depth partly through entity coverage, the named tools, brands and concepts a page discusses. This project counts how many times each entity from a known list appears in a passage using an escaped regex inside a Counter, then reports the number of distinct entities mentioned at least once. Counting both per-entity frequency and distinct coverage matters because depth comes from breadth of entities, not just repeating one name many times.

What You'll Build & Learn

Count mentions of known entities in a text and report how many distinct ones the page covers.

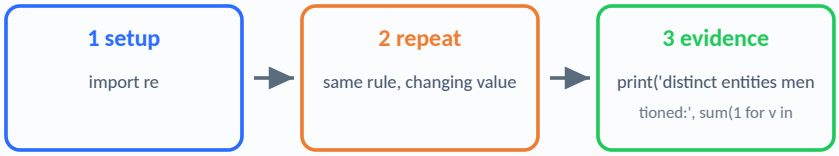
- Count substring hits with re.escape
- Tally frequencies in a Counter
- Measure distinct entity coverage

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 474: detect a substantive author bio. Project 476 changes the surface problem while preserving the underlying method.

progress check

Reading target: count distinct entity mentions is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated library calls.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.

- Evidence: `print('distinct entities mentioned:', sum(1 for v in counts.values() if v))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('distinct entities mentioned:', sum(1 for v in counts.values() if v))`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('distinct entities mentioned:', sum(1 for v in counts.values() if v))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('distinct entities mentioned:', sum(1 for v in counts.values() if v))`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Distinct Entity Mentions: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, collections, Counter, text, Google. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: print('distinct entities mentioned:', sum(1 for v in counts.values() if... | Evidence: print('distinct entities mentioned:', sum(1 for v in counts.values() if...

🛠️ Reader to Writer Bridge

1. Read: explain count distinct entity mentions in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 474.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 476 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('distinct entities mentioned:', sum(1 for v in counts.values() if v))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count distinct entity mentions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting each entity phrase with `re.escape` tallies mentions, and summing the entities with a nonzero count gives breadth of entity coverage.

```
import re
from collections import Counter
text = '''Google Search Console reports indexing status. Search Console
connects to
Googlebot data, while Bing Webmaster Tools offers similar coverage for Bing.'''
entities = ['Google Search Console', 'Googlebot', 'Bing Webmaster Tools',
'Bing']
counts = Counter()
for e in entities:
    counts[e] = len(re.findall(re.escape(e), text))
for e in sorted(counts):
    print(f'{e}: {counts[e]}')
print('distinct entities mentioned:', sum(1 for v in counts.values() if v))
```

```
output
Bing: 2
Bing Webmaster Tools: 1
Google Search Console: 1
Googlebot: 1
distinct entities mentioned: 4
```

How it works:

1. A multi-line text mentions several SEO tools, and a list names the four entities to track.
2. A Counter is filled by running re.findall with re.escape for each entity against the text.
3. Escaping the entity protects literal characters so brand names match exactly, not as patterns.
4. Iterating the sorted Counter prints each entity alongside its raw mention count.
5. A final sum counts entities with a non-zero tally to report distinct coverage.

Try it:

1. Make matching case-insensitive and word-bounded so partial overlaps do not double-count.
2. Build the entity list automatically from a competitor's page rather than hard-coding it.
3. Report the share of expected entities covered as a percentage to grade topical completeness.
4. Use word-boundary matching to stop `Bing` counting inside the longer phrase.

⚠ Common Mistakes

- `Bing` shows 2 because it is also a substring of `Bing Webmaster Tools`; overlapping entities double-count.
- Without `re.escape`, an entity containing regex metacharacters would break the pattern.
- Case-sensitive matching misses `bing` written in lower case in the body.

Skills gained `entity counting` `Counter usage` `regex escaping` `topical depth`

→ **Where You'll Use This:** Entity-coverage analysis informs content briefs, showing which related tools, brands or concepts a page must mention to read as authoritative to entity-driven AI search.

⚡ Mental Model

Entities are the cast list of a topic; a thin page names one or two actors, while a deep one introduces the whole ensemble.

Project 476 Classify a Block's Answer Format

💡 The Idea Behind It

Answer engines extract differently from lists, tables, definitions and plain prose, so labelling each block by its format predicts how it might be reused. This code walks a dictionary of HTML blocks and applies an ordered set of tests: list tags first, then table tags, then a definition pattern matching an X is a opener, falling through to prose. The ordering is deliberate, because the most distinctive structural markers are checked before the looser linguistic one, avoiding misclassification.

What You'll Build & Learn

Classify each content block as a list, table, definition, or plain prose by its markup and phrasing.

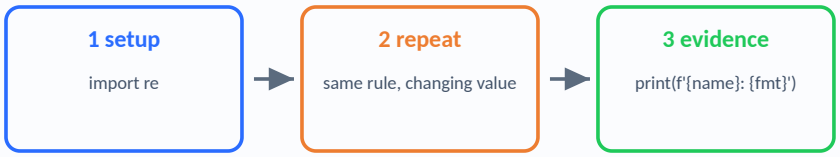
- Order tests from specific to general
- Match a definition with a regex opener
- Map blocks to answer-format labels

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 475: count distinct entity mentions. Project 477 changes the surface problem while preserving the underlying method.

progress check

Reading target: classify a block's answer format is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a

32-point technical audit.

- Evidence: `print(f'{name}: {fmt}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if re.search(r'<ol>|<ul>', h):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{name}: {fmt}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if re.search(r'<ol>|<ul>', h):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Classify a Block's Answer Format: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, blocks, definition, Crawl, budget. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if re.search(r' | ', h): | Evidence: print(f'{name}: {fmt}')

🛠️ Reader to Writer Bridge

1. Read: explain classify a block's answer format in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 475.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 477 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {fmt}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify a block's answer format and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Ordered checks (list, then table, then a `term is/are a ...` definition pattern, else prose) bucket each block into the format an engine would most likely lift.

```
import re
blocks = {
    'definition': '<p>Crawl budget is the number of pages Googlebot will fetch.
</p>',
    'steps': '<ol><li>Open Search Console</li><li>Submit sitemap</li></ol>',
    'comparison': '<table><tr><th>301</th><th>302</th></tr></table>',
    'plain': '<p>We think SEO is great and you should try it sometime soon.
</p>',
}
for name, h in blocks.items():
    if re.search(r'<ol>|<ul>', h):
        fmt = 'list/steps'
    elif '<table' in h:
        fmt = 'table/comparison'
    elif re.match(r'<p>\w+( \w+)? (is|are) (a |an |the )', h):
        fmt = 'definition'
    else:
        fmt = 'prose'
    print(f'{name}: {fmt}')
```

```
output
definition: definition
steps: list/steps
comparison: table/comparison
plain: prose
```

How it works:

1. A dictionary pairs four named blocks with HTML for a definition, steps, a comparison, and plain text.
2. For each block, an ordered chain tests for list tags, then a table tag, then a definition pattern.
3. The definition regex matches a paragraph opening with an optional article and an is or are verb.
4. Any block matching none of those rules falls through to the prose label.
5. Each block name prints next to its inferred answer-format category.

Try it:

1. Add a steps-versus-unordered-list distinction so how-to content is labelled separately.
2. Return a confidence score alongside each label rather than a single hard category.
3. Handle blocks that mix formats, such as a paragraph followed by a list, with a combined tag.
4. Add a numbered `<ol>` block and confirm it reads as list/steps.

⚠ Common Mistakes

- The definition pattern requires an article after `is/are`, so `SEO is great` correctly falls through to prose.
- Checking definition before lists would misclassify a list item that happens to read like a sentence.

- A `<table>` used for layout still classifies as a comparison table here.

Skills gained `block classification` `ordered conditionals` `definition regex` `format mapping`

→ **Where You'll Use This:** Profiling the mix of answer formats across a page or site shows whether content is shaped for extraction, guiding where to convert dense prose into lists or tables.

⚡ Mental Model

It is a recycling sorter: each block drops down a chute of shape tests until it lands in the bin labelled list, table, definition or prose.

Project 477 Run an Answer-Box Readiness Checklist

💡 The Idea Behind It

Winning an answer box needs several conditions at once, so this project scores readiness against a five-item checklist rather than any single test. It stores five boolean page properties, pairs each with a human-readable label in a list of tuples, then sums the passing ones and prints a checkbox line for each. The tuple-of-label-and-flag structure is the useful pattern: it keeps the display text beside the data, so the report and the score are driven by one source of truth.

What You'll Build & Learn

Score a page against a five-point answer-box checklist and render a readable pass-or-fail report.

- Pair labels with flags in tuples
- Sum booleans to score a checklist
- Render checkbox-style report lines

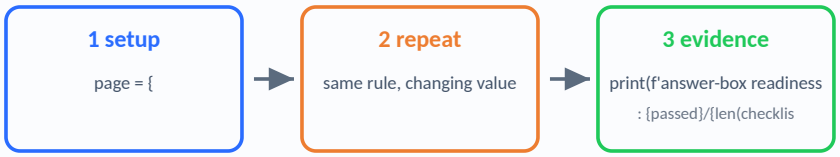
🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 476: classify a block's answer format. Project 478 changes the surface problem while preserving the underlying method.

progress check

Reading target: run an answer-box readiness checklist is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



🔎 Logic Lens

- Setup: `page = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'answer-box readiness: {passed}/{len(checklist)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`page = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`passed = sum(1 for _, ok in checklist if ok)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'answer-box readiness: {passed}/{len(checklist)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `passed = sum(1 for _, ok in checklist if ok)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run an Answer-Box Readiness Checklist: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: page, question_heading, concise_answer_first, answer_under_60_words, supporting_detail. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.

🛠️ Reader to Writer Bridge

1. Read: explain run an answer-box readiness checklist in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 476.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 478 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'answer-box readiness: {passed}/{len(checklist)}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `page = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run an answer-box readiness checklist and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each readiness criterion is a boolean in the page dict; printing a ticked checklist and the pass tally turns the abstract goal into an actionable score.

```
page = {
    'question_heading': True,
    'concise_answer_first': True,
    'answer_under_60_words': True,
    'supporting_detail': True,
    'schema_qapage': False,
}
checklist = [
    ('Question-style heading', page['question_heading']),
    ('Concise answer up top', page['concise_answer_first']),
    ('Answer under 60 words', page['answer_under_60_words']),
    ('Supporting detail below', page['supporting_detail']),
    ('QAPage schema', page['schema_qapage']),
]
passed = sum(1 for _, ok in checklist if ok)
for name, ok in checklist:
    print(f'[{"x" if ok else " "}] {name}')
print(f'answer-box readiness: {passed}/{len(checklist)}')
```

```
output
[x] Question-style heading
[x] Concise answer up top
[x] Answer under 60 words
[x] Supporting detail below
[ ] QAPage schema
answer-box readiness: 4/5
```

How it works:

1. A page dictionary records five answer-box readiness booleans, one of them False for QAPage schema.
2. A checklist list pairs each human-readable criterion name with its corresponding page flag.
3. passed sums the truthy flags by iterating the tuples and counting where ok is True.
4. A loop prints each criterion with an x in brackets when passed and a space when not.
5. The closing line reports the score as passed over the total number of checklist items.

Try it:

1. Append the failing criteria to a separate list and print them as next-step actions.
2. Add weights so the concise-answer item counts more than the supporting-detail one.
3. Read the page flags from a real HTML parse instead of a pre-filled dictionary.
4. Flip `schema_qapage` to True and watch the score hit 5/5.

⚠ Common Mistakes

- Reading missing dict keys would raise; every criterion must be present in the fixture.
- Counting `True` values without printing them hides which criterion failed.
- Treating the 5/5 as required ignores that 4/5 can still win an answer box.

Skills gained checklist scoring | tuple pairing | boolean summing | answer-box readiness

→ Where You'll Use This: This checklist-plus-report pattern is the backbone of client-facing audit deliverables, where each unchecked item becomes a concrete recommendation to chase an answer box.

Mental Model

Like a pre-flight checklist: every box must be ticked before the plane, or the page, is cleared to claim the answer box.

Project 478 Score AI-Mode Readiness With Weights

The Idea Behind It

AI-mode search rewards clear structure, schema, concise answers, freshness and citations, but it does not value them equally, so a weighted score is more honest than a flat count. The code holds page signals in one dictionary and per-signal weights in another, sums the weights of the truthy signals, and converts that to a percentage of the maximum. Looking up each signal's weight only when its flag is True is the crux: it lets the most important factors, like concise answers, dominate the readiness number.

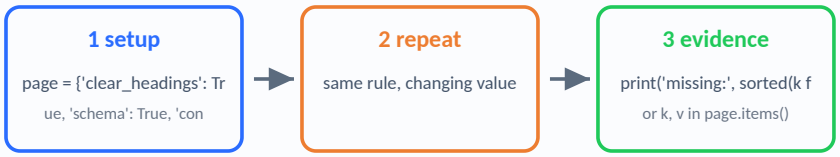
What You'll Build & Learn

Score AI-mode readiness with per-signal weights, give a percentage verdict, and list what is missing.

- Weight signals with a parallel dict
- Sum weights only for passing signals
- Convert a score into a percentage

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 477: run an answer-box readiness checklist. Project 479 changes the surface problem while preserving the underlying method.



progress check

Reading target: score ai-mode readiness with weights is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `page = {'clear_headings': True, 'schema': True, 'concise_answers': True, 'fresh': False, 'cited_sources': True}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('missing:', sorted(k for k, v in page.items() if not v))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`page = {'clear_headings': True, 'schema': True, 'concise_answers': True, 'fresh': False, 'cited_sources': True}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`got = sum(weights[k] for k, v in page.items() if v)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('missing:', sorted(k for k, v in page.items() if not v))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `got = sum(weights[k] for k, v in page.items() if v)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score AI-Mode Readiness With Weights: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: page, clear_headings, schema, concise_answers, fresh. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: page = {'clear_headings': True, 'schema': True, 'concise_answers': True... | Core: got = sum(weights[k] for k, v in page.items() if v) | Evidence: print('missing:', sorted(k for k, v in page.items() if not v))

🛠️ Reader to Writer Bridge

1. Read: explain score ai-mode readiness with weights in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 477.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 479 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('missing:', sorted(k for k, v in page.items() if not v))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `page = {'clear_headings': True, 'schema': True, 'concise_answers': True, 'fresh': False, 'cited_sources': True}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score ai-mode readiness with weights and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Summing the weights of only the present signals over the total weight gives a percentage; concise answers and schema carry more weight than freshness.

```
page = {'clear_headings': True, 'schema': True, 'concise_answers': True,
'fresh': False, 'cited_sources': True}
weights = {'clear_headings': 2, 'schema': 2, 'concise_answers': 3, 'fresh': 1,
'cited_sources': 2}
got = sum(weights[k] for k, v in page.items() if v)
total = sum(weights.values())
pct = round(100 * got / total)
print(f'AI-mode readiness: {got}/{total} ({pct}%)')
print('verdict:', 'ready' if pct >= 70 else 'needs work')
print('missing:', sorted(k for k, v in page.items() if not v))
```

```
output
AI-mode readiness: 9/10 (90%)
verdict: ready
missing: ['fresh']
```

How it works:

1. One dictionary stores five readiness booleans and a parallel dictionary stores each signal's weight.
2. got sums the weight of every signal whose flag is True by iterating the page items.
3. total sums all weights so the percentage uses the full possible score as its denominator.
4. The percentage is rounded and compared against seventy to decide ready or needs work.
5. A final print lists the sorted names of any signals that are still False.

Try it:

1. Tune the weights from observed correlation with citations rather than fixed guesses.
2. Add an interpolated grade band so scores near the threshold are not a binary cliff.
3. Print each missing signal alongside the points it would add if fixed.
4. Bump the `fresh` weight to 3 and watch the percentage fall.

⚠ Common Mistakes

- Using equal weights would over-value freshness relative to concise answers.
- Dividing by the count of present signals instead of total weight inflates the percentage.
- A signal absent from the weights dict would raise `KeyError` during the sum.

Skills gained weighted scoring | percentage math | verdict thresholds | AI-mode readiness

→ Where You'll Use This: A weighted readiness score lets you prioritise fixes by impact when preparing pages for generative search, focusing effort on the heavily weighted signals first.

Mental Model

Like a recipe where some ingredients are essential and others optional: leaving out the salt costs more than skipping a garnish.

Project 479 Count Extractable Lists and Tables

The Idea Behind It

Lists and tables are the structures answer engines most readily lift into rich results, so counting them gauges how much extractable structure a page offers. The code uses regexes to find unordered-list blocks, individual list items, and table rows, then computes a simple extractable-structures total that adds the list count plus one if any table rows exist. Treating an entire table as a single extractable unit while counting lists individually reflects how engines reuse a whole table versus separate list blocks.

What You'll Build & Learn

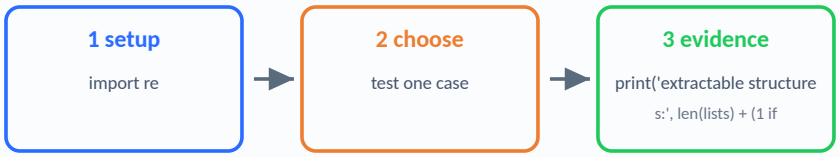
Count the lists, list items, and table rows on a page and report how many extractable structures exist.

- Match block and item tags separately
- Count table rows with a row regex
- Combine counts into one structure total

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 478: score ai-mode readiness with weights. Project 480 changes the surface problem while preserving the underlying method.

progress check



Reading target: count extractable lists and tables is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('extractable structures:', len(lists) + (1 if rows else 0))` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('extractable structures:', len(lists) + (1 if rows else 0))`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('extractable structures:', len(lists) + (1 if rows else 0))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('extractable structures:', len(lists) + (1 if rows else 0))`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Count Extractable Lists and Tables: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, h2, Sitemap, Limits. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('extractable structures:', len(lists) + (1 if rows else 0)) | Evidence: print('extractable structures:', len(lists) + (1 if rows else 0))

🛠️ Reader to Writer Bridge

1. Read: explain count extractable lists and tables in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 478.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 480 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('extractable structures:', len(lists) + (1 if rows else 0))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of count extractable lists and tables and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Regexes over `<ul>`/`<li>`/`<tr>` count the list blocks, their items, and the table rows; a list plus a table is two extractable structures.

```
import re
html = '''<h2>Sitemap Limits</h2>
<ul><li>50,000 URLs max</li><li>50MB uncompressed</li><li>One sitemap
index</li></ul>
<table><tr><th>Type</th><th>Limit</th></tr><tr><td>URLs</td><td>50000</td></tr>
</table>'''
lists = re.findall(r'<ul>(.*?)</ul>', html, re.S)
list_items = re.findall(r'<li>(.*?)</li>', html)
rows = re.findall(r'<tr>', html)
print('lists found:', len(lists))
print('list items:', len(list_items))
print('table rows:', len(rows))
print('extractable structures:', len(lists) + (1 if rows else 0))
```

```
output
lists found: 1
list items: 3
table rows: 2
extractable structures: 2
```

How it works:

1. A multi-line HTML string holds a heading, a three-item unordered list, and a small two-row table.
2. re.findall with re.S captures whole list blocks, while a second call counts individual list items.
3. A third findall counts opening table-row tags to measure the table's size.
4. The extractable total adds the number of lists plus one when any table rows were found.
5. Four prints report the list count, item count, row count, and combined extractable-structure total.

Try it:

1. Include ordered lists and definition lists so every structured block is counted.
2. Count each table as a structure rather than collapsing all tables into a single unit.
3. Report items per list so a one-item list does not count the same as a rich ten-item list.
4. Add a second `<ul>` and watch the list count rise.

⚠ Common Mistakes

- A greedy `<ul>(.*)</ul>` across two lists would merge them into one match; `.*?` with `re.S` keeps them separate.
- Counting `<tr>` includes the header row, so subtract one for data-row counts if needed.
- Nested lists are counted as separate `<ul>` blocks, which can overstate distinct structures.

Skills gained structure counting | regex with re.S | row tallying | extractability

→ Where You'll Use This: Quantifying extractable structures helps prioritise which dense pages to restructure into lists and tables when chasing rich results and AI-citation eligibility.

⚡ Mental Model

Lists and tables are pre-cut handles on the page; the more handles, the easier it is for an engine to grab a piece and carry it away.

Project 480 Detect Definition-Format Sentences

💡 The Idea Behind It

A clean definition sentence is exactly what answer engines quote for what-is queries, so detecting that pattern surfaces a page's quotable lines. The code compiles a case-insensitive regex that matches a sentence opening with an optional article, a captured subject word, and a defining verb such as is, are, means or refers to. Running match rather than search anchors the test to the start of each paragraph, which keeps it from firing on a defining phrase buried mid-sentence where it would not read as a clean definition.

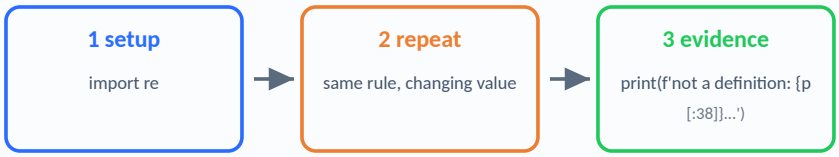
What You'll Build & Learn

Detect paragraphs written as clean definitions and report the term each one defines.

- Compile a reusable regex pattern
- Anchor a match to the sentence start
- Capture the defined subject term

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 479: count extractable lists and tables. Project 481 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect definition-format sentences is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'not a definition: {p[:38]}...')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if m:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'not a definition: {p[:38]}...')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Definition-Format Sentences: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, paras, Canonicalization, is, the. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if m: | Evidence: print(f'not a definition: {p[:38]}...')

🛠️ Reader to Writer Bridge

1. Read: explain detect definition-format sentences in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 479.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 481 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'not a definition: {p[:38]}...')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect definition-format sentences and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

An anchored regex allowing an optional leading article then `term is/are/means/refers to` captures the defined term and rejects sentences that merely contain `is`.

```
import re
paras = [
    'Canonicalization is the process of selecting one URL among duplicates.',
    'You should always check your robots file before launch.',
    'A redirect is a server response that forwards one URL to another.',
]
pat = re.compile(r'^(?:A |An |The )?(\w+) (?:is|are|means|refers to) ', re.I)
for p in paras:
    m = pat.match(p)
    if m:
        print(f'DEFINITION of {m.group(1)!r}')
    else:
        print(f'not a definition: {p[:38]}...')
```

```
output
DEFINITION of 'Canonicalization'
not a definition: You should always check your robots fi...
DEFINITION of 'redirect'
```

How it works:

1. A list holds three paragraphs, two of which are phrased as definitions and one as advice.
2. re.compile builds a case-insensitive pattern with an optional leading article and a defining verb.
3. Using match, the pattern only succeeds when the paragraph starts with the definition shape.
4. When it matches, group one yields the subject term, printed as DEFINITION of that term.
5. Non-matching paragraphs print a truncated preview labelled not a definition.

Try it:

1. Capture multi-word subjects so a phrase like canonical URL is reported whole.
2. Add more defining verbs such as describes and denotes to widen detection.
3. Score each definition by length and flag ones too long to be quoted cleanly.
4. Add `consists of` to the verb alternation and test a new sentence.

⚠ Common Mistakes

- Requiring the verb to be followed by a space stops `is.` style false ends, but a comma after the term would still pass.
- An imperative sentence like `You should check ...` has no defining verb early, so it falls through.
- Multi-word terms before the verb are collapsed to one captured token here.

Skills gained compiled regex | anchored matching | group capture | definition detection

→ Where You'll Use This: Finding a page's definition sentences pinpoints the lines most likely to be quoted in featured snippets and AI answers, and shows where a missing definition could be added.

⚡ Mental Model

Think of a dictionary entry: the headword followed by a crisp gloss is exactly the shape an engine reaches for when someone asks what something means.

Project 481 Detect a Comparison Table

💡 The Idea Behind It

Comparison tables answer X versus Y queries and earn table-style rich results, so it helps to tell a true comparison from an incidental table. The code captures the header row, extracts its column headers, and separates the body rows, then declares a comparison only when there are three or more columns and at least one body row. Requiring three columns is the insight: a feature column plus two or more compared items is what makes a table a side-by-side comparison rather than a simple two-column list.

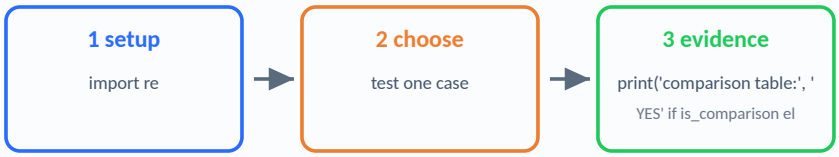
What You'll Build & Learn

Detect whether a table is a genuine comparison by checking its columns and body rows.

- Capture a table's header row
- Extract column headers with regex
- Define comparison by column count

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 480: detect definition-format sentences. Project 482 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a comparison table is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('comparison table:', 'YES' if is_comparison else 'NO')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('compared items:', cols[1:] if cols else [])`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('comparison table:', 'YES' if is_comparison else 'NO')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('compared items:', cols[1:] if cols else [])`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Comparison Table: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, html, table, tr, th. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('compared items:', cols[1:] if cols else []) | Evidence: print('comparison table:', 'YES' if is_comparison else 'NO')

🛠️ Reader to Writer Bridge

1. Read: explain detect a comparison table in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 480.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 482 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('comparison table:', 'YES' if is_comparison else 'NO')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect a comparison table and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The first `<tr>` holds the header; three or more `<th>` columns and at least one body `<tr>` indicate a comparison of the items named after the leading label column.

```
import re
html = '''<table>
<tr><th>Feature</th><th>301</th><th>302</th></tr>
<tr><td>Permanent</td><td>Yes</td><td>No</td></tr>
<tr><td>Passes equity</td><td>Yes</td><td>Partial</td></tr>
</table>'''
header = re.search(r'<tr>(.*?)</tr>', html, re.S).group(1)
cols = re.findall(r'<th>(.*?)</th>', header)
body_rows = re.findall(r'<tr>(.*?)</tr>', html, re.S)[1:]
is_comparison = len(cols) >= 3 and len(body_rows) >= 1
print('columns:', cols)
print('compared items:', cols[1:] if cols else [])
print('comparison table:', 'YES' if is_comparison else 'NO')
```

```
output
columns: ['Feature', '301', '302']
compared items: ['301', '302']
comparison table: YES
```

How it works:

1. A multi-line HTML table compares two redirect types across two feature rows.
2. re.search with re.S captures the first row, and findall pulls its header cells into a list.
3. Slicing all rows from index one onward separates the body rows from the header.
4. is_comparison is True when there are at least three columns and one or more body rows.
5. Prints report the columns, the compared items after the first column, and the verdict.

Try it:

1. Validate that every body row has the same number of cells as the header.
2. Report which feature differs most between the compared items by scanning the body cells.
3. Handle tables whose header uses table-data cells instead of table-header cells.
4. Drop a column so only two remain and watch the verdict flip to NO.

⚠ Common Mistakes

- Using `re.S` is needed because the rows span newlines in the fixture.

- Counting `<th>` across the whole table, not just the header row, would overcount columns.
- A two-column table is a key/value list, not a comparison, so the `>= 3` test excludes it.

Skills gained table parsing | header extraction | row slicing | comparison detection

→ Where You'll Use This: Identifying real comparison tables helps target X-versus-Y queries, since these tables both serve users and earn the table rich results that drive clicks.

⚡ Mental Model

A comparison table is a head-to-head scorecard: one column names the criteria and each rival gets its own column to be judged against them.

Project 482 Detect Statistics Backed by a Source

💡 The Idea Behind It

A statistic with a named source is far more trustworthy and citable than a bare number, so this project separates cited stats from unsourced ones. It splits the text into sentences with a lookbehind regex, then for each sentence tests two independent conditions: whether a number with a percent marker appears, and whether a source cue like a parenthetical Source or according to is present. Printing only the sentences that contain a statistic, labelled by whether a source backs them, turns prose into a list of claims to keep or fix.

What You'll Build & Learn

Split text into sentences and flag each statistic as cited or unsourced based on a named source cue.

- Split sentences with a lookbehind
- Detect a percentage with regex
- Test for source-attribution cues

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 481: detect a comparison table. Project 483 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect statistics backed by a source is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('UNSOURCED STAT:', s)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`sents = [s.strip() for s in re.split(r'(?<=[.!?])\s+', text) if s.strip()]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('UNSOURCED STAT:', s)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `sents = [s.strip() for s in re.split(r'(?<=[.!?])\s+', text) if s.strip()]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Statistics Backed by a Source: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: re, text, Organic, traffic, grew. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: sents = [s.strip() for s in re.split(r'(?<=[.!?])\s+', text) if s.strip... | Evidence: print('UNSOURCED STAT:', s)

🛠️ Reader to Writer Bridge

1. Read: explain detect statistics backed by a source in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 481.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 483 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('UNSOURCED STAT:', s)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect statistics backed by a source and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Splitting into sentences, then testing each for a number-with-percent and a source cue (`Source:`, `according to`, `per`) separates cited statistics from unsourced ones.

```
import re
text = '''Organic traffic grew 53% in 2025 (Source: BrightEdge).
Most pages load in under 2 seconds.
Pages with schema earn 30 percent more clicks according to Search Engine
Land.'''
sents = [s.strip() for s in re.split(r'(?<=[.!?])\s+', text) if s.strip()]
for s in sents:
    has_stat = bool(re.search(r'\d+\s?(%|percent)', s))
    has_source = bool(re.search(r'\(Source:|according to|per ', s, re.I))
    if has_stat and has_source:
        print('CITED STAT:', s)
    elif has_stat:
        print('UNSOURCED STAT:', s)
```

```
output
CITED STAT: Organic traffic grew 53% in 2025 (Source: BrightEdge).
CITED STAT: Pages with schema earn 30 percent more clicks according to Search Engine
Land.
```

How it works:

1. A multi-line text mixes two sourced statistics with one vague unsourced claim.
2. A regex split on sentence-ending punctuation with a lookbehind yields trimmed sentences.
3. Each sentence is tested for a digit followed by a percent sign or the word percent.
4. A second test looks for a Source parenthetical, the phrase according to, or a leading per.
5. Sentences with a stat print as CITED STAT when a source is found and UNSOURCED STAT otherwise.

Try it:

1. Extract and report the cited source name alongside each flagged statistic.
2. Detect plain numbers and currency figures, not only percentages, as statistics.
3. Count the ratio of cited to total stats as a page-level sourcing score.
4. Add a stat with no source and watch it print as UNSOURCED.

⚠ Common Mistakes

- The sentence split on `(?<=[.!?])\s+` keeps `2.5 seconds` intact only because it has no following space-capital; tune the lookbehind for decimals.
- A statistic written as `half of pages` has no digit and is missed entirely.
- `according to` inside an unrelated clause could falsely mark a non-statistic as cited.

Skills gained sentence splitting | stat detection | source attribution | claim auditing

→ Where You'll Use This: Flagging unsourced statistics is a fact-checking step in content audits, since AI engines and reviewers favour pages whose numbers carry verifiable attributions.

Mental Model

A statistic without a source is a rumour with a number attached; a citation is the receipt that lets a reader, or an engine, verify the claim.

Project 483 Write a robots.txt Audit Check

The Idea Behind It

The very first audit check has to confirm crawlers can reach and read the site at all, because nothing downstream matters if they cannot. This project defines check_robots, which safely pulls a nested robots dictionary, reads whether the file is reachable, and reads whether it disallows everything, returning a pass only when the file is reachable and not blocking the whole site. Using dict.get with defaults makes the function robust against missing keys, so an incomplete site fixture fails gracefully rather than raising.

What You'll Build & Learn

Write a robots audit check that passes only when the robots file is reachable and not blocking the whole site.

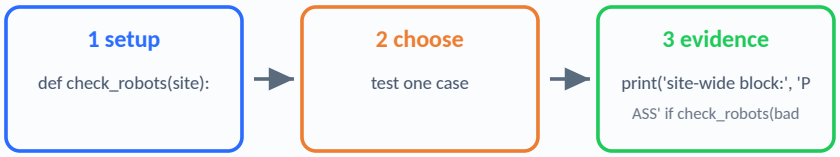
- Safely read nested dict values
- Combine two failure conditions
- Return a clear pass-or-fail boolean

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 482: detect statistics backed by a source. Project 484 changes the surface problem while preserving the underlying method.

progress check

Reading target: write a robots.txt audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `def check_robots(site):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The function boundary is the lesson: inputs enter, a rule runs, and a return value can be reused somewhere else.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('site-wide block:', 'PASS' if check_robots(bad) else 'FAIL')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def check_robots(site):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print('robots.txt check:', 'PASS' if ok else 'FAIL')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('site-wide block:', 'PASS' if check_robots(bad) else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('robots.txt check:', 'PASS' if ok else 'FAIL')`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Write a robots.txt Audit Check: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: check_robots, site, get, robots, reachable. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def check_robots(site): | Core: print('robots.txt check:', 'PASS' if ok else 'FAIL') | Evidence: print('site-wide block:', 'PASS' if check_robots(bad) else 'FAIL')

🛠️ Reader to Writer Bridge

1. Read: explain write a robots.txt audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 482.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 484 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('site-wide block:', 'PASS' if check_robots(bad) else 'FAIL')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `def check_robots(site):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write a robots.txt audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A tiny function over a site-signal dict returns pass only when robots.txt is reachable and does not carry a site-wide Disallow, the building block of the larger audit.

```
def check_robots(site):
    r = site.get('robots', {})
    reachable = r.get('reachable', False)
    blocks_all = r.get('disallow_all', False)
    return reachable and not blocks_all
site = {'robots': {'reachable': True, 'disallow_all': False}}
ok = check_robots(site)
print('robots.txt check:', 'PASS' if ok else 'FAIL')
bad = {'robots': {'reachable': True, 'disallow_all': True}}
print('site-wide block:', 'PASS' if check_robots(bad) else 'FAIL')
```

```
output
robots.txt check: PASS
site-wide block: FAIL
```

How it works:

1. check_robots reads a nested robots dictionary from a site, defaulting to empty when absent.
2. It pulls reachable and disallow_all flags with get so missing keys default to False.
3. The function returns True only when the file is reachable and does not disallow everything.
4. A healthy site fixture is checked and prints PASS for a reachable, open robots file.
5. A second fixture that disallows all is checked and prints FAIL for the site-wide block.

Try it:

1. Also fail when the robots file returns a non-200 status or times out.
2. Parse specific disallow rules and warn when key sections are blocked, not only all.
3. Confirm the robots file references a sitemap and report its absence.
4. Add a `crawl_delay` signal and fail values above 30 seconds.

⚠ Common Mistakes

- Treating a missing `robots` key as a pass would hide an unreachable file; `.get` defaults guard that.
- Confusing `disallow_all` (block everything) with a targeted Disallow over-fails normal sites.

- A reachable file that blocks all bots still fails despite being present.

Skills gained robots audit | safe dict access | boolean combination | crawlability

→ Where You'll Use This: A reusable robots check is the gateway of any automated technical audit, catching the catastrophic case where a stray disallow rule has deindexed an entire site.

Mental Model

Robots.txt is the front door's welcome mat: if the door is locked or the mat says keep out, no other room in the house gets seen.

Project 484 Write a Sitemap Audit Check

The Idea Behind It

A sitemap audit confirms a valid, in-bounds sitemap exists, since discovery quietly breaks without one. The check_sitemap function reads a nested sitemap dictionary and returns True only when it is present, holds a URL count strictly above zero and within the fifty-thousand limit, and reports valid XML. Chaining the present, the bounded count, and the validity tests with and in one expression means any single failing condition rejects the sitemap, which is how the healthy, missing and oversized cases each resolve correctly.

What You'll Build & Learn

Write a sitemap audit check that passes only for a present, valid, in-bounds sitemap and run it on three cases.

- Bound a count between two limits
- Chain conditions in one return
- Test multiple fixtures in a loop

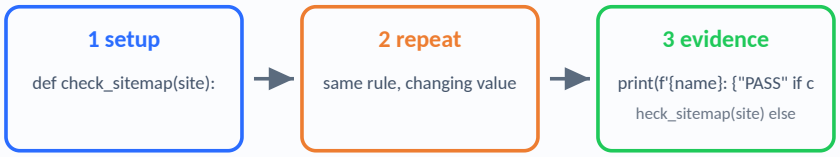
Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 483: write a robots.txt audit check. Project 485 changes the surface problem while preserving the underlying method.

progress check

Reading target: write a sitemap audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `def check_sitemap(site):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def check_sitemap(site):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Evidence	Entry: def check_sitemap(site): | Core: print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}') | Evidence: print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')

🛠️ Reader to Writer Bridge

1. Read: explain write a sitemap audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 483.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 485 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `def check_sitemap(site):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write a sitemap audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The check passes only when the sitemap is present, holds between 1 and 50,000 URLs, and parses as valid XML, mirroring the real sitemap limits.

```
def check_sitemap(site):
    s = site.get('sitemap', {})
    return bool(s.get('present')) and 0 < s.get('url_count', 0) <= 50000 and
s.get('valid_xml', False)
cases = {
    'healthy': {'sitemap': {'present': True, 'url_count': 1200, 'valid_xml':
True}},
    'missing': {'sitemap': {'present': False, 'url_count': 0, 'valid_xml':
False}},
    'oversized': {'sitemap': {'present': True, 'url_count': 60000, 'valid_xml':
True}},
}
for name, site in cases.items():
    print(f'{name}: {"PASS" if check_sitemap(site) else "FAIL"}')
```

```
output
healthy: PASS
missing: FAIL
oversized: FAIL
```

How it works:

1. check_sitemap reads a nested sitemap dictionary, defaulting to empty when the key is absent.
2. The return chains present, a URL count above zero and at or below fifty thousand, and valid XML.
3. A cases dictionary defines a healthy, a missing, and an oversized sitemap fixture.
4. Iterating the cases, each fixture is passed to the check function.
5. Each name prints PASS or FAIL, so only the healthy in-bounds sitemap passes.

Try it:

1. Add a check that a sitemap index is used once the URL count nears the per-file limit.
2. Validate the lastmod dates inside the sitemap are present and recent.
3. Fail when the sitemap is present but its declared count and actual entries disagree.
4. Raise the cap to 60,000 and watch the oversized case pass.

⚠ Common Mistakes

- A `url_count` of 0 must fail even if `present` is True; the `0 < count` bound enforces it.
- Forgetting the 50,000-URL cap lets an oversized sitemap pass.
- Skipping the `valid_xml` flag would accept a present-but-broken sitemap.

Skills gained sitemap audit | range bounding | condition chaining | fixture testing

→ Where You'll Use This: Validating sitemap presence, size and well-formedness is standard in crawl audits, since an oversized or malformed sitemap silently strands pages outside discovery.

Mental Model

A sitemap is the building directory in the lobby: missing, blank, or wildly over-length, it sends visitors and crawlers to the wrong floors.

Project 485 Write a Canonical Audit Check

The Idea Behind It

The canonical check confirms each page declares itself as its own canonical, because a missing or misdirected tag risks the page being dropped in favour of another URL. check_canonical reads the page's canonical and its own URL, returning a tuple of a pass flag plus a reason string: missing when no tag exists, points elsewhere when they differ, and self-referencing when they match. Returning the reason alongside the boolean is the design choice that lets the audit explain a failure, not merely report it.

What You'll Build & Learn

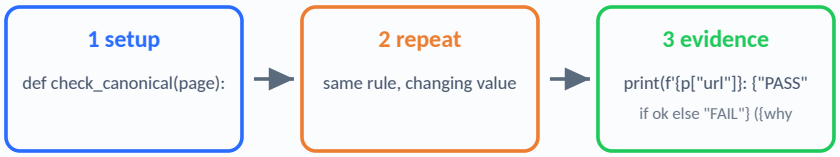
Write a canonical audit check that returns a pass flag and a reason for each page's canonical tag.

- Return a boolean plus a reason
- Detect a self-referencing canonical
- Distinguish missing from misdirected

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 484: write a sitemap audit check. Project 486 changes the surface problem while preserving the underlying method.

progress check



Reading target: write a canonical audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `def check_canonical(page):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{p["url"]}: {"PASS" if ok else "FAIL"} ({why})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

🛠️ Reader to Writer Bridge

1. Read: explain write a canonical audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 484.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 486 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p["url"]}: {"PASS" if ok else "FAIL"} ({why})')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `def check_canonical(page):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write a canonical audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The check returns pass plus a reason only when the canonical equals the page's own URL, distinguishing a self-reference from a missing or cross-pointing tag.

```
def check_canonical(page):
    c = page.get('canonical')
    url = page.get('url')
    if not c:
        return False, 'missing'
    if c != url:
        return False, 'points elsewhere'
    return True, 'self-referencing'
pages = [
    {'url': 'https://x.com/a', 'canonical': 'https://x.com/a'},
    {'url': 'https://x.com/b', 'canonical': 'https://x.com/a'},
    {'url': 'https://x.com/c', 'canonical': None},
]
for p in pages:
    ok, why = check_canonical(p)
    print(f'{p["url"]}: {"PASS" if ok else "FAIL"} ({why})')
```

```
output
https://x.com/a: PASS (self-referencing)
https://x.com/b: FAIL (points elsewhere)
https://x.com/c: FAIL (missing)
```

How it works:

1. check_canonical reads the page's canonical and url values from the page dictionary.
2. When no canonical exists it returns False with the reason string missing.
3. When the canonical differs from the URL it returns False with points elsewhere.
4. When they match it returns True with self-referencing as the reason.
5. Three sample pages are checked and each prints PASS or FAIL with its reason.

Try it:

1. Treat a canonical that differs only by trailing slash or protocol as a near-match warning.
2. Allow an intentional cross-page canonical when the page is flagged as a known duplicate.
3. Resolve relative canonical values against the page URL before comparing.
4. Normalise trailing slashes before comparing and re-test page b.

⚠ Common Mistakes

- A `None` canonical must fail as missing rather than crash on the equality test.
- Comparing canonicals ignoring trailing slashes would wrongly pass `/b/` vs `/b`.
- A page canonicalising to an equivalent but differently-cased URL still fails strict equality.

Skills gained canonical audit | tuple returns | self-reference check | indexability

→ Where You'll Use This: Auditing canonical tags catches duplicate-content and consolidation bugs that quietly bleed ranking signals or deindex pages, a frequent finding in large-site crawls.

⚡ Mental Model

A canonical tag is a page pointing at its own ID badge; point it at someone else's badge and the system files your work under their name.

Project 486 Write a Status-Code Audit Check

💡 The Idea Behind It

The status-code check confirms that key pages actually return 200, because redirects and errors all mean the indexable page is not being served as expected. check_status maps a code to a pass flag and a human label using range tests: exactly 200 passes, the three-hundred range is a redirect, the four-hundred range a client error, and anything else a server error. Bucketing by numeric range rather than listing individual codes keeps the function compact while still naming the failure class precisely.

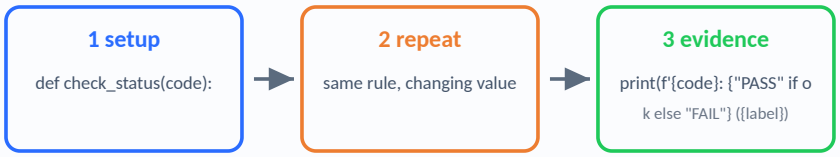
What You'll Build & Learn

Write a status-code audit check that passes only on 200 and labels redirects and error classes otherwise.

- Bucket status codes by range
- Return a flag with a class label
- Treat anything but 200 as a failure

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 485: write a canonical audit check. Project 487 changes the surface problem while preserving the underlying method.



progress check

Reading target: write a status-code audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def check_status(code):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.

3. Transfer: change one small part of write a status-code audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Bucketing the numeric code into 200, the 3xx, 4xx, or 5xx ranges returns a pass/fail plus a human label, the status leg of the audit.

```
def check_status(code):
    if code == 200:
        return True, 'OK'
    if 300 <= code < 400:
        return False, 'redirect'
    if 400 <= code < 500:
        return False, 'client error'
    return False, 'server error'
for code in [200, 301, 404, 503]:
    ok, label = check_status(code)
    print(f'{code}: {"PASS" if ok else "FAIL"} ({label})')
```

```
output
200: PASS (OK)
301: FAIL (redirect)
404: FAIL (client error)
503: FAIL (server error)
```

How it works:

1. check_status returns True with OK only when the code equals exactly 200.
2. A code in the three-hundred range returns False labelled redirect.
3. A code in the four-hundred range returns False labelled client error.
4. Any remaining code falls through to False labelled server error.
5. A loop checks 200, 301, 404 and 503, printing each code's verdict and label.

Try it:

1. Treat a 304 not-modified response as a pass for conditional requests.
2. Distinguish a 410 gone from other client errors since it signals intentional removal.
3. Return the full status reason phrase alongside the class label.
4. Add a 410 case and label it as gone.

⚠ Common Mistakes

- Testing `code == 300` instead of the `300 <= code < 400` range misses 301/302.
- Treating a 3xx as a soft pass hides that a key page should serve 200 directly.
- A 204 (no content) would fall through to server-error labelling here.

Skills gained status audit range bucketing labelled returns HTTP codes

→ Where You'll Use This: Verifying that priority URLs serve a clean 200 catches accidental redirects, soft errors and outages before they cost rankings, a core step in any crawl audit.

Mental Model

A status code is a receptionist's answer: only a clear yes, we have that, is a pass; sorry, moved, or it broke all turn the visitor away.

Project 487 Write a Core Web Vitals Audit Check

The Idea Behind It

The Core Web Vitals check confirms LCP, INP and CLS are all within Google's good thresholds, and one failing metric fails the whole check. check_cwv tests each metric against its limit, collects the names of the passing ones into a list, and returns a pass only when all three pass. Returning the list of passing metrics alongside the verdict is useful because it tells you not just that the check failed but precisely which vital, here CLS, dragged it down.

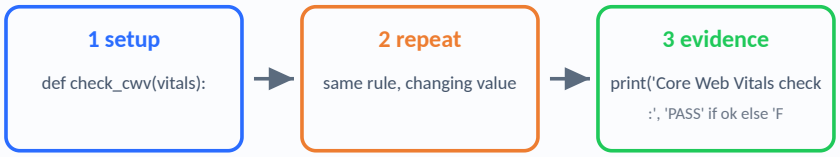
What You'll Build & Learn

Write a Core Web Vitals check that passes only when LCP, INP and CLS are all within good thresholds.

- Compare metrics against thresholds
- Collect passing names into a list
- Require all three to pass

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 486: write a status-code audit check. Project 488 changes the surface problem while preserving the underlying method.



progress check

Reading target: write a core web vitals audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def check_cwv(vitals):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('Core Web Vitals check:', 'PASS' if ok else 'FAIL')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def check_cwv(vitals):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`passed = [n for n, ok in [('LCP', lcp_ok), ('INP', inp_ok), ('CLS', cls_ok)] if ok]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('Core Web Vitals check:', 'PASS' if ok else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `passed = [n for n, ok in [('LCP', lcp_ok), ('INP', inp_ok), ('CLS', cls_ok)] if ok]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Write a Core Web Vitals Audit Check: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: check_cwv, vitals, lcp_ok, lcp_s, inp_ok. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def check_cwv(vitals): | Core: passed = [n for n, ok in [('LCP', lcp_ok), ('INP', inp_ok), ('CLS', cls... | Evidence: print('Core Web Vitals check:', 'PASS' if ok else 'FAIL')

🛠️ Reader to Writer Bridge

1. Read: explain write a core web vitals audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 486.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 488 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('Core Web Vitals check:', 'PASS' if ok else 'FAIL')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `def check_cwv(vitals):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write a core web vitals audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing each metric to its threshold (LCP <= 2.5s, INP <= 200ms, CLS <= 0.1) and requiring all three to pass implements the all-or-nothing CWV verdict.

```
def check_cwv(vitals):
    lcp_ok = vitals['lcp_s'] <= 2.5
    inp_ok = vitals['inp_ms'] <= 200
    cls_ok = vitals['cls'] <= 0.1
    passed = [n for n, ok in [('LCP', lcp_ok), ('INP', inp_ok), ('CLS',
cls_ok)] if ok]
    return len(passed) == 3, passed
v = {'lcp_s': 2.1, 'inp_ms': 180, 'cls': 0.18}
ok, passed = check_cwv(v)
print('passing vitals:', passed)
print('Core Web Vitals check:', 'PASS' if ok else 'FAIL')
```

```
output
passing vitals: ['LCP', 'INP']
Core Web Vitals check: FAIL
```

How it works:

1. check_cwv reads a vitals dictionary and tests LCP, INP and CLS against their good limits.
2. Each metric's boolean is paired with its name in a list comprehension that keeps only passers.
3. The function returns True only when the passing list contains all three metrics.
4. A sample with a failing CLS is checked, yielding LCP and INP as the passing metrics.
5. Prints report the passing metrics list and the overall PASS or FAIL verdict.

Try it:

1. Return the failing metrics with their measured values and target thresholds.
2. Add a needs-improvement band so borderline metrics are not lumped with outright failures.
3. Weight the three vitals so a small CLS miss is not treated like a large LCP miss.
4. Lower CLS to 0.09 and watch the whole check pass.

⚠ Common Mistakes

- A CLS of 0.18 fails even though LCP and INP pass; the check is all-or-nothing.
- Using a `<` instead of `<=` would fail a metric sitting exactly on the threshold.

- Mixing up the units (seconds vs milliseconds) silently breaks the comparison.

Skills gained Core Web Vitals | threshold checks | list comprehension | all-pass logic

→ Where You'll Use This: A Core Web Vitals gate is a standard part of performance audits and CI checks, flagging the specific vital that needs work before a page can earn its good experience signal.

⚡ Mental Model

Core Web Vitals are a three-part medical panel: every reading must sit in the healthy range, because one bad result means the checkup is not passed.

Project 488 Write an Hreflang Audit Check

💡 The Idea Behind It

The hreflang check confirms a multilingual cluster has reciprocal annotations and an x-default, since missing return tags or no default break international targeting. check_hreflang short-circuits to a pass for monolingual pages, then for multilingual ones collects any language whose reciprocal flag is False and confirms an x-default is listed, passing only when nothing is missing and the default exists. Treating the monolingual case as not applicable rather than a failure is the nuance that keeps the audit fair on single-language sites.

What You'll Build & Learn

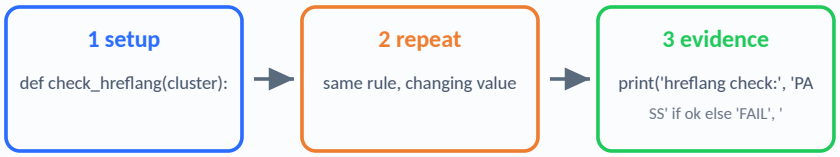
Write an hreflang audit check that passes when alternates reciprocate and an x-default is present.

- Short-circuit a not-applicable case
- Find non-reciprocating alternates
- Require an x-default annotation

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 487: write a core web vitals audit check. Project 489 changes the surface problem while preserving the underlying method.

progress check



Reading target: write an hreflang audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def check_hreflang(cluster):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('hreflang check:', 'PASS' if ok else 'FAIL', '|', why)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def check_hreflang(cluster):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if not langs:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('hreflang check:', 'PASS' if ok else 'FAIL', '|', why)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not langs:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Write an Hreflang Audit Check: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: check_hreflang, cluster, langs, get, not. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: def check_hreflang(cluster): | Core: if not langs: | Evidence: print('hreflang check:', 'PASS' if ok else 'FAIL', '|', why)

🛠️ Reader to Writer Bridge

1. Read: explain write an hreflang audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 487.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 489 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('hreflang check:', 'PASS' if ok else 'FAIL', '|', why)`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `def check_hreflang(cluster):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write an hreflang audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For a multilingual cluster the check requires every alternate to reciprocate and an x-default to be declared; a monolingual page is simply not applicable.

```
def check_hreflang(cluster):
    langs = cluster.get('langs', [])
    if not langs:
        return True, 'monolingual, n/a'
    # every alternate must reciprocate (point back)
    missing = [l for l, back in cluster['reciprocal'].items() if not back]
    has_xdefault = 'x-default' in langs
    ok = not missing and has_xdefault
    return ok, f'missing-return: {missing} xdefault: {has_xdefault}'
c = {'langs': ['en', 'de', 'x-default'], 'reciprocal': {'en': True, 'de':
True}}
ok, why = check_hreflang(c)
print('hreflang check:', 'PASS' if ok else 'FAIL', '|', why)
```

```
output
hreflang check: PASS | missing-return: [] xdefault: True
```

How it works:

1. check_hreflang reads the cluster's language list, returning a pass labelled monolingual when it is empty.
2. A comprehension collects every language whose reciprocal flag is False into a missing list.
3. It checks whether x-default appears among the declared languages.
4. The cluster passes only when nothing is missing and an x-default is present.
5. A sample cluster is checked and prints PASS with the empty missing list and x-default True.

Try it:

1. Validate that every declared language uses a well-formed locale code.
2. Detect a language that points to itself, which is an invalid self-reference.
3. Warn when an x-default points to a locale-specific page rather than a neutral one.
4. Set one locale's `reciprocal` to False and watch the check fail.

⚠ Common Mistakes

- A cluster with no `langs` is correctly treated as not applicable, not a failure.

- Checking only that tags exist, not that they reciprocate, misses one-way hreflang errors.
- Forgetting the x-default requirement passes clusters that lack a fallback locale.

Skills gained hreflang audit | reciprocity check | short-circuit logic | internationalisation

→ Where You'll Use This: Hreflang reciprocity and x-default bugs are common on multilingual sites and silently misroute users to the wrong locale, so this check is essential in international SEO audits.

⚡ Mental Model

Hreflang is a set of road signs between translated pages; if a sign only points one way, or there is no default exit, travellers get stranded.

Project 489 Write a Structured-Data Audit Check

💡 The Idea Behind It

The structured-data check confirms JSON-LD blocks parse and declare a @type, because invalid JSON or a missing type means engines cannot use the markup. check_structured_data attempts to json.loads each block inside a try, returning a failure on a ValueError, then rejects any object lacking an @type, and otherwise collects the types. Wrapping the parse in exception handling is the safeguard that lets the audit report invalid JSON-LD as a clean failure instead of crashing on the first malformed block.

What You'll Build & Learn

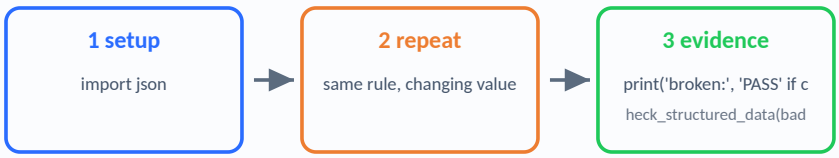
Write a structured-data check that passes only when every JSON-LD block parses and declares a @type.

- Guard json.loads with try-except
- Reject objects missing a key
- Collect parsed types for reporting

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 488: write an hreflang audit check. Project 490 changes the surface problem while preserving the underlying method.

progress check



Reading target: write a structured-data audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import json` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('broken:', 'PASS' if check_structured_data(bad)[0] else 'FAIL', '|', check_structured_data(bad)[1])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import json`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if '@type' not in obj:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('broken:', 'PASS' if check_structured_data(bad)[0] else 'FAIL', '|', check_structured_data(bad)[1])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if '@type' not in obj:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Write a Structured-Data Audit Check: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: json, check_structured_data, blocks, parsed, obj. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import json | Core: if '@type' not in obj: | Evidence: print('broken:', 'PASS' if check_structured_data(bad)[0] else 'FAIL', '...

🛠️ Reader to Writer Bridge

1. Read: explain write a structured-data audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 488.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 490 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('broken:', 'PASS' if check_structured_data(bad)[0] else 'FAIL', '|',`

`check_structured_data(bad)[1]`). Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import json` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write a structured-data audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Parsing each block with `json.loads` (catching `ValueError`) and requiring an `@type` validates the markup; the collected types report what the page exposes.

```
import json
def check_structured_data(blocks):
    parsed = []
    for b in blocks:
        try:
            obj = json.loads(b)
        except ValueError:
            return False, 'invalid JSON-LD'
        if '@type' not in obj:
            return False, 'missing @type'
        parsed.append(obj['@type'])
    return bool(parsed), f'types: {sorted(parsed)}'
good = ['{"@type": "Article"}', '{"@type": "FAQPage"}']
ok, why = check_structured_data(good)
print('structured data:', 'PASS' if ok else 'FAIL', '|', why)
bad = ['{"@type": "Article"', '{"name": "x"}']
print('broken:', 'PASS' if check_structured_data(bad)[0] else 'FAIL', '|',
check_structured_data(bad)[1])
```

```
output
structured data: PASS | types: ['Article', 'FAQPage']
broken: FAIL | invalid JSON-LD
```

How it works:

1. check_structured_data iterates the JSON-LD blocks, attempting json.loads on each one.
2. A ValueError during parsing returns a failure labelled invalid JSON-LD.
3. Any parsed object without an @type key returns a failure labelled missing @type.
4. Valid objects contribute their type to a list, and the function returns a pass when types were found.
5. A good pair of blocks prints PASS while a broken pair prints FAIL with invalid JSON-LD.

Try it:

1. Validate required properties for each type, such as a name on an Organization.
2. Handle a graph array of multiple objects within one script block.

3. Report every block's type and pinpoint exactly which block failed to parse.
4. Add a third valid block and watch the types list grow.

⚠ Common Mistakes

- Catching only `KeyError` and not `ValueError` would crash on truly invalid JSON.
- A block that parses but omits `@type` must fail even though the JSON is valid.
- Sorting the collected types keeps the printed order deterministic.

Skills gained structured-data audit | exception handling | JSON parsing | key validation

→ Where You'll Use This: Validating that JSON-LD actually parses and carries a type is a recurring rich-results audit step, catching the truncated or mistyped markup that quietly disqualifies a page.

Mental Model

JSON-LD is a customs form: if it is filled out wrong or missing the declaration line, the package, your rich result, gets refused at the gate.

Project 490 Write an On-Page Audit Check

The Idea Behind It

The on-page check confirms the table-stakes basics: a sane title length, a meta description in range, exactly one H1, and a viewport tag. check_onpage builds a dictionary of four named boolean results from length and count tests, sums the passers, and returns a pass only when all four hold along with the per-check detail. Returning the individual results dictionary, not just the verdict, is what lets the report show that the meta description failed while everything else passed.

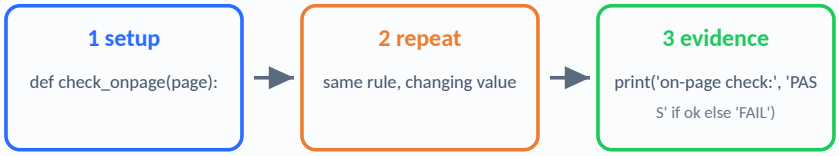
What You'll Build & Learn

Write an on-page audit check covering title length, meta length, a single H1, and a viewport tag.

- Bound title and meta lengths
- Require exactly one H1
- Return per-check results plus verdict

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 489: write a structured-data audit check. Project 491 changes the surface problem while preserving the underlying method.



progress check

Reading target: write an on-page audit check is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def check_onpage(page):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('on-page check:', 'PASS' if ok else 'FAIL')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def check_onpage(page):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`print(f' {name}: {"ok" if checks[name] else "fail"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('on-page check:', 'PASS' if ok else 'FAIL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f' {name}: {"ok" if checks[name] else "fail"}')`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Write an On-Page Audit Check: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: check_onpage, page, checks, title, len. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def check_onpage(page): | Core: print(f' {name}: {"ok" if checks[name] else "fail"}') | Evidence: print('on-page check:', 'PASS' if ok else 'FAIL')

🛠️ Reader to Writer Bridge

1. Read: explain write an on-page audit check in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 489.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 491 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('on-page check:', 'PASS' if ok else 'FAIL')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `def check_onpage(page):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of write an on-page audit check and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each sub-check is a boolean over the page dict; the function passes only when all four hold, and the per-check printout shows exactly which basic failed.

```
def check_onpage(page):
    checks = {
        'title': 10 <= len(page.get('title', '')) <= 60,
        'meta_desc': 50 <= len(page.get('meta_desc', '')) <= 160,
        'single_h1': page.get('h1_count', 0) == 1,
        'has_viewport': page.get('viewport', False),
    }
    passed = sum(checks.values())
    return passed == len(checks), checks
page = {'title': 'Technical SEO Audit Guide', 'meta_desc': 'A short desc.',
'h1_count': 1, 'viewport': True}
ok, checks = check_onpage(page)
for name in sorted(checks):
    print(f'  {name}: {"ok" if checks[name] else "fail"}')
print('on-page check:', 'PASS' if ok else 'FAIL')
```

```
output
  has_viewport: ok
  meta_desc: fail
  single_h1: ok
  title: ok
on-page check: FAIL
```

How it works:

1. check_onpage builds a checks dictionary with four named boolean results for a page.
2. Title and meta tests bound their character lengths, and the H1 test requires a count of exactly one.
3. passed sums the truthy values, and the function passes only when all four checks hold.
4. A sample page with a short meta description is checked, failing that one item.
5. Sorted check names print ok or fail, then the overall on-page verdict prints.

Try it:

1. Add a check that the title is unique across the crawled page set.
2. Warn when the H1 text duplicates the title verbatim rather than complementing it.
3. Confirm the meta description contains the page's primary keyword.

4. Lengthen the meta description into the 50-160 band and watch the check pass.

⚠ Common Mistakes

- A 12-character meta description fails the 50-160 band even though a title that short would pass its own 10-60 band.
- Counting two H1s as a pass ignores that a page should have exactly one.
- A missing viewport key would be falsy and fail rather than crash thanks to `.get` defaults.

Skills gained on-page audit | length bounding | H1 counting | result reporting

→ Where You'll Use This: On-page basics are the most common findings in real audits, and a reusable check like this lets you scan thousands of pages for missing or malformed titles, metas and H1s.

Mental Model

On-page basics are a uniform inspection: title, description, one headline and a viewport are the buttons that must all be done up before the page steps out.

Project 491 Group the Crawlability Checks

The Idea Behind It

The full audit is assembled from groups, and this first group bundles eight crawlability points covering robots health, sitemap validity, orphans and internal linking. crawlability_points builds a list of named checks from a site dictionary, including a not-disallow-all test and bounded sitemap and crawl-delay tests, then returns both the count of passers and the labelled list. Returning the detailed checks alongside the score is the pattern that lets the printed report show seven of eight passing with the orphan check as the lone failure.

What You'll Build & Learn

Group eight crawlability checks, score how many pass, and print a checkbox report for a site fixture.

- Bundle related checks into a group
- Negate a flag inside a check
- Return both a score and details

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 490: write an on-page audit check. Project 492 changes the surface problem while preserving the underlying method.

progress check

Reading target: group the crawlability checks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def crawlability_points(s):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'crawlability: {pts}/8')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def crawlability_points(s):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return sum(1 for _, ok in checks if ok), checks`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'crawlability: {pts}/8')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return sum(1 for _, ok in checks if ok), checks`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Group the Crawlability Checks: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: crawlability_points, checks, robots, reachable, robots_reachable. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def crawlability_points(s): | Core: return sum(1 for _, ok in checks if ok), checks | Evidence: print(f'crawlability: {pts}/8')

🛠️ Reader to Writer Bridge

1. Read: explain group the crawlability checks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 490.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 492 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'crawlability: {pts}/8')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `def crawlability_points(s):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group the crawlability checks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Collecting eight crawlability booleans into a list of (name, ok) pairs lets the group both score itself out of 8 and report exactly which point failed.

```
def crawlability_points(s):
    checks = [
        ('robots reachable', s['robots_reachable']),
        ('not disallow-all', not s['disallow_all']),
        ('crawl-delay sane', s['crawl_delay'] <= 10),
        ('sitemap present', s['sitemap_present']),
        ('sitemap within 50k', s['sitemap_urls'] <= 50000),
        ('sitemap valid xml', s['sitemap_valid']),
        ('no orphan key pages', s['orphans'] == 0),
        ('internal links ok', s['avg_internal_links'] >= 1),
    ]
    return sum(1 for _, ok in checks if ok), checks
site = {'robots_reachable': True, 'disallow_all': False, 'crawl_delay': 5,
        'sitemap_present': True, 'sitemap_urls': 3000, 'sitemap_valid': True,
        'orphans': 2, 'avg_internal_links': 4}
pts, checks = crawlability_points(site)
for name, ok in checks:
    print(f'[{"x" if ok else " "}] {name}')
print(f'crawlability: {pts}/8')
```

```
output
[x] robots reachable
[x] not disallow-all
[x] crawl-delay sane
[x] sitemap present
[x] sitemap within 50k
[x] sitemap valid xml
[ ] no orphan key pages
[x] internal links ok
crawlability: 7/8
```

How it works:

1. crawlability_points builds a list of eight named checks from a site dictionary.
2. Tests include robots reachability, a negated disallow-all flag, and bounded crawl-delay and sitemap size.
3. Orphan and internal-link tests compare counts against zero and a minimum.
4. The function returns the number of passing checks plus the full labelled list.

5. A site fixture is scored, printing a checkbox per check and seven out of eight overall.

Try it:

1. Add a check for an excessive crawl-delay that throttles indexing.
2. Weight orphan pages more heavily since they are invisible to crawlers entirely.
3. Return the failing check names so the group feeds a remediation list directly.
4. Set `orphans` to 0 and watch the group hit 8/8.

⚠ Common Mistakes

- Mixing a boolean signal with a numeric one (orphans count) needs the right comparison per check.
- Returning only the score loses the per-check detail the audit report needs.
- A `crawl_delay` over 10 seconds fails the politeness sub-check even with everything else green.

Skills gained check grouping | flag negation | score and detail | crawlability

→ Where You'll Use This: Grouping checks into crawlability, indexability, performance and content sections is how scalable audit tools stay organised, letting you report a sub-score per pillar.

Mental Model

This group is the access-and-discovery inspection: can crawlers get in, find the map, and reach every room without any locked-off orphan corridors.

Project 492 Group the Indexability and Status Checks

The Idea Behind It

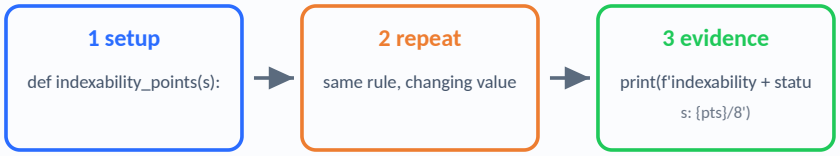
The second audit group covers eight indexability and status points: canonicals, noindex, HTTPS, status codes, redirect length, hreflang and broken links. indexability_points builds the labelled checks from a site dictionary, negating the noindex flag and bounding redirect hops, then returns the passing count and the detailed list. Mirroring the structure of the crawlability group means the four pillar functions stay interchangeable, which is what later lets a capstone sum their scores into one audit total.

What You'll Build & Learn

Group eight indexability and status checks, score the passes, and print a report for a site fixture.

- Negate noindex within a check
- Bound redirect-hop length
- Keep group functions parallel

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 491: group the crawlability checks. Project 493 changes the surface problem while preserving the underlying method. *progress check*

Reading target: group the indexability and status checks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def indexability_points(s):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'indexability + status: {pts}/8')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def indexability_points(s):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return sum(1 for _, ok in checks if ok), checks`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'indexability + status: {pts}/8')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return sum(1 for _, ok in checks if ok), checks`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Group the Indexability and Status Checks: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: indexability_points, checks, canonical, self, ref. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def indexability_points(s): | Core: return sum(1 for _, ok in checks if ok), checks | Evidence: print(f'indexability + status: {pts}/8')

🛠️ Reader to Writer Bridge

1. Read: explain group the indexability and status checks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 491.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 493 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'indexability + status: {pts}/8')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def indexability_points(s):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group the indexability and status checks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The same (name, ok) pattern bundles indexability and status into a second group of 8 that scores itself and exposes the two failing points here.

```
def indexability_points(s):
    checks = [
        ('canonical self-ref', s['canonical_self']),
        ('no noindex on key pages', not s['noindex_key']),
        ('https everywhere', s['https']),
        ('all key pages 200', s['non_200'] == 0),
        ('redirect chains <= 3', s['max_redirect_hops'] <= 3),
        ('hreflang reciprocal', s['hreflang_reciprocal']),
        ('x-default present', s['x_default']),
        ('no broken links', s['broken_links'] == 0),
    ]
    return sum(1 for _, ok in checks if ok), checks
site = {'canonical_self': True, 'noindex_key': False, 'https': True, 'non_200':
0,
        'max_redirect_hops': 2, 'hreflang_reciprocal': True, 'x_default':
False, 'broken_links': 1}
pts, checks = indexability_points(site)
for name, ok in checks:
    print(f'[{"x" if ok else " "}] {name}')
print(f'indexability + status: {pts}/8')
```

```
output
[x] canonical self-ref
[x] no noindex on key pages
[x] https everywhere
[x] all key pages 200
[x] redirect chains <= 3
[x] hreflang reciprocal
[ ] x-default present
[ ] no broken links
indexability + status: 6/8
```

How it works:

1. indexability_points builds eight named checks from a site dictionary.
2. Tests cover self-canonical, a negated noindex flag, HTTPS, and a zero non-200 count.
3. Further checks bound redirect hops at three and confirm hreflang reciprocity and x-default.
4. A broken-links test passes only when the count is exactly zero.
5. A fixture is scored, printing each checkbox and six out of eight overall.

Try it:

1. Tighten the redirect-hop limit to two and warn on any chain over one.
2. Add a mixed-content check that fails HTTPS pages loading insecure assets.
3. Report the count of broken links so a single dead link reads differently from many.
4. Set `broken_links` to 0 and `x_default` to True for a perfect 8/8.

⚠ Common Mistakes

- `non_200 == 0` is the right test; counting `>= 0` would always pass.
- A redirect chain of exactly 3 passes the `<= 3` bound; off-by-one here changes the verdict.
- Treating one broken link as acceptable would let a real navigation bug slip through.

Skills gained indexability audit | flag negation | hop bounding | status checks

→ Where You'll Use This: Indexability is where rankings are won or lost, so a grouped check covering canonicals, noindex, redirects and broken links is core to any site-health monitoring setup.

Mental Model

If crawlability is getting in the door, this group is whether each room is open for filing: indexed, served cleanly, and not pointing visitors down dead ends.

Project 493 Group the Performance Checks

The Idea Behind It

The third audit group is eight performance points: the three Core Web Vitals plus mobile-friendliness, compression, render-blocking resources, page weight and TTFB. performance_points builds the labelled checks from a site dictionary, bounding each metric against its threshold, then returns the passing count and the detailed list. Folding the vitals in with broader performance signals like TTFB and page weight gives a fuller speed picture than the vitals alone, which is why CLS failing here still leaves seven of eight passing.

What You'll Build & Learn

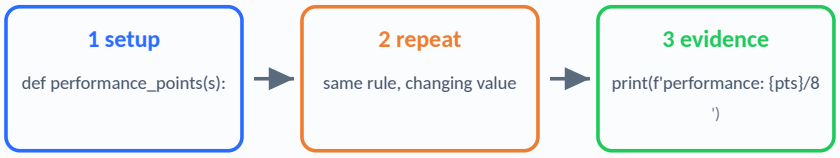
Group eight performance checks spanning the vitals and broader speed signals, score them, and report.

- Combine vitals with broader metrics

- Bound each metric to a threshold
- Score a performance pillar

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 492: group the indexability and status checks. Project 494 changes the surface problem while preserving the underlying method.



progress check

Reading target: group the performance checks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def performance_points(s):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'performance: {pts}/8')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def performance_points(s):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return sum(1 for _, ok in checks if ok), checks`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 494 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'performance: {pts}/8')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def performance_points(s):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group the performance checks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Bundling the vitals with delivery metrics into a third group of 8 keeps performance in one scorable unit that names the one failing metric (CLS).

```
def performance_points(s):
    checks = [
        ('LCP <= 2.5s', s['lcp_s'] <= 2.5),
        ('INP <= 200ms', s['inp_ms'] <= 200),
        ('CLS <= 0.1', s['cls'] <= 0.1),
        ('mobile-friendly', s['mobile_friendly']),
        ('compression on', s['compressed']),
        ('render-blocking <= 2', s['render_blocking'] <= 2),
        ('page weight <= 2MB', s['weight_kb'] <= 2048),
        ('TTFB <= 800ms', s['ttfb_ms'] <= 800),
    ]
    return sum(1 for _, ok in checks if ok), checks
site = {'lcp_s': 2.3, 'inp_ms': 190, 'cls': 0.12, 'mobile_friendly': True,
        'compressed': True, 'render_blocking': 1, 'weight_kb': 1500, 'ttfb_ms':
600}
pts, checks = performance_points(site)
for name, ok in checks:
    print(f'[{"x" if ok else " "}] {name}')
print(f'performance: {pts}/8')
```

```
output
[x] LCP <= 2.5s
[x] INP <= 200ms
[ ] CLS <= 0.1
[x] mobile-friendly
[x] compression on
```

```
[x] render-blocking <= 2
[x] page weight <= 2MB
[x] TTFB <= 800ms
performance: 7/8
```

How it works:

1. performance_points builds eight named checks from a site dictionary.
2. The first three checks bound LCP, INP and CLS against their good thresholds.
3. Further checks cover mobile-friendliness, compression, render-blocking count, weight and TTFB.
4. The function returns the count of passing checks plus the labelled list.
5. A fixture with a high CLS is scored, printing each checkbox and seven out of eight.

Try it:

1. Add a check for an excessive number of third-party scripts.
2. Tighten the page-weight limit for pages targeting mobile-first audiences.
3. Report the worst-performing metric so optimisation effort goes where it counts most.
4. Drop CLS to 0.08 and watch the group reach 8/8.

⚠ Common Mistakes

- CLS just over 0.1 fails while the other seven pass; one metric sinks the point, not the group.
- Comparing page weight in the wrong unit (bytes vs KB) silently mis-scores it.
- A render-blocking count of exactly 2 passes the `<= 2` bound.

Skills gained performance audit | metric bounding | vitals plus speed | pillar scoring

→ Where You'll Use This: A grouped performance check that goes beyond the three vitals is what page-speed audits use to explain why a fast-feeling page still has a heavy payload or slow server response.

Mental Model

This group is the speed-and-stability dyno test: not just the headline lap times of the vitals but the engine weight, fuel delivery and how fast it leaves the line.

Project 494 Group the On-Page, AEO and E-E-A-T Checks

The Idea Behind It

The fourth audit group is eight content points spanning on-page, AEO and E-E-A-T: title and meta lengths, a single H1, valid schema, a concise lead answer, FAQ or HowTo schema, an author bio and freshness. content_points builds these labelled checks from a site dictionary, with the lead-answer test requiring a positive word count at or below sixty, and returns the score plus the detail. Bundling traditional on-page basics

together with answer-engine and trust signals reflects how a modern audit treats content quality as one combined pillar.

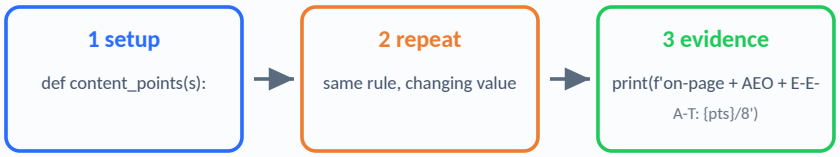
What You'll Build & Learn

Group eight content checks across on-page, AEO and E-E-A-T signals, score them, and print a report.

- Mix on-page, AEO and E-E-A-T
- Bound a lead-answer word count
- Score a combined content pillar

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 493: group the performance checks. Project 495 changes the surface problem while preserving the underlying method.



progress check

Reading target: group the on-page, aeo and e-e-a-t checks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `def content_points(s):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'on-page + AEO + E-E-A-T: {pts}/8')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def content_points(s):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return sum(1 for _, ok in checks if ok), checks`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'on-page + AEO + E-E-A-T: {pts}/8')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return sum(1 for _, ok in checks if ok), checks`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Group the On-Page, AEO and E-E-A-T Checks: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: content_points, checks, title, chars, title_len. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def content_points(s): | Core: return sum(1 for _, ok in checks if ok), checks | Evidence: print(f'on-page + AEO + E-E-A-T: {pts}/8')

🛠️ Reader to Writer Bridge

1. Read: explain group the on-page, aeo and e-e-a-t checks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 493.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 495 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'on-page + AEO + E-E-A-T: {pts}/8')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def content_points(s):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group the on-page, aeo and e-e-a-t checks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

This group fuses classic on-page checks with the GEO/AEO and E-E-A-T signals from earlier in the chapter into the final scorable group of 8.

```
def content_points(s):
    checks = [
        ('title 10-60 chars', 10 <= s['title_len'] <= 60),
        ('meta desc 50-160', 50 <= s['meta_len'] <= 160),
        ('single H1', s['h1_count'] == 1),
        ('valid schema', s['valid_schema']),
        ('concise lead answer', s['lead_answer_words'] <= 60 and
s['lead_answer_words'] > 0),
        ('FAQ/HowTo schema', s['aeo_schema']),
        ('author bio', s['author_bio']),
        ('content fresh', s['fresh']),
    ]
    return sum(1 for _, ok in checks if ok), checks
site = {'title_len': 42, 'meta_len': 120, 'h1_count': 1, 'valid_schema': True,
        'lead_answer_words': 38, 'aeo_schema': True, 'author_bio': True,
'fresh': False}
pts, checks = content_points(site)
for name, ok in checks:
```

```
    print(f'[{"x" if ok else " "}] {name}')
print(f'on-page + AEO + E-E-A-T: {pts}/8')
```

```
output
[x] title 10-60 chars
[x] meta desc 50-160
[x] single H1
[x] valid schema
[x] concise lead answer
[x] FAQ/HowTo schema
[x] author bio
[ ] content fresh
on-page + AEO + E-E-A-T: 7/8
```

How it works:

1. content_points builds eight named checks from a site dictionary.
2. Title and meta length tests sit beside a single-H1 and a valid-schema check.
3. The lead-answer check requires a positive word count at or below sixty words.
4. Further checks cover AEO schema, an author bio, and content freshness.
5. A fixture failing only freshness is scored, printing each checkbox and seven out of eight.

Try it:

1. Split the pillar into separate on-page and AEO sub-scores for finer reporting.
2. Add an entity-coverage check drawn from the earlier entity-counting project.
3. Require the lead answer to also exceed a minimum so empty leads do not pass.
4. Flip `fresh` to True and watch the group hit 8/8.

⚠ Common Mistakes

- A lead answer of 0 words must fail even though `<= 60` alone would pass; both bounds are needed.
- Title length is character-based, so a 9-character title fails the 10-60 band.
- Freshness here is a precomputed boolean; deriving it from a date belongs in an earlier step.

Skills gained content audit | AEO signals | word-count bounding | pillar scoring

→ Where You'll Use This: As answer engines reshape SEO, audits increasingly fold AEO and E-E-A-T signals into the content pillar, and this grouped check is how that combined quality view gets scored.

Mental Model

This group grades the writing itself: is it well-labelled, quotable by an engine, backed by a credible author, and recently kept up to date.

Project 495 Map an Audit Score to a Letter Grade

The Idea Behind It

A thirty-two point score is far easier to act on as a letter grade, so this project maps percentage bands to A through F. The grade function divides the score by a default total of thirty-two, scales to a percentage, and returns a letter using descending threshold checks where the first satisfied band wins. Ordering the comparisons from highest to lowest is the trick that lets a simple chain of returns replace nested conditionals while still assigning each score to exactly one grade band.

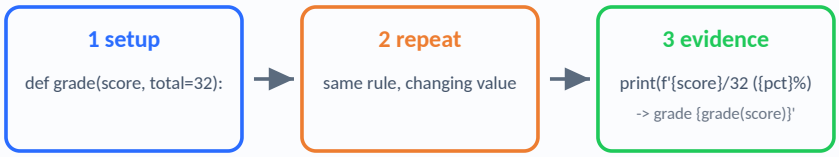
What You'll Build & Learn

Map a thirty-two point audit score to an A-through-F letter grade using percentage bands.

- Convert a score to a percentage
- Order thresholds high to low
- Return on the first matching band

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 494: group the on-page, aeo and e-e-a-t checks. Project 496 changes the surface problem while preserving the underlying method.



progress check

Reading target: map an audit score to a letter grade is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `def grade(score, total=32):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{score}/32 ({pct}%) -> grade {grade(score)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def grade(score, total=32):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`if pct >= 90: return 'A'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{score}/32 ({pct}%) -> grade {grade(score)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if pct >= 90: return 'A'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Map an Audit Score to a Letter Grade: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: grade, score, total, pct, round. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def grade(score, total=32): | Core: if pct >= 90: return 'A' | Evidence: print(f'{score}/32 ({pct}%) -> grade {grade(score)}')

🛠️ Reader to Writer Bridge

1. Read: explain map an audit score to a letter grade in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 494.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 496 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{score}/32 ({pct}%) -> grade {grade(score)}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `def grade(score, total=32):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of map an audit score to a letter grade and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Converting the score to a percentage and bucketing into 90/80/70/60 bands yields the familiar A-F grade used in the final audit report.

```
def grade(score, total=32):
    pct = 100 * score / total
    if pct >= 90: return 'A'
    if pct >= 80: return 'B'
    if pct >= 70: return 'C'
    if pct >= 60: return 'D'
```

```
    return 'F'
for score in [31, 27, 23, 20, 14]:
    pct = round(100 * score / 32)
    print(f'{score}/32 ({pct}%) -> grade {grade(score)}')
```

```
output
31/32 (97%) -> grade A
27/32 (84%) -> grade B
23/32 (72%) -> grade C
20/32 (62%) -> grade D
14/32 (44%) -> grade F
```

How it works:

1. The grade function takes a score and a default total of thirty-two.
2. It computes the percentage as one hundred times the score over the total.
3. Descending if-returns check ninety, eighty, seventy and sixty for grades A through D.
4. Any percentage below sixty falls through to grade F.
5. A loop grades five sample scores, printing each score, its rounded percentage, and its letter.

Try it:

1. Add plus and minus modifiers so a high B reads differently from a low one.
2. Make the band thresholds parameters so different audit rubrics can be applied.
3. Return both the letter and a short descriptive label such as healthy or critical.
4. Change the A cutoff to 95% and watch the 31/32 case fall to B.

⚠ Common Mistakes

- Using `>` instead of `>=` at the band edges drops a score sitting exactly on 90%.
- Computing the percentage with integer division would truncate and shift grades.
- Hard-coding `total=32` means reusing this for a different scale needs the argument passed.

Skills gained grade mapping | percentage conversion | threshold ordering | early returns

→ Where You'll Use This: Translating a raw audit score into a letter grade is how findings get communicated to non-technical stakeholders, turning a number into an at-a-glance site-health verdict.

Mental Model

This is a school report card: the long list of marks collapses into one letter a parent, or a client, instantly understands.

Project 496 Run the Full 32-Point Technical SEO Audit

The Idea Behind It

The capstone runs all thirty-two checks over one site fixture, scores it, assigns a letter grade, and lists every failing point. The code stores thirty-two boolean results in a single dictionary, partitions the keys into passed and failed comprehensions, counts the passers as the score, and inlines the grade banding. Driving both the score and the failure list from one dictionary of results is what makes this the chapter's complete audit, since every earlier check now feeds one consolidated verdict.

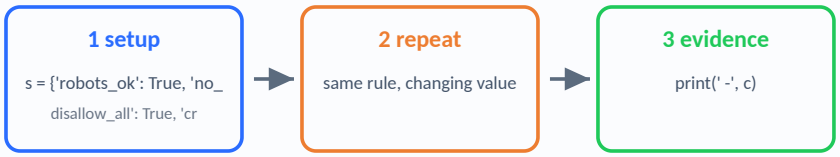
What You'll Build & Learn

Run the complete thirty-two point audit over one site fixture, score and grade it, and list every failure.

- Hold all results in one dict
- Partition keys into pass and fail
- Inline the grade banding

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 495: map an audit score to a letter grade. Project 497 changes the surface problem while preserving the underlying method.



progress check

Reading target: run the full 32-point technical seo audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `s = {'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True, 'sitemap_present': True,` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(' –', c)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`s = {'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True, 'sitemap_present': True,`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`passed = [c for c in checks if s[c]]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(' –', c)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `passed = [c for c in checks if s[c]]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run the Full 32-Point Technical SEO Audit: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: robots_ok, no_disallow_all, crawl_delay_ok, sitemap_present, sitemap_size_ok. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: s = {'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True... | Core: passed = [c for c in checks if s[c]] | Evidence: print(' -', c)

🛠️ Reader to Writer Bridge

1. Read: explain run the full 32-point technical seo audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 495.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 497 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' –', c)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `s = {'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True, 'sitemap_present': True,` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run the full 32-point technical seo audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Flattening all 32 boolean checks into one dict lets a single pass count passes, derive the percentage and grade, and emit the exact list of failures to fix.

```
s = {'robots_ok': True, 'no_disallow_all': True, 'crawl_delay_ok': True,
'sitemap_present': True,
     'sitemap_size_ok': True, 'sitemap_valid': True, 'no_orphans': False,
'internal_links_ok': True,
     'canonical_self': True, 'no_noindex_key': True, 'https': True, 'all_200':
```

```
True,
     'redirects_short': True, 'hreflang_reciprocal': True, 'x_default': False,
'no_broken': True,
     'lcp_ok': True, 'inp_ok': True, 'cls_ok': False, 'mobile_ok': True,
     'compressed': True, 'render_block_ok': True, 'weight_ok': True, 'ttfb_ok':
True,
     'title_ok': True, 'meta_ok': True, 'h1_ok': True, 'schema_valid': True,
     'lead_answer_ok': True, 'aeo_schema': True, 'author_bio': True, 'fresh':
False}
checks = list(s.keys())
passed = [c for c in checks if s[c]]
failed = [c for c in checks if not s[c]]
score = len(passed)
pct = round(100 * score / 32)
g = 'A' if pct >= 90 else 'B' if pct >= 80 else 'C' if pct >= 70 else 'D' if
pct >= 60 else 'F'
print('=== 32-POINT TECHNICAL SEO AUDIT ===')
print(f'score: {score}/32 ({pct}%)  grade: {g}')
print(f'failures ({len(failed)}):')
for c in failed:
    print('  -', c)
```

```
output
=== 32-POINT TECHNICAL SEO AUDIT ===
score: 28/32 (88%)  grade: B
failures (4):
  - no_orphans
  - x_default
  - cls_ok
  - fresh
```

How it works:

1. A single dictionary records thirty-two boolean check results for one site fixture.
2. Comprehensions split the keys into a passed list and a failed list by their value.
3. The score is the length of the passed list, and the percentage is rounded against thirty-two.
4. An inline chained conditional maps the percentage to a letter grade A through F.
5. A banner prints the score, percentage and grade, then loops to list each failing check.

Try it:

1. Group the failures by pillar so the report shows where the worst cluster of problems sits.
2. Read the site results from a real crawl rather than a hard-coded fixture.
3. Emit the result as JSON so the audit can feed a dashboard or alert.
4. Flip `cls_ok` and `fresh` to True and watch the grade climb to A.

⚠ Common Mistakes

- The dict must hold exactly 32 keys or the `/32` denominator no longer matches reality.
- Iterating `s.items()` for failures preserves insertion order; sorting would reorder the report.
- A boolean stored as the string `'False'` would be truthy and silently pass.

Skills gained `full audit` `dict partitioning` `inline grading` `failure listing`

→ **Where You'll Use This:** A single function that scores a site against a fixed checklist and prints its failures is the deliverable clients want, and the foundation any automated audit dashboard is built on.

⚡ Mental Model

This is the full physical exam: every individual test from the chapter run at once, rolled into one chart with a grade and a list of what to treat.

Project 497 Turn Audit Failures Into a Remediation Plan

💡 The Idea Behind It

A list of failing check names is only useful if it tells you what to do, so this project maps each failure to a concrete fix. A FIXES dictionary pairs check names with remediation sentences, and the code loops over a list of failures, printing a numbered plan that looks up each fix and falls back to investigate manually for unknown names. Using dict.get with a default is the safeguard that keeps the plan from crashing on a failure the lookup table has not yet been taught to fix.

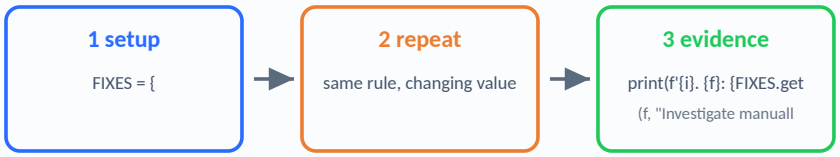
What You'll Build & Learn

Turn a list of audit failures into a numbered remediation plan by mapping each failure to a fix.

- Map failures to fix instructions
- Default unknown failures gracefully
- Number a plan with enumerate

🧭 Skill Roadmap

`Skill step:` pushes the same idea into a less automatic situation. It builds on Project 496: run the full 32-point technical seo audit. Project 498 changes the surface problem while preserving the underlying method.



progress check

`Reading target:` turn audit failures into a remediation plan is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `FIXES = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print(f'{i}. {f}: {FIXES.get(f, "Investigate manually.")}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`FIXES = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`'x_default': 'Add an x-default hreflang for unmatched locales.',`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{i}. {f}: {FIXES.get(f, "Investigate manually.")}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `'x_default': 'Add an x-default hreflang for unmatched locales.',`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Turn Audit Failures Into a Remediation Plan: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: no_orphans, Add, internal, links, to. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: FIXES = { | Core: 'x_default': 'Add an x-default hreflang for unmatched locales.', | Evidence: print(f'{i}. {f}: {FIXES.get(f, "Investigate manually.")}')

🛠️ Reader to Writer Bridge

1. Read: explain turn audit failures into a remediation plan in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 496.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 498 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{i}. {f}: {FIXES.get(f, "Investigate manually.")}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `FIXES = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of turn audit failures into a remediation plan and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A fix dictionary keyed by check name converts each failure into a numbered, human-readable remediation step, with a fallback for unknown checks.

```
FIXES = {
    'no_orphans': 'Add internal links to orphan pages or include them in the
sitemap.',
    'x_default': 'Add an x-default hreflang for unmatched locales.',
    'cls_ok': 'Reserve space for images and embeds to stop layout shift.',
    'fresh': 'Refresh the content and update the lastmod date.',
}
failures = ['no_orphans', 'cls_ok', 'fresh']
print('REMEDIATION PLAN')
for i, f in enumerate(failures, 1):
    print(f'{i}. {f}: {FIXES.get(f, "Investigate manually.")}')
```

```
output
REMEDIATION PLAN
1. no_orphans: Add internal links to orphan pages or include them in the sitemap.
2. cls_ok: Reserve space for images and embeds to stop layout shift.
3. fresh: Refresh the content and update the lastmod date.
```

How it works:

1. A FIXES dictionary pairs each known check name with a plain-language remediation sentence.
2. A failures list names the three checks that did not pass this audit.
3. enumerate starting at one numbers the plan as it iterates the failures.
4. Each line looks up the fix with get, defaulting to investigate manually when unknown.
5. The printed output is a clean, numbered remediation plan.

Try it:

1. Attach an effort or impact estimate to each fix and sort the plan accordingly.
2. Expand the FIXES table to cover all thirty-two checks from the audit.
3. Group related fixes so a single engineering ticket can address several at once.
4. Add a fix entry for `x_default` and re-run with it in the list.

⚠ Common Mistakes

- A failure with no entry in `FIXES` falls back to a generic message rather than crashing.
- Enumerating from 0 instead of 1 produces an off-putting zero-indexed plan.
- Reordering the failures list changes the step numbering, so sort it first if stability matters.

Skills gained remediation mapping | dict get default | enumerate numbering | actionable audits

→ Where You'll Use This: Turning failures into prioritised fix instructions is what makes an audit actionable, and this lookup pattern is how audit tools generate the recommendation section of a report.

Mental Model

The audit is a diagnosis and this is the prescription: each problem named gets a specific instruction, so the patient knows exactly what to take and when.

Project 498 Diff Two Audits for Regressions

The Idea Behind It

Audits are most valuable over time, so this project diffs a baseline run against the latest to surface regressions and wins. A score helper sums passing booleans, and the code computes both totals, then derives regressions as checks that were True before and False now, and fixes as the reverse. Sorting the regression and fix lists makes the diff stable and readable, while the score delta gives a one-number summary of whether the site got healthier or worse since the baseline.

What You'll Build & Learn

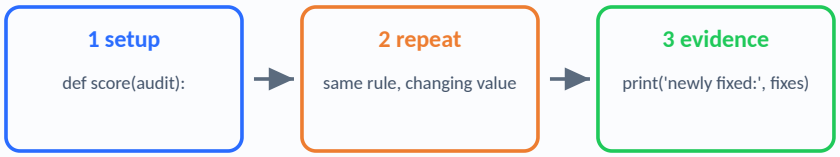
Diff a baseline audit against the latest run to report the score delta, regressions, and newly fixed checks.

- Sum booleans for an audit score
- Derive regressions from two runs
- Compute a score delta

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 497: turn audit failures into a remediation plan. Project 499 changes the surface problem while preserving the underlying method.

progress check



Reading target: diff two audits for regressions is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `def score(audit):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('newly fixed:', fixes)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def score(audit):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`return sum(1 for v in audit.values() if v)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('newly fixed:', fixes)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return sum(1 for v in audit.values() if v)`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Diff Two Audits for Regressions: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: score, audit, sum, values, baseline. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: def score(audit): | Core: return sum(1 for v in audit.values() if v) | Evidence: print('newly fixed:', fixes)

🛠️ Reader to Writer Bridge

1. Read: explain diff two audits for regressions in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 497.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 499 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('newly fixed:', fixes)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `def score(audit):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of diff two audits for regressions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Scoring both audits and taking set-style differences over the shared keys identifies exactly which checks regressed and which were newly fixed since the baseline.

```
def score(audit):
    return sum(1 for v in audit.values() if v)
baseline = {'lcp_ok': True, 'cls_ok': True, 'schema_valid': True, 'fresh':
True, 'all_200': True}
latest =   {'lcp_ok': True, 'cls_ok': False, 'schema_valid': True, 'fresh':
True, 'all_200': False}
b, l = score(baseline), score(latest)
regressions = sorted(k for k in baseline if baseline[k] and not latest[k])
fixes = sorted(k for k in baseline if not baseline[k] and latest[k])
print(f'baseline {b}/{len(baseline)} -> latest {l}/{len(latest)} (delta {l -
b})')
print('regressions:', regressions)
print('newly fixed:', fixes)
```

```
output
baseline 5/5 -> latest 3/5 (delta -2)
regressions: ['all_200', 'cls_ok']
newly fixed: []
```

How it works:

1. A score helper sums the truthy values in any audit dictionary.
2. Baseline and latest dictionaries record the same five checks at two points in time.
3. Their scores are computed and the delta printed as latest minus baseline.
4. A comprehension finds checks that were True in baseline but False in latest as regressions.
5. A mirror comprehension finds newly fixed checks, and both sorted lists print.

Try it:

1. Handle checks present in one run but not the other rather than assuming identical keys.
2. Print the regressions with the fixes from the remediation table beside them.
3. Track the delta across many runs to plot a site-health trend line.
4. Fix `cls_ok` in `latest` and watch it move to the newly-fixed list.

⚠ Common Mistakes

- Comparing scores alone hides which checks changed; the per-key diff is what matters.

- Iterating only the latest dict misses checks present in the baseline but dropped later.
- Sorting the regression and fix lists keeps the diff output deterministic.

Skills gained audit diffing boolean summing regression detection trend tracking

→ **Where You'll Use This:** Diffing audits between deploys or months is how teams catch SEO regressions introduced by a release, making this comparison a natural fit for continuous monitoring.

Mental Model

Like comparing two blood-test results: the single number tells you better or worse, but the regression list shows exactly which marker slipped since last time.

Project 499 Aggregate an Audit Across Many Pages

The Idea Behind It

A site-wide audit rolls per-page results into pass rates per check and names the weakest page, showing where a problem is systemic versus isolated. The code iterates a fixed list of checks, counts how many pages pass each, and prints the rate as a fraction and percentage, then uses min with a key that sums each page's booleans to find the weakest page. Summing each page's passing checks as the sort key is what cleanly identifies the single page most in need of attention.

What You'll Build & Learn

Aggregate per-page audit results into per-check pass rates and identify the weakest page on the site.

- Compute per-check pass rates
- Iterate a fixed list of checks
- Find the weakest page with min

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 498: diff two audits for regressions. Project 500 changes the surface problem while preserving the underlying method.

progress check

Reading target: aggregate an audit across many pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('weakest page:', worst)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`hits = sum(1 for p in pages.values() if p[c])`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('weakest page:', worst)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `hits = sum(1 for p in pages.values() if p[c])`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Aggregate an Audit Across Many Pages: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: pages, home, title_ok, schema, lead_answer. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: hits = sum(1 for p in pages.values() if p[c]) | Evidence: print('weakest page:', worst)

🛠️ Reader to Writer Bridge

1. Read: explain aggregate an audit across many pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 498.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 500 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('weakest page:', worst)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of aggregate an audit across many pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Counting how many pages pass each check gives per-check pass rates, and summing each page's passes (with a sorted tiebreak) finds the weakest page to prioritise.

```
pages = {
    '/home': {'title_ok': True, 'schema': True, 'lead_answer': True, 'fresh':
True},
    '/blog/a': {'title_ok': True, 'schema': False, 'lead_answer': True,
'fresh': False},
    '/blog/b': {'title_ok': False, 'schema': False, 'lead_answer': True,
'fresh': True},
}
checks = ['title_ok', 'schema', 'lead_answer', 'fresh']
n = len(pages)
print('site-wide pass rate per check:')
for c in checks:
    hits = sum(1 for p in pages.values() if p[c])
    print(f'  {c}: {hits}/{n} ({round(100 * hits / n)}%)')
worst = min(sorted(pages), key=lambda p: sum(pages[p].values()))
print('weakest page:', worst)
```

```
output
site-wide pass rate per check:
  title_ok: 2/3 (67%)
  schema: 1/3 (33%)
  lead_answer: 3/3 (100%)
  fresh: 2/3 (67%)
weakest page: /blog/a
```

How it works:

1. A pages dictionary records four boolean checks for each of three pages.
2. For each check in a fixed list, the code counts how many pages pass it.
3. Each pass rate prints as a fraction of pages and a rounded percentage.
4. min with a key that sums each page's check values finds the weakest page.
5. The weakest page path is printed after the per-check pass rates.

Try it:

1. Report the worst-performing check across the whole site, not only the worst page.
2. Weight pages by traffic so a popular weak page outranks an obscure one.
3. Output the per-page and per-check matrix as a CSV for further analysis.

4. Add a page that fails every check and watch it become the weakest.

⚠ Common Mistakes

- A tie for weakest page resolves by sorted URL order, so `min` over `sorted(pages)` is deterministic.
- Computing pass rate over a subset of pages, not all, would misstate the percentage.
- Summing boolean values relies on True==1; a stray string value would break the count.

Skills gained site-wide audit | pass-rate aggregation | min with key | weakest page

→ Where You'll Use This: Rolling per-page checks into site-wide pass rates is how large-site audits separate a systemic schema gap from a one-off bad page, focusing remediation where it scales.

⚡ Mental Model

This is the class gradebook view: pass rates per question show which topic the whole class struggled with, while the lowest total flags the student needing help.

Project 500 Build a Combined GEO and Technical Scorecard

💡 The Idea Behind It

The final scorecard fuses the thirty-two point technical audit with a five-point GEO and AEO readiness score into one holistic number. The code takes the technical score as given, counts the passing GEO signals from a dictionary, adds the two scores and their two totals, computes a combined percentage, assigns a letter grade, and surfaces the single top gap. Combining classic technical health with answer-engine readiness in one figure is the chapter's culminating idea, reflecting how a modern audit must judge both at once.

What You'll Build & Learn

Fuse the technical audit score with a GEO and AEO readiness score into one combined grade and top gap.

- Combine two score dimensions
- Sum scores and totals together
- Surface the single top gap

🧭 Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 499: aggregate an audit across many pages. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: build a combined geo and technical scorecard is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `technical = 28 # out of 32` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
- Evidence: `print('top gap:', sorted(k for k, v in geo.items() if not v)[0])` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`technical = 28 # out of 32`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
2. Apply the rule	`geo_score = sum(1 for v in geo.values() if v)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('top gap:', sorted(k for k, v in geo.items() if not v)[0])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: GEO, AEO and the End-to-End Technical Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `geo_score = sum(1 for v in geo.values() if v)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Combined GEO and Technical Scorecard: connect the surface task to the chapter skill, score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit.
Names	Watch these names first: technical, of, geo, concise_answers, schema_aeo. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: technical = 28 # out of 32 | Core: geo_score = sum(1 for v in geo.values() if v) | Evidence: print('top gap:', sorted(k for k, v in geo.items() if not v)[0])

🛠️ Reader to Writer Bridge

1. Read: explain build a combined geo and technical scorecard in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 499.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('top gap:', sorted(k for k, v in geo.items() if not v)[0])`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `technical = 28 # out of 32` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a combined geo and technical scorecard and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Adding the technical score to the GEO/AEO score over a combined 37-point total produces one percentage and grade that balance crawlability and answer-readiness.

```
technical = 28  # out of 32
geo = {'concise_answers': True, 'schema_aeo': True, 'eeat_strong': True,
'fresh': False, 'entities_clear': True}
geo_score = sum(1 for v in geo.values() if v)
geo_total = len(geo)
combined = technical + geo_score
combined_total = 32 + geo_total
pct = round(100 * combined / combined_total)
g = 'A' if pct >= 90 else 'B' if pct >= 80 else 'C' if pct >= 70 else 'D' if
pct >= 60 else 'F'
print('=== GEO + TECHNICAL SCORECARD ===')
print(f'technical:    {technical}/32')
print(f'GEO/AEO:      {geo_score}/{geo_total}')
print(f'combined:     {combined}/{combined_total} ({pct}%) grade {g}')
print('top gap:', sorted(k for k, v in geo.items() if not v)[0])
```

```
output
=== GEO + TECHNICAL SCORECARD ===
technical:    28/32
GEO/AEO:      4/5
combined:     32/37 (86%) grade B
top gap: fresh
```

How it works:

1. A technical score out of thirty-two is given, and a GEO dictionary holds five readiness booleans.
2. geo_score counts the passing GEO signals and geo_total is the dictionary length.
3. The combined score and total add the technical and GEO figures together.
4. A rounded percentage drives an inline chained grade band of A through F.
5. A banner prints the technical, GEO and combined scores, and the sorted first GEO gap.

Try it:

1. Weight the technical and GEO halves rather than adding their raw points equally.
2. List all GEO gaps in priority order instead of only the first one.
3. Track the combined score over time to show progress on both dimensions at once.

4. Push the technical score to 32 and the GEO score to 5 for a grade-A sheet.

⚠ Common Mistakes

- Combining raw scores without a shared denominator would make the percentage meaningless.
- If every GEO signal passed, `sorted(...)[0]` over an empty list would raise; guard for a clean sheet.
- Weighting technical and GEO equally per-point may under-value whichever matters more for the site.

Skills gained combined scorecard | score fusion | grade banding | GEO plus technical

→ Where You'll Use This: A unified technical-plus-GEO scorecard is the deliverable a modern SEO audit should produce, giving stakeholders one health figure that spans both crawlability and answer-engine readiness.

Mental Model

Like a hybrid car's combined rating: it is not enough to score well on the engine alone; the final grade fuses traditional power with the new electric drive.

✅ Chapter Progress Checkpoint

What this chapter added: after 36 mini-projects, GEO, AEO and the End-to-End Technical Audit should feel like a reusable Python move: score answer-extractability and e-e-a-t signals, ai-mode readiness, and run a 32-point technical audit. *chapter checkpoint*

1 Read
Open any project from Projects 465-500 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.
transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, the same habits become your independent review loop: read, trace, modify, test, and explain.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

9 questions · 4 categories · graded

3 Recall | 2 Meaning | 2 Structure | 2 Transfer

14.1.Q1 Recall MEDIUM Turn back to Project 488 (Write an Hreflang Audit Check). Without running it, what exactly does it print?

14.1.Q2 Meaning MEDIUM Turn back to Project 483 (Write a robots.txt Audit Check). Without running it, what exactly does it print?

14.1.Q3 Structure MEDIUM Turn back to Project 487 (Write a Core Web Vitals Audit Check). Without running it, what exactly does it print?

14.1.Q4 Transfer MEDIUM Turn back to Project 465 (Score a Page's Answer-Extractability Lead). Without running it, what exactly does it print?

14.1.Q5 Recall EASY What is the core difference between classic SEO and GEO/AEO?

A. GEO/AEO ignores keywords entirely

B. GEO/AEO optimises to be the source an answer engine extracts and cites, not just a ranked blue link

C. GEO/AEO only applies to images

D. They are the same thing with different names

14.1.Q6 Meaning MEDIUM An answer engine is choosing which sentence to quote for a query. Which page is most likely to be picked?

A. The longest article on the topic

B. A page whose first paragraph is a tight 30-word direct answer in a quotable shape

C. A page that mentions the keyword the most times

D. A page with the most images

14.1.Q7 Structure EASY Why turn E-E-A-T into a checklist score (e.g. /7) instead of judging it by feel?

A. Because Google publishes the exact formula

B. Because engines infer trust from concrete signals (author bio, credentials, dates, citations, about/contact), so summing those signals makes a fuzzy concept measurable and actionable

C. Because E-E-A-T does not affect ranking

D. Because it removes the need for good content

14.1.Q8 Transfer MEDIUM The 32-point audit returns 28/32 with failures [no_orphans, x_default, cls_ok, fresh]. Why is mapping each failure to a fix the essential last step?

14.1.Q9 Recall MEDIUM A page is fully extractable (concise lead, list, table) but has no named author, no dates, and no outbound citations. What is the likely outcome with answer engines?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 14 – GEO, AEO and the End-to-End Technical Audit

14.1.Q1. `hreflang check: PASS | missing-return: [] xdefault: True`

14.1.Q2. `robots.txt check: PASS` then `site-wide block: FAIL`

14.1.Q3. `passing vitals: ['LCP', 'INP']` then `Core Web Vitals check: FAIL`

14.1.Q4. `lead answer words: 27` then `extractable lead: YES`

14.1.Q5. B answer engines synthesise an answer from several pages and cite a few; GEO/AEO is about being one of those cited, extracted sources.

14.1.Q6. B extractability wins: a concise, self-contained lead answer is the easiest passage to lift, regardless of overall length.

14.1.Q7. B the concept is fuzzy but its inputs are concrete page signals, so a checklist turns it into a number you can improve.

14.1.Q8. A list of failing check names is not actionable on its own; mapping each (e.g. fresh → refresh content and update lastmod) turns the score into a remediation plan a person can execute, and the audit can then be re-run to confirm the fix.

14.1.Q9. It is quotable but rarely quoted — extraction is satisfied but trust is not, and a citation needs both. The fix is to add E-E-A-T signals (author bio with credentials, published/updated dates, citations to authoritative sources).

Appendix A – Glossary

@context. the key naming the vocabulary the field names come from — always "https://schema.org" for SEO.

@type. the key naming what the object is, such as Article, Product, FAQPage, BreadcrumbList or LocalBusiness.

301 redirect. a permanent redirect; engines pass ranking signals to the target and swap the old URL for it in the index.

302 redirect. a temporary redirect; engines keep the original URL indexed and transfer little signal to the target.

access log. the server-written diary of every request received, one line per hit, in arrival order; ground truth for what was actually crawled.

AEO. answer engine optimization — structuring content (question headings, concise answers, FAQ/HowTo schema) so answer engines can extract a direct answer.

alt text. the `alt` attribute on an image; describes it for screen readers and crawlers. Missing = fault, empty = decorative, filled = described.

anchor text. the clickable words of a link, read as a description of the target; a healthy profile spreads anchor types instead of repeating one exact-match phrase.

answer-extractability. how easily a machine can lift a self-contained answer: a concise lead, a clean definition, a list, or a table.

cannibalization. when two or more of your own pages target the same keyword and compete, splitting rankings instead of one page winning.

canonical link. a `<link rel="canonical">` naming the master URL so duplicate variants consolidate their ranking signals.

canonical tag. a `<link rel="canonical">` hint naming which URL is the indexing representative for a set of duplicates; ordinary pages self-reference.

changefreq / priority. optional crawl hints: a keyword from always..never, and a 0.0–1.0 decimal (default 0.5) — neither is a ranking signal.

citation. an online mention of a business's NAP, such as a Yelp, Apple Maps, or directory entry.

CLS. Cumulative Layout Shift — a unitless visual-stability score; good ≤ 0.1, poor > 0.25.

Common Log Format. the standard log line layout packing IP, timestamp, request line, status, bytes, referer and User-Agent into one space-separated string.

content freshness. how recently a page was published or updated; flagged stale when older than a chosen audit threshold (e.g. one year).

crawl budget. the number of fetches a bot will make on a site in a window; measured from the log as the bot-hit count and the distinct paths reached.

crawl waste. bot fetches spent on dead ends — 404s, redirects, blocked paths or duplicate parameter URLs — and so stolen from pages that matter.

crawl-delay. a (non-standard) directive asking a bot to wait N seconds between fetches; a per-minute fetch ceiling of 60/N.

crawler. an automated bot that fetches pages and follows their links to discover more URLs.

damping factor. the chance (classically 0.85) the surfer follows a link rather than teleporting; the (1 - d) slice keeps every page above zero and totals at 1.0.

duplicate content. multiple URLs serving identical visible text, detected by grouping pages with the same content hash (e.g. hashlib.sha1).

E-E-A-T. Experience, Expertise, Authoritativeness, Trust — inferred from signals like author bio, credentials, citations, and about/contact pages.

field vs lab data. field data is real users (CrUX); lab data is a single synthetic test on a simulated device.

GEO. generative engine optimization — making a page the content a generative AI engine selects, synthesises from, and cites.

Google Business Profile. a business's Google listing (name, address, phone, hours, categories, photos) whose completeness and verification feed local ranking.

H1 / heading hierarchy. the <h1>–<h6> outline; a sound page has one H1 and steps levels down one at a time with no skips.

hreflang. an annotation mapping each language/region version of a page to its URL, so the engine serves the right version per user.

hreflang cluster. the set of all language alternates for one piece of content; the same block is repeated identically on every page in it.

in-degree. the number of links pointing at a page; high in-degree is where link equity collects.

INP. Interaction to Next Paint — responsiveness from interaction to the next painted frame; good ≤ 200ms, poor > 500ms. Replaced FID in 2024.

inverted index. a map from each term to the set of pages containing it — the structure a query is answered from.

Jaccard similarity. shared shingles over total shingles (intersection / union), a 0-to-1 overlap score; the classic near-duplicate metric.

JSON-LD. JSON for Linked Data; the recommended structured-data format, placed in a <script type="application/ld+json"> tag.

keyword cluster. a set of keywords sharing intent and topic that belong on one pillar page rather than many.

keyword difficulty. a 0–100 estimate of how hard it is to reach page one for a keyword, based on the strength of the pages already ranking.

lastmod. an optional ISO/W3C date (e.g. 2026-01-01) telling crawlers when the page last changed.

LCP. Largest Contentful Paint — time until the largest visible element renders; good ≤ 2.5s, poor > 4.0s.

link equity. the ranking value a link passes; a page splits it evenly across its out-links, so more out-links dilute each share.

loc. the required absolute URL inside each <url>; must be fully-qualified, same-host and (in practice) HTTPS.

local pack. the map plus (usually three) business profiles shown atop a local-intent search.

locale code. an hreflang value: a lowercase ISO 639-1 language, optionally a hyphen and an uppercase ISO 3166-1 alpha-2 region (e.g. `en-GB`), plus the special `x-default`.

long-tail keyword. a longer, more specific query (often 4+ words): low volume, low difficulty, high intent.

longest-match precedence. when several rules match a path, the one whose pattern matches the most characters wins; Allow breaks a length tie.

meta description. a `<meta name="description">` whose text often becomes the results snippet; drives clicks and is clipped near ~155 characters.

NAP. Name, Address, Phone — the core identifying facts that must match across every listing.

NAP consistency. the share of a business's citations whose NAP exactly matches the canonical record.

nofollow. a rel attribute marking a link as a non-vote: it may pass traffic and signal interest but passes no ranking equity.

orphan page. a page no internal link points to, so the crawler may never discover it.

p75. the 75th percentile of real-user field data; the value Google grades a metric against.

PageRank. a page's long-run share of a random surfer's visits, found by iterating the even-split link flow with damping until it converges.

performance budget. a hard cap on transfer size, per-type KB, request count or score that a page may not exceed.

priority score. a single combined number, e.g. volume × intent_weight ÷ difficulty, used to rank a keyword list into action order.

prominence. how well-known and trusted a business is, driven largely by reviews and citation breadth.

redirect chain. a sequence of redirects (A → B → C → page); extra hops add latency and bleed link equity.

redirect loop. a cycle of redirects that never reaches a live page; caught with a seen-set or a hop limit.

referring domain. a distinct site that links to you; the headline backlink metric, since independent domains count far more than repeated links from one site.

render-blocking resource. CSS or synchronous JavaScript in the head that the browser must process before it can paint, delaying LCP.

required property. a field a type must have, or it earns no rich result; recommended properties only enrich an already-valid result.

return tag (reciprocity). the requirement that if page A names B as an alternate, B must name A back, or the relationship is ignored.

rich result. an enhanced search listing (stars, prices, FAQ accordion, breadcrumbs) granted to a page with valid structured data.

robots meta. a `<meta name="robots">` carrying directives like `noindex` (keep out of the index) and `nofollow` (do not pass link credit).

robots.txt. a root-level text file that tells crawlers which paths they may fetch; controls crawling, not indexing, and is obeyed voluntarily.

search intent. the goal behind a query: informational, navigational, commercial, or transactional. Decides what content can rank.

search volume. estimated monthly searches for a keyword — its demand, independent of how hard it is to rank for.

self-reference. the rule that every page must list its own locale among its hreflang alternates, or the cluster is invalid for that page.

shingle. a sliding window of k consecutive tokens; the set of a page's shingles is what near-duplicate detectors compare.

sitemap. an XML file listing the URLs you want crawled, giving the bot a discovery seed independent of internal links.

sitemapindex. a root element whose <sitemap> children point to child sitemaps, used to fan out past the 50,000-URL / 50 MB limit.

soft-404. a page that returns 200 but whose body says it is missing, so engines index nothing of value.

status class. a status code grouped by its leading digit: 2xx success, 3xx redirect, 4xx client error, 5xx server error.

status code. the three-digit integer a server returns for each request; its first digit sets the class (2xx/3xx/4xx/5xx).

structured data. a machine-readable fact sheet attached to a page, stating what its content is in an agreed vocabulary.

technical audit. a repeatable pass running many checks over a site, scoring them out of a total, grading the percentage, and listing fixes.

term frequency. how often a query term appears in a page relative to the page length; an early ranking signal.

thin content. a page with too few unique words or too much boilerplate to satisfy a searcher; a soft 404 (200 status, no real content) is the extreme case.

title tag. the `<title>` in the head; the clickable results headline and the strongest on-page signal, healthiest at ~50-60 characters.

URL normalization. rewriting every variant of a URL into one canonical string (lowercase host, drop fragment, strip tracking params, sort query, trim slash) so duplicates become equal.

urlset. the root element of a normal sitemap, containing one <url> entry per page.

user-agent group. a `User-agent:` line and the Allow/Disallow rules beneath it; a bot obeys one group — its own, or * as fallback.

wildcard. pattern characters * (any run of characters) and trailing $ (end of path) that let one rule target a family of URLs.

x-default. the hreflang value naming the fallback page for users whose locale matches none you serve.

X-Robots-Tag. an HTTP response header carrying indexing directives (noindex, nofollow, noarchive) for files that cannot hold a meta tag, such as PDFs.

Appendix B – Operator & Symbol Reference

The operators that appear throughout the projects, gathered for quick reference.

Operator	Meaning
`+ − * / // % **`	add, subtract, multiply, true-divide, floor-divide, remainder, power
`== != < <= > >=`	equality and ordering comparisons
`and or not`	logical AND, OR, NOT
`in / not in`	membership test in strings, lists, sets, dicts
`= += −= *= /=`	assignment and in-place update
`[a:b:c]`	slice from a up to (not including) b, stepping by c
`f"…{x}…"`	f-string: interpolate the value of x into text
`& | ^ ~ << >>`	bitwise AND, OR, XOR, NOT, shifts
