Preface

This edition turns technical SEO into a guided, hands-on course: 14 chapters, full concept lessons, worked traces, visual models, checkpoints, quizzes and executed practice projects that crawl, parse and audit the way a real search engine does — from robots.txt and XML sitemaps to status codes, on-page signals, Core Web Vitals, structured data, hreflang and the new world of AI answer engines.

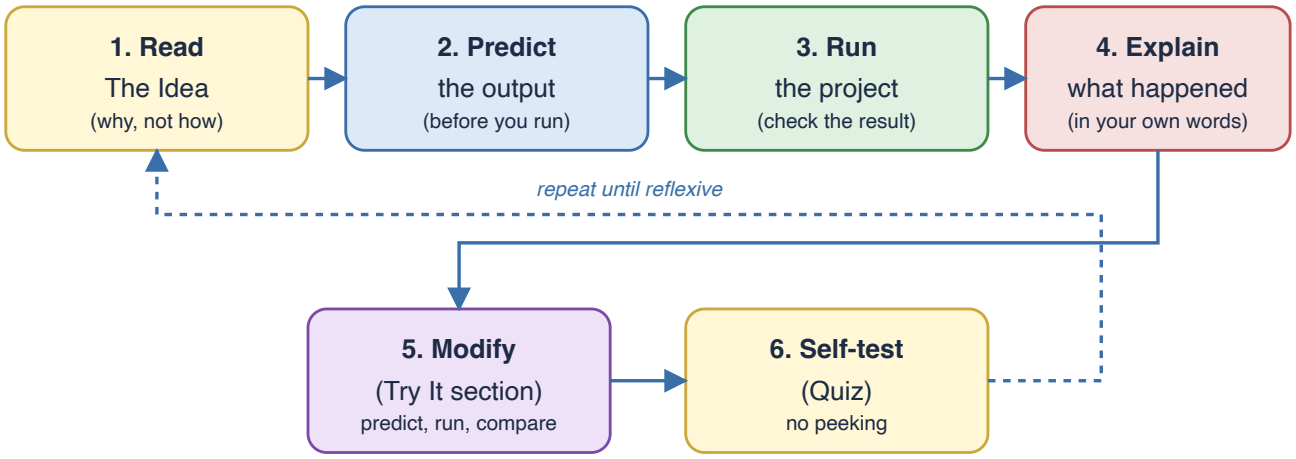
The book keeps a strict code-and-output rhythm: every project is a small, deterministic Python tool that runs against a worked example — a robots.txt string, a sitemap, an HTML snippet, a redirect chain, a JSON-LD block — prints a verdict, and shows you the exact output. You read the audit logic, predict the result, then change one detail and watch what moves. In production you point the same logic at a live URL; here you point it at a fixture so the lesson is reproducible.

Work through the chapters in order for a complete path from how crawling and indexing actually work, through on-page and content signals, performance and structured data, to international, off-page, local and AI-era optimization — finishing with an end-to-end technical audit you can run on any site. Each chapter opens with the concept, then builds the tools, so the tactics never feel like a checklist you memorize: they are habits you can execute.

About the Author

Luke McLaughlin is an independent author and publisher who grew up across several countries, an upbringing that left him endlessly curious and gave him a lifetime of overlapping passions. His path has wound through molecular biology, writing, digital growth, and software and artificial intelligence, including building *Codemonkey AI*, a desktop tutor that teaches people to code. The thread running through all of it is a love of taking something that looks complicated and uncovering the simple ideas underneath.

That is also his philosophy of learning. He treats every subject as a series of **building blocks**, each one resting on the one before it. Master the blocks in order and no subject is truly out of reach: give a little time, effort, and patience to each step, and even the most daunting topic gives way. This book was written in exactly that spirit.



> *"Every journey of a thousand miles begins with a single step."*

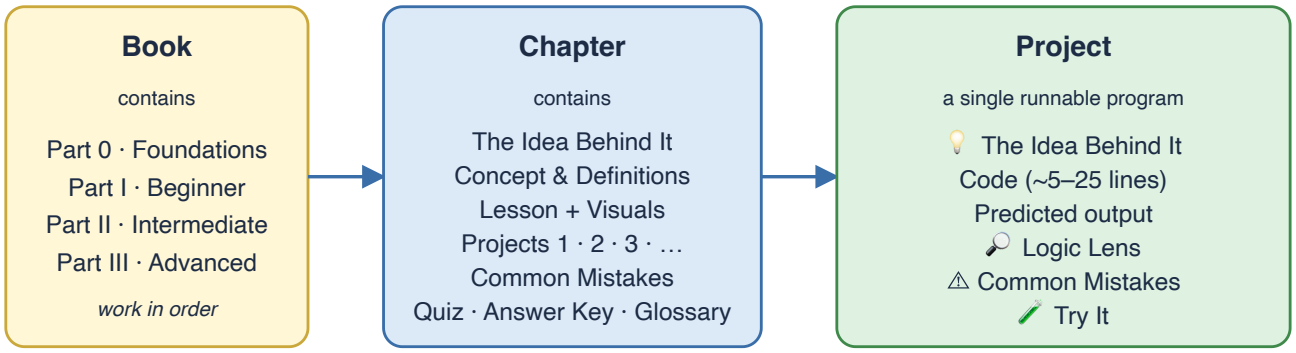
How to Use This Book



Every chapter in this book is built around one promise: a complete novice with only basic arithmetic should finish able to read, write, debug, and reason about real programs. To get there, the book follows the **essentials educational method** — a small, predictable rhythm repeated until the moves become reflexive.

The essentials method, in six steps

Every project is a turn of this loop. Run it deliberately five times per chapter and the patterns wear in.

The structure that supports the loop

Parts contain chapters; chapters contain ideas, lessons, and projects; every project contains the same internal rhythm — concept, code, prediction, mistake list, experiment.

The signposts you will see

> 💡 ***The Idea Behind It*** – **The why before the how.** Every chapter and every project opens with the thinking that produced the code. Read this slowly. If the idea is clear, the code will be obvious; if the idea is fuzzy, the code will feel like magic.

📖 ***Concept & Definitions*** – **The vocabulary in plain English.** A handful of terms a learner needs before reading the lesson. Each term is paired with a one-line definition and an example.

🧭 ***Chapter Skill Map & Roadmap*** – **Where you are and what you are building.** A short orientation showing what skill the chapter adds, what it assumes from earlier chapters, and how the projects step through the new idea.

🛠️ ***Lesson Walkthrough*** – **The idea applied, step by step.** Short sections with worked code, tables that compare options, and visuals that turn abstract structure into something you can see.

Project N → code + output – **The complete, runnable program with the exact output to check against.** Predict the output *before* running; matching the prediction proves you understood the idea, not just typed the code.

🔎 ***Logic Lens*** – **What this line really does.** A short stack of explanations that re-reads the project as a sequence of small decisions — useful when a project surprises you.

⚠️ ***Common Mistakes*** – **Traps most learners fall into.** Each entry names the mistake and the one-line fix; reading them before you start a project saves an hour of debugging.

🧪 ***Try It*** – **Small modifications that turn the example into your own experiment.** Change one thing, predict, run, compare. This is where ideas become reflexes.

📝 ***Quiz & Answer Key*** – **A short self-check at the end of every chapter.** Full answers follow in the chapter's answer key — every quiz answer is explained, not just marked.

📚 ***Glossary*** – **The chapter's vocabulary in one place.** Use it as you read, and again later when you come back to refresh the chapter.

Working the book the essentials way

1. **Read each chapter's Idea before any code.** Programming is a translation skill, not a typing skill. The *idea* is what you are translating from; the code is what you are translating to.
2. **Predict every project's output before running it.** The point is not to be right — the point is to make your mental model concrete enough to be wrong. Mismatches are the most useful learning events in the book.
3. **Do every Try It.** They are short on purpose. Changing one thing, predicting, and re-running is how the patterns become reflexes; reading without modifying does not transfer to your own programs.
4. **Take the quiz with the book closed.** If you peek, you are reading; if you predict, you are learning. Use the answer key after — the explanations are written to teach, not just to mark.
5. **Treat every mistake as data.** When the code does not match the prediction, write down what surprised you in one sentence before you fix it. Those sentences become your personal debugger over time.
6. **Move forward only when you can explain the chapter aloud.** If you can tell a friend in two minutes what the idea was and why the projects show it, you are ready. If not, re-read the Idea, re-run two projects, and try again — a day of consolidation now saves a week later.

> *Programming rewards consistency more than intensity. Thirty focused minutes a day, applied through the loop above, will carry you remarkably far. The book is structured so that every chapter you finish is one you understand — never finish a chapter you cannot explain. That is the whole method.*

Contents

Part I – Beginner Practice

Chapter 1 – How Search Engines Work 10
Chapter 2 – robots.txt and Crawl Directives 136
Chapter 3 – XML Sitemaps and URL Discovery 304
Chapter 4 – HTTP Status Codes and Redirects 468

Part II – Intermediate Skills

Chapter 5 – On-Page Signals and the HTML Audit 631
Chapter 6 – Keyword Research and Intent as Data 794
Chapter 7 – Canonicalization, Duplicate and Thin Content 941
Chapter 8 – Site Speed and Core Web Vitals 1102
Chapter 9 – Structured Data and Rich Results 1257

Part III – Advanced Mastery

Chapter 10 – International SEO and hreflang 1410
Chapter 11 – Off-Page, Links and Authority 1542
Chapter 12 – Local and Map SEO 1680
Chapter 13 – Log-File and Server Analysis 1804
Chapter 14 – GEO, AEO and the End-to-End Technical Audit 1940

PART I

Beginner Practice

Apply the foundations to small, runnable projects. Drill the patterns that will appear in every program you ever write.

Chapter 1 – How Search Engines Work · Chapter 2 – robots.txt and Crawl Directives · Chapter 3 – XML Sitemaps and URL Discovery · Chapter 4 – HTTP Status Codes and Redirects

Chapter 1 · How Search Engines Work

Crawl, index and rank — what a bot sees, crawl budget, and how URLs are discovered.

Chapter Skill Map

What this chapter adds: In How Search Engines Work, the focus is crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered. You practise it across 30 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: This is the starting layer, so the main job is learning to connect visible code with visible output.

Where it leads: Chapter 2, robots.txt and Crawl Directives, reuses this chapter's discipline with a new kind of problem.

1 **Projects 1-10** Recognise the pattern and read the code slowly. *name it first*	2 **Projects 11-20** Trace similar programs with less prompting and explain what changed.	3 **Projects 21-30** Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

A search engine is three machines in a row: crawl → index → rank. *find it, understand it, order it*

Type a query and the answer feels instant, but the work happened long before you pressed Enter. A search engine runs three separate jobs. First it crawls — automated programs called *bots* follow links from page to page, fetching HTML. Then it indexes — it reads each page, pulls out the words and signals, and stores them in a giant lookup structure. Only then can it rank — when a query arrives, it pulls every candidate page from the index and orders them by how well they answer the question.

Technical SEO is the craft of making those three jobs easy. A page that the crawler never reaches cannot be indexed; a page that is indexed but mis-understood cannot rank; a page that ranks but loads slowly loses the click. So the whole field reduces to one question asked three ways: *can the bot reach this, can it understand this, and have I given it reasons to prefer this?*

The crawler's view of your site is brutally simple — it is a graph. Each URL is a node; each link is a directed edge. The bot starts at a seed (your homepage or a sitemap), follows edges, and keeps a `seen` set so it never visits the same page twice. That single data structure is the entire crawler:

```
from collections import deque

links = {'home': ['about', 'blog'], 'about': ['home'],
         'blog': ['post'], 'post': []}
seen, order, q = {'home'}, [], deque(['home'])
while q:
    page = q.popleft()
    order.append(page)
```

```
    for nxt in links[page]:
        if nxt not in seen:
            seen.add(nxt); q.append(nxt)
print(' -> '.join(order))
```

```
output
home -> about -> blog -> post
```

Read that and you have read Googlebot in miniature: a queue of URLs to fetch, a set of URLs already fetched, and a loop. Everything technical SEO does — robots.txt, sitemaps, internal linking, redirects — is just changing which edges exist and which nodes the bot is allowed to reach.

change the graph, change what gets found

Reaching pages is not free. A bot will only fetch so many URLs from your site in a given window — its `crawl budget`. Spend it on duplicate, broken, or junk URLs and your important pages wait days to be re-crawled. So a recurring move in this book is *pruning the graph*: block the junk, surface the priorities, and let the limited budget land where it matters.

CRAWLER (BOT)

An automated program that fetches pages and follows their links to discover more. Googlebot, Bingbot and others identify themselves in the `User-Agent` string of each request.

CRAWL

Phase one: discovering and fetching URLs by walking the link graph from a set of seed URLs and any submitted sitemaps.

INDEX

Phase two: parsing each fetched page into terms and signals and storing them so they can be looked up by query. A page not in the index can never appear in results.

RANK

Phase three: for a given query, ordering the indexed candidates by relevance and quality signals.

CRAWL BUDGET

The number of URLs a bot will fetch from one site in a given period. Wasting it on duplicates or errors delays the crawling of pages that matter.

INVERTED INDEX

The core index structure: a map from each term to the set of pages that contain it, so a query becomes a fast set lookup instead of a scan of every page.

The crawler sees a graph, not a website

A human sees menus, headlines and images. A crawler sees URLs and the links between them — a directed graph. The most important consequence: if no link points to a page, the crawler may never find it. Such *orphan pages* are invisible no matter how good their content. Finding them is pure graph reachability — start at the seed, collect everything reachable, and whatever is left over is orphaned:

```
all_pages = {'home', 'about', 'blog', 'secret'}
links = {'home': ['about', 'blog'], 'about': [], 'blog': []}
reachable, stack = set(), ['home']
while stack:
    p = stack.pop()
    if p in reachable:
        continue
    reachable.add(p)
    stack.extend(links.get(p, []))
print(sorted(all_pages - reachable))
```

```
output
['secret']
```

`secret` exists but nothing links to it, so the crawl never lands there. The fix is not better content — it is an *edge*: link to the page, or list it in a sitemap.

Discovered is not indexed; indexed is not ranked

These three sets shrink as you go: every URL the bot *discovers* is a superset of what it *indexes*, which is a superset of what actually *ranks* for any query. A page can drop out at each step — discovered but blocked, indexed but thin, indexed but out-ranked. Naming which set a page is stuck in is the first diagnostic move of any audit.

discovered ⊇ indexed ⊇ ranking

```
discovered = {'/', '/a', '/b', '/dup', '/blocked'}
indexed    = {'/', '/a', '/b'}          # /dup folded, /blocked disallowed
```

```
print('not indexed:', sorted(discovered - indexed))
```

```
output
not indexed: ['/blocked', '/dup']
```

Indexing: a page becomes a bag of terms

To make pages searchable the engine tokenizes each one — lowercases the text, splits on non-letters, and records which terms appear where. Build that for several pages and you have an inverted index: term → set of pages. A one-word query is then just a dictionary lookup, not a scan of the whole web.

```
import re
docs = {1: 'Fast SEO audit', 2: 'SEO crawl budget', 3: 'Audit your site'}
index = {}
for pid, text in docs.items():
    for term in re.findall(r'[a-z]+', text.lower()):
        index.setdefault(term, set()).add(pid)
print('audit ->', sorted(index['audit']))
print('seo   ->', sorted(index['seo']))
```

```
output
audit -> [1, 3]
seo   -> [1, 2]
```

Notice the engine never re-reads the documents to answer a query — it reads the *index*. That is why how your words are written (and whether the crawler can read them at all) decides everything downstream.

Ranking: order the candidates by a score

Once the index hands back the candidate pages, ranking sorts them by a score. Real scoring blends hundreds of signals; the oldest and most intuitive is term frequency — how often the query word appears, relative to page length. Here three pages compete for the word "seo":

```
pages = {'A': 'seo seo audit', 'B': 'seo crawl index rank',
         'C': 'marketing tips'}
def score(text, term):
    words = text.split()
    return round(words.count(term) / len(words), 3)
ranked = sorted(pages, key=lambda p: score(pages[p], 'seo'), reverse=True)
print(ranked)
```

```
output
['A', 'B', 'C']
```

Page A wins on raw frequency, B is on-topic but diluted, C does not mention the term at all. Modern engines add quality, links and intent on top — but the shape is always the same: *retrieve candidates from the index, score each,*

sort descending. retrieve → score → sort

Example 1

A site has pages home, services, blog, and a checkout page reachable only from services. The homepage links to services and blog. Is checkout crawlable?

SOLUTION

1. Build the reachable set from the seed `home`: home links to `services` and `blog`, so both are reached.
2. From services we reach `checkout` — there is an edge services → checkout, so the bot follows it.
3. Every page is reachable from home, so checkout is crawlable even though only one page links to it.

Yes — checkout is crawlable because a path home → services → checkout exists.

reachability, not link count, is what matters

Example 2

Your crawl budget is 3 fetches this visit. The frontier holds [home (depth 0), a (1), b (1), c (2)]. Which pages get crawled, and what is the risk if a, b are duplicates?

SOLUTION

1. A bot generally crawls breadth-first, so it spends the budget on the shallowest URLs first: `home, a, b`.
2. Page c (depth 2) is left for a later visit — the budget ran out before reaching it.
3. If a and b are duplicates, two of three fetches were wasted on the same content, and the unique page c was the one delayed.

home, a, b are crawled; c waits. Duplicates burned the budget and starved a real page — the core argument for pruning duplicate URLs. budget spent on junk is budget stolen from value

Example 3

For the query "seo", the index returns pages A ("seo seo seo", 3 words) and B ("seo guide for beginners", 4 words). Rank them by term frequency.

SOLUTION

1. Page A: the term "seo" appears 3 times in 3 words → frequency 3/3 = `1.0`.
2. Page B: "seo" appears 1 time in 4 words → frequency 1/4 = `0.25`.
3. Sort descending by score: A (1.0) before B (0.25).

Ranked A, then B. Raw term frequency favours A — though a real engine would notice A is keyword-stuffed and discount it. frequency is a start, not the finish

⚡ Mental-Math Shortcut

Reach, read, reason. Before any tactic, ask the three questions in order: can the bot *reach* the page (crawl), can it *read* the meaning (index), have I given it *reasons* to prefer it (rank)? A problem almost always lives in the earliest phase you have not yet checked — fix crawl before you obsess over ranking.

⚠ Common Mistakes

- Optimising ranking signals on a page the crawler cannot reach — no internal link or sitemap entry means it is never even a candidate.
- Assuming "indexed" means "ranking". A page can sit in the index and still never surface because stronger pages out-score it for every query.
- Letting duplicate and parameter URLs soak up crawl budget, so important pages are re-crawled days late.
- Confusing what humans see with what the bot sees — JavaScript-built links and menus may not be in the HTML the crawler first fetches.

This chapter contains 30 hands-on mini-projects (Projects 1–30). Type each one out, run it, and experiment.

Project 1 Model a Tiny Web as a Link Graph

💡 The Idea Behind It

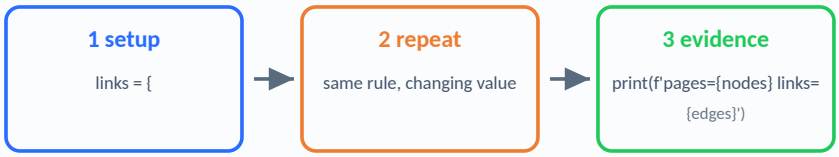
Everything a search engine does begins with one data structure: a directed graph where pages are keys and the lists they map to are the links leaving them. This project encodes that graph as a Python dict, then derives two headline numbers, node count and edge count, by measuring the dict's length and summing the lengths of its values. It proves the web is just nodes and arrows you can count.

What You'll Build & Learn

Represent a five-page site as an adjacency dict and report how many pages and links it contains.

- Pages are nodes, links are directed edges
- A dict of lists is an adjacency list
- Summing value lengths counts total edges

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 2 changes the surface problem while preserving the underlying method. *progress check*

Reading target: model a tiny web as a link graph is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'pages={nodes} links={edges}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`edges = sum(len(v) for v in links.values())`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'pages={nodes} links={edges}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `edges = sum(len(v) for v in links.values())`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Model a Tiny Web as a Link Graph: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: links, home, about, blog, post1. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: links = { | Core: edges = sum(len(v) for v in links.values()) | Evidence: print(f'pages={nodes} links={edges}')

🛠️ Reader to Writer Bridge

1. Read: explain model a tiny web as a link graph in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 2 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'pages={nodes} links={edges}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of model a tiny web as a link graph and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A dict of `url -> [linked urls]` is an adjacency list, the standard graph representation; the number of pages is the key count and the number of links is the total length of all value lists.

```
links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['post1', 'post2'],
    'post1': [],
    'post2': ['blog'],
}
nodes = len(links)
edges = sum(len(v) for v in links.values())
print(f'pages={nodes} links={edges}')
```

```
output
pages=5 links=6
```

How it works:

1. The links dict maps each page name to a list of the pages it points to, so home links out to about and blog.
2. nodes = len(links) counts the dict keys, giving five pages.
3. edges sums len(v) across every value list, totalling six outgoing links.
4. The f-string prints both counts as pages=5 links=6.

Try it:

1. Add a page that links to two existing pages and re-run the counts.
2. Compute the average out-degree by dividing edges by nodes.
3. Find pages with zero outgoing links by filtering for empty value lists.
4. Add a page `'contact': []` and watch the page count rise but edge count stay.

⚠ Common Mistakes

- Counting `len(links)` as edges instead of nodes confuses pages with links.
- Summing `len(v)` over a dict of dicts (not lists) would count keys, not links.
- A page that links to itself still counts as one edge, which is easy to overlook.

Skills gained adjacency list dict comprehension graph modelling

→ Where You'll Use This: Every crawl audit, internal-link map, and PageRank calculation starts from exactly this adjacency representation of a site's link structure.

⚡ Mental Model

Think of the dict like an airport departures board: each city lists the destinations you can fly to directly from there.

Project 2 Crawl a Tiny Web with BFS

💡 The Idea Behind It

A crawler discovers pages by following links outward from a seed, and breadth-first search captures the natural order: visit the seed, then everything one click away, then two clicks away. This code uses a deque as a FIFO queue plus a seen set to avoid revisiting, popping from the left so the nearest pages always come first. The output traces that expanding wavefront across the link graph.

What You'll Build & Learn

Crawl the sample site breadth-first from home and print the exact order pages are visited.

- BFS visits nearest pages first
- A deque gives FIFO queue behaviour
- A seen set prevents revisiting pages

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 1: model a tiny web as a link graph. Project 3 changes the surface problem while preserving the underlying method.

progress check

Reading target: crawl a tiny web with bfs is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print(' -> '.join(order))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' -> '.join(order))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in seen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Crawl a Tiny Web with BFS: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, about. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if nxt not in seen: | Evidence: print(' -> '.join(order))

🛠️ Reader to Writer Bridge

1. Read: explain crawl a tiny web with bfs in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 1.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 3 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -> '.join(order))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of crawl a tiny web with bfs and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A queue (FIFO) plus a `seen` set is the whole crawler: dequeue a page, record it, enqueue its unseen links. The `seen` set stops the crawler revisiting pages and looping forever.

```
from collections import deque

links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['post1', 'post2'],
    'post1': [],
    'post2': ['blog'],
}
seen, order, q = {'home'}, [], deque(['home'])
while q:
    page = q.popleft()
    order.append(page)
    for nxt in links[page]:
        if nxt not in seen:
            seen.add(nxt)
            q.append(nxt)
print(' -> '.join(order))
```

```
output
home -> about -> blog -> post1 -> post2
```

How it works:

1. seen, order, and q start with home as the seed in all three.
2. While the queue is non-empty, popleft removes the front page and appends it to order.
3. Each linked page not already in seen is added to seen and enqueued.
4. Joining order with arrows shows home reaching about and blog before their children.

Try it:

1. Add a fresh page linked from post1 and confirm it appears last.
2. Track and print each page's discovery distance from the seed.
3. Seed the crawl from blog instead and compare the visit order.
4. Swap the deque for a stack (`pop()`) to crawl depth-first and compare the order.

⚠ Common Mistakes

- Adding to `seen` only when you dequeue, not when you enqueue, lets the same URL enter the queue twice.
- Using a list with `.pop(0)` instead of a deque works but is O(n) per pop on large crawls.
- Forgetting a page key in the dict raises KeyError mid-crawl.

Skills gained BFS traversal | deque queue | set deduplication

→ Where You'll Use This: Real crawlers like Googlebot use breadth-first ordering to spread limited crawl budget evenly across a site rather than tunnelling into one branch.

⚡ Mental Model

BFS is ripples spreading from a stone dropped in water: every ring is fully explored before the next one forms.

Project 3 Crawl Depth-First and Compare the Order

💡 The Idea Behind It

Swap the breadth-first queue for a stack and the identical graph is explored in a completely different shape: the crawler plunges down one branch to its end before backing up to try alternatives. Here a list used with pop() and append() acts as the LIFO stack, and pushing children in reversed order keeps left-to-right priority. The seen check guards against revisiting, mirroring depth-first traversal.

What You'll Build & Learn

Crawl the same site depth-first using a stack and contrast the resulting order with BFS.

- A stack drives depth-first exploration
- pop() removes the most recently added item
- reversed() preserves natural child ordering

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 2: crawl a tiny web with bfs. Project 4 changes the surface problem while preserving the underlying method. *progress check*

Reading target: crawl depth-first and compare the order is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print(' -> '.join(order))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if page in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' -> '.join(order))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if page in seen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Crawl Depth-First and Compare the Order: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: links, home, about, blog, post1. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: links = { | Core: if page in seen: | Evidence: print(' -> '.join(order))

🛠️ Reader to Writer Bridge

1. Read: explain crawl depth-first and compare the order in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 2.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 4 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -> '.join(order))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of crawl depth-first and compare the order and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Popping from the end of a list (LIFO stack) drives depth-first traversal; reversing the link list before pushing keeps the visit order left-to-right so the output is intuitive.

```
links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['post1', 'post2'],
    'post1': [],
    'post2': ['blog'],
}
seen, order, stack = set(), [], ['home']
while stack:
    page = stack.pop()
    if page in seen:
        continue
    seen.add(page)
    order.append(page)
    for nxt in reversed(links[page]):
        if nxt not in seen:
            stack.append(nxt)
print(' -> '.join(order))
```

```
output
home -> about -> blog -> post1 -> post2
```

How it works:

1. stack starts holding only home, with empty seen and order.
2. pop() takes the top page; if already seen it is skipped via continue.
3. An unseen page is recorded in seen and order, then its children push on in reversed order.
4. The arrows show the crawler diving into one branch before exploring siblings.

Try it:

1. Remove the reversed() call and observe how the order flips.
2. Add a deeper chain of three pages and trace the dive.
3. Convert this into a recursive depth-first function instead of a stack.
4. Remove `reversed(...)` and observe the reordered output.

⚠ Common Mistakes

- Without `reversed(...)` the children are visited right-to-left, which surprises readers comparing to BFS.
- Checking `seen` only at enqueue time (not at pop) can still record a page twice because a node may be pushed before it is first visited.
- Using `stack.pop(0)` turns the stack back into a queue and silently gives BFS order.

Skills gained DFS traversal | stack with list | reversed iteration

→ **Where You'll Use This:** Understanding DFS versus BFS explains why crawler architecture matters: depth-first can strand a wide site's shallow pages while it tunnels into deep paths.

⚡ Mental Model

DFS is exploring a maze by always taking the first unexplored corridor and only backtracking when you hit a dead end.

Project 4 Crawl Within a Depth Limit

💡 The Idea Behind It

Crawlers cap how many clicks deep they descend so endless pagination and faceted navigation never drain their budget. This BFS carries each page's depth alongside it in the queue tuple, and when a page sits at the depth limit the loop hits continue and refuses to enqueue its children. With limit one, only home and its direct neighbours survive, leaving deeper pages unreached and unfetched.

What You'll Build & Learn

Run a depth-limited BFS so only pages within one hop of the seed are reached, then list them.

- Depth limits bound crawl reach
- Queue entries can carry their own depth
- continue skips enqueuing past the limit

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 3: crawl depth-first and compare the order. Project 5 changes the surface problem while preserving the underlying method.

progress check

Reading target: crawl within a depth limit is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print(sorted(reached))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if d == limit:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(sorted(reached))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if d == limit:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Crawl Within a Depth Limit: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, about. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if d == limit: | Evidence: print(sorted(reached))

🛠️ Reader to Writer Bridge

1. Read: explain crawl within a depth limit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 3.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 5 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(sorted(reached))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of crawl within a depth limit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Pairing each queued page with its depth and refusing to expand nodes at the limit confines the crawl to a radius-N ball around the seed.

```
from collections import deque

links = {
    'home': ['about', 'blog'],
    'about': ['team'],
    'blog': ['post1'],
    'post1': ['deep'],
    'team': [], 'deep': [],
}
limit = 1
reached, q = {'home': 0}, deque([('home', 0)])
while q:
    page, d = q.popleft()
    if d == limit:
        continue
    for nxt in links[page]:
        if nxt not in reached:
            reached[nxt] = d + 1
            q.append((nxt, d + 1))
print(sorted(reached))
```

```
output
['about', 'blog', 'home']
```

How it works:

1. reached maps home to depth zero and the queue holds the (home, 0) tuple.
2. Each iteration unpacks page and its depth d from the front of the queue.
3. If d equals the limit, continue stops the page's children being added.
4. Otherwise unseen children get depth d+1 and are enqueued, yielding about, blog, home.

Try it:

1. Raise the limit to two and see which deeper pages appear.
2. Print each reached page alongside its recorded depth.
3. Change the seed and observe how the reachable set shifts.
4. Raise `limit` to 2 and watch `post1`'s neighbour `deep` appear.

⚠ Common Mistakes

- Comparing `d > limit` instead of `d == limit` before skipping expands one level too far.
- Tracking depth in a separate structure that drifts out of sync with the queue.
- Re-adding an already-reached page at a greater depth and overwriting its smaller depth.

Skills gained `depth-limited BFS` `tuple unpacking` `frontier pruning`

→ **Where You'll Use This:** Click-depth limits map directly to real crawl-budget policy: pages buried many clicks from the homepage are crawled rarely or skipped entirely.

⚡ Mental Model

It is like exploring a city but refusing to walk more than one block from the hotel, no matter how many streets branch off.

Project 5 Watch the Crawl Frontier Evolve

💡 The Idea Behind It

The frontier is the live queue of URLs a crawler still has to fetch, and printing it at every step turns an abstract algorithm into a visible wavefront. This BFS prints list(q) before each pop and once more after the loop, so you watch the queue swell as children arrive and shrink as pages are processed. The snapshots reveal exactly how the breadth-first sweep moves through the graph.

What You'll Build & Learn

Instrument a BFS to print the queue at each step, making the crawl frontier visible as it evolves.

- The frontier is the pending-fetch queue
- Printing state exposes algorithm behaviour
- The frontier grows then drains to empty

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 4: crawl within a depth limit. Project 6 changes the surface problem while preserving the underlying method. *progress check*

Reading target: watch the crawl frontier evolve is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print('frontier:', list(q))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('frontier:', list(q))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in seen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Watch the Crawl Frontier Evolve: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, seen. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if nxt not in seen: | Evidence: print('frontier:', list(q))

🛠️ Reader to Writer Bridge

1. Read: explain watch the crawl frontier evolve in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 4.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 6 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('frontier:', list(q))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of watch the crawl frontier evolve and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Printing the queue before each pop shows the frontier expanding as new links are discovered and shrinking as pages are processed, ending empty when the crawl is done.

```python
from collections import deque

links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c', 'd'],
    'c': [], 'd': [],
}
seen, q = {'home'}, deque(['home'])
while q:
    print('frontier:', list(q))
    page = q.popleft()
    for nxt in links[page]:
        if nxt not in seen:
            seen.add(nxt)
            q.append(nxt)
print('frontier:', list(q))
```

```
output
frontier: ['home']
frontier: ['a', 'b']
frontier: ['b', 'c']
frontier: ['c', 'd']
frontier: ['d']
frontier: []
```

How it works:

1. seen and the queue both begin with home only.
2. Each loop prints the current frontier as a list before popping the front page.
3. Unseen children are added to seen and the queue, so the printed frontier shifts.
4. A final print after the loop shows the empty frontier once every page is fetched.

Try it:

1. Also print the seen set at each step beside the frontier.
2. Add a wider node with three children and watch the surge.
3. Print the size of the frontier instead of its contents.
4. Add an extra page linked from `d` and watch the frontier refill late.

⚠ Common Mistakes

- Printing after the pop instead of before hides the page about to be processed.
- Mutating `q` while iterating its snapshot would corrupt the displayed frontier.
- Forgetting the final `print` after the loop omits the empty-frontier end state.

Skills gained `state logging` `frontier inspection` `BFS instrumentation`

→ **Where You'll Use This:** Logging the frontier is how engineers debug a stalled or runaway crawler in production, confirming which URLs are queued versus already processed.

⚡ Mental Model

The frontier is a to-do list of doors not yet opened: you add new doors as you find them and cross off each one you walk through.

Project 6 Separate Discovered from Indexed Pages

💡 The Idea Behind It

Discovering a URL and actually crawling it are two distinct events, and a limited budget splits them apart. This code keeps a discovered set and a visited list, halting the BFS once visited reaches the budget of two even though more URLs are queued. Subtracting visited from discovered yields the backlog: pages the crawler knows about but has not yet fetched this pass.

What You'll Build & Learn

Crawl under a budget of two fetches, then separate the indexed pages from the backlog still queued.

- Discovery and crawling are separate stages
- A budget halts the loop early
- Set difference reveals the backlog

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 5: watch the crawl frontier evolve. Project 7 changes the surface problem while preserving the underlying method.

progress check

Reading target: separate discovered from indexed pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print('still queued:', sorted(backlog))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of separate discovered from indexed pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

The `discovered` set grows whenever a link is found, but `visited` only grows when a page is actually fetched; with a budget of 2 the difference is the unfetched backlog.

```
from collections import deque

links = {
    'home': ['a', 'b', 'c'],
    'a': ['d'], 'b': ['e'], 'c': [],
    'd': [], 'e': [],
}
budget = 2
discovered, visited, q = {'home'}, [], deque(['home'])
while q and len(visited) < budget:
    page = q.popleft()
    visited.append(page)
    for nxt in links[page]:
        if nxt not in discovered:
            discovered.add(nxt)
            q.append(nxt)
backlog = discovered - set(visited)
print('indexed:', visited)
print('still queued:', sorted(backlog))
```

```
output
indexed: ['home', 'a']
still queued: ['b', 'c', 'd']
```

How it works:

1. discovered holds home, visited is empty, and the queue starts at home.
2. The loop runs while the queue has items and visited is below the budget of two.
3. Each popped page is appended to visited and its unseen children added to discovered.
4. backlog = discovered minus visited lists b, c, d as still queued.

Try it:

1. Raise the budget to four and see the backlog shrink.
2. Print the discovered set's full size next to visited.
3. Track the order in which URLs entered the discovered set.
4. Raise `budget` to 5 and confirm the backlog empties.

⚠ Common Mistakes

- Adding the seed to `visited` up front double-counts it against the budget.
- Comparing `discovered` to `visited` as lists (not sets) breaks the set subtraction.
- Stopping on `len(q)` instead of `len(visited)` miscounts the budget.

Skills gained `set difference` `budget gating` `backlog tracking`

→ **Where You'll Use This:** This mirrors the gap in Search Console between Discovered currently not indexed and actually indexed pages on a large site.

⚡ Mental Model

Discovery is adding books to a reading list; the budget is how many you actually finish before the library closes.

Project 7 Find Orphan Pages No Link Reaches

💡 The Idea Behind It

An orphan page exists on a site yet no internal link points to it, so a link-following crawler never reaches it. This code crawls breadth-first from home to build the seen set of everything reachable, then subtracts that from the full set of pages in the links dict. Whatever remains, here secret and old, is orphaned despite secret itself linking outward.

What You'll Build & Learn

Crawl from the seed, then compute which pages exist but are never reached by any link.

- Orphan pages have no inbound links
- Reachability comes from a crawl traversal
- set(links) minus seen finds orphans

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 6: separate discovered from indexed pages. Project 8 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find orphan pages no link reaches is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print('orphans:', sorted(orphans))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('orphans:', sorted(orphans))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in seen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Orphan Pages No Link Reaches: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, about. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if nxt not in seen: | Evidence: print('orphans:', sorted(orphans))

🛠️ Reader to Writer Bridge

1. Read: explain find orphan pages no link reaches in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 6.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 8 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('orphans:', sorted(orphans))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find orphan pages no link reaches and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Crawl from the seed to build the `seen` set, then subtract it from all known page keys; whatever is left was never reachable by following links.

```python
from collections import deque

links = {
    'home': ['about', 'blog'],
    'about': [], 'blog': ['post1'],
    'post1': [],
    'secret': ['home'],
    'old': [],
}
seen, q = {'home'}, deque(['home'])
while q:
    page = q.popleft()
    for nxt in links[page]:
        if nxt not in seen:
            seen.add(nxt)
            q.append(nxt)
orphans = set(links) - seen
print('orphans:', sorted(orphans))
```

```
output
orphans: ['old', 'secret']
```

How it works:

1. A standard BFS from home fills the seen set with every reachable page.
2. set(links) is the full inventory of pages declared in the graph.
3. Subtracting seen from that inventory leaves the unreached pages.
4. Sorting gives orphans as old and secret, even though secret links to home.

Try it:

1. Add an internal link to old and confirm it stops being an orphan.
2. List orphans together with any links they point out.
3. Seed the crawl from a sitemap set instead of home.
4. Add a link from `home` to `old` and watch `old` stop being an orphan.

⚠ Common Mistakes

- Listing pages with no outbound links as orphans confuses out-links with in-links.
- Forgetting that a page reachable only via an orphan is itself an orphan.
- Treating the seed as a possible orphan even though it is always reachable.

Skills gained reachability analysis set difference orphan detection

→ Where You'll Use This: Finding orphans is a staple SEO audit: pages with no internal links rarely get indexed and leak no link equity to the rest of the site.

Mental Model

An orphan page is a room in a house with no door: it is fully built but nobody can ever walk in.

Project 8 Normalize and Dedupe URLs

The Idea Behind It

One page can hide behind many URLs that differ only in case, a trailing slash, or a fragment, so a crawler folds them to a single canonical form before fetching. The normalize function splits scheme from host and path, drops anything after a hash, strips a trailing slash, and lowercases the host. Feeding the results through a set comprehension collapses the four raw URLs into two unique ones.

What You'll Build & Learn

Normalize messy URLs and deduplicate them into the canonical set a crawler would actually fetch.

- URLs vary without changing the page
- Hosts are case-insensitive, paths are not
- Fragments and trailing slashes are noise

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 7: find orphan pages no link reaches. Project 9 changes the surface problem while preserving the underlying method.

progress check

Reading target: normalize and dedupe urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `raw = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print('\n'.join(unique))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`raw = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if '/' in rest:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('\n'.join(unique))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if '/' in rest:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Normalize and Dedupe URLs: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: raw, https, Site, com, page. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: raw = [| Core: if '/' in rest: | Evidence: print('\n'.join(unique))

🛠️ Reader to Writer Bridge

1. Read: explain normalize and dedupe urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 7.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 9 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('\n'.join(unique))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `raw = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize and dedupe urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Lowercasing the host, dropping the `#fragment`, and trimming a trailing slash collapses cosmetic variants; feeding the results into a set removes the now-identical duplicates.

```
raw = [
    'https://Site.com/page/',
    'https://site.com/page',
    'https://SITE.com/page#section',
    'https://site.com/other/',
]

def normalize(u):
    scheme, rest = u.split('://', 1)
    if '/' in rest:
        host, path = rest.split('/', 1)
        path = '/' + path
    else:
        host, path = rest, ''
    path = path.split('#', 1)[0]
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]
    return scheme + '://' + host.lower() + path

unique = sorted({normalize(u) for u in raw})
print('\n'.join(unique))
```

```
output
https://site.com/other
https://site.com/page
```

How it works:

1. normalize splits off the scheme, then separates host from path.
2. It cuts everything after a hash to discard the fragment.
3. A trailing slash on a non-root path is removed and the host is lowercased.
4. A set comprehension over raw drops duplicates, leaving two sorted canonical URLs.

Try it:

1. Also strip a leading www. from the host before comparing.
2. Sort and drop tracking query parameters like utm_source.
3. Add an http versus https pair and decide how to fold them.
4. Add `'https://site.com/page?x=1'` and decide whether the query should survive.

⚠ Common Mistakes

- Lowercasing the whole URL breaks case-sensitive paths; only the host is safe to lowercase.
- Stripping a trailing slash from the root path `'/'` would wrongly empty it.
- Dropping the query string along with the fragment loses meaningful parameters.

Skills gained URL normalization string parsing set deduplication

→ Where You'll Use This: URL normalization underpins canonicalization audits and stops crawlers wasting budget indexing the same page under dozens of equivalent addresses.

Mental Model

Normalization is like recognising that Bob, bob, and Bob. all name the same person before you add them to a guest list.

Project 9 Resolve Relative Links Against a Base

The Idea Behind It

Pages link with relative paths like boots or /sale, but a crawler can only fetch absolute URLs, so resolving a relative link against the current page is a core step. The join function splits the base into scheme, host, and path, then branches: a leading slash means root-relative, otherwise the link is appended to the base's parent directory. Each relative form resolves to a full, fetchable address.

What You'll Build & Learn

Resolve a set of relative links against a base URL to produce absolute, crawlable URLs.

- Crawlers need absolute URLs to fetch
- A leading slash means root-relative
- Otherwise resolve against the parent path

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 8: normalize and dedupe urls. Project 10 changes the surface problem while preserving the underlying method.

progress check

Reading target: resolve relative links against a base is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `base = 'https://shop.example/cat/shoes'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print(join(base, r))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`base = 'https://shop.example/cat/shoes'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if rel.startswith('/'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(join(base, r))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if rel.startswith('/'):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Resolve Relative Links Against a Base: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: base, https, shop, example, cat. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: base = 'https://shop.example/cat/shoes' | Core: if rel.startswith('/'): | Evidence: print(join(base, r))

🛠️ Reader to Writer Bridge

1. Read: explain resolve relative links against a base in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 8.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 10 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(join(base, r))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `base = 'https://shop.example/cat/shoes'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of resolve relative links against a base and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

An absolute path (leading `/`) replaces the whole path, while a relative one is appended to the current path's parent directory; the scheme and host are carried over unchanged.

```
base = 'https://shop.example/cat/shoes'
rels = ['boots', '/sale', 'shoes?p=2']

def join(base, rel):
    scheme, rest = base.split('://', 1)
    host, _, path = rest.partition('/')
```

```
    path = '/' + path
    if rel.startswith('/'):
        new = rel
    else:
        parent = path.rsplit('/', 1)[0]
        new = parent + '/' + rel
    return scheme + '://' + host + new

for r in rels:
    print(join(base, r))
```

```
output
https://shop.example/cat/boots
https://shop.example/sale
https://shop.example/cat/shoes?p=2
```

How it works:

1. join splits the base into scheme, host, and the path after the host.
2. If the relative link starts with a slash it replaces the path entirely.
3. Otherwise rsplit drops the base's last segment and appends the relative link.
4. The loop prints boots, /sale, and shoes?p=2 each resolved to a full URL.

Try it:

1. Handle a ../ parent reference that climbs one directory.
2. Support a protocol-relative link beginning with double slashes.
3. Resolve a bare fragment like #top to the base page.
4. Add a `../` relative link and decide how to climb a directory.

⚠ Common Mistakes

- Joining `boots` to the full path instead of its parent yields `/cat/shoes/boots`, not `/cat/boots`.
- Treating a `/sale` absolute path like a relative one doubles up the directory.
- Splitting the host off with `split('/')` instead of `partition('/')` raises if there is no path.

Skills gained URL resolution | string partitioning | path joining

→ Where You'll Use This: Every HTML parser in a crawler must resolve relative hrefs to absolute URLs before queuing them, exactly as the browser address bar does.

Mental Model

Resolving relative links is reading directions from where you stand: turn left means something different on every street corner.

Project 10 Spend a Crawl Budget of K Fetches

The Idea Behind It

Googlebot never fetches every URL on every visit; it spends a finite crawl budget, and breadth-first order decides which pages win this pass. This code crawls with a deque but stops once the crawled list reaches the budget of four, leaving deeper pages untouched. The output reports four of seven pages fetched, showing budget directly capping coverage regardless of how many URLs exist.

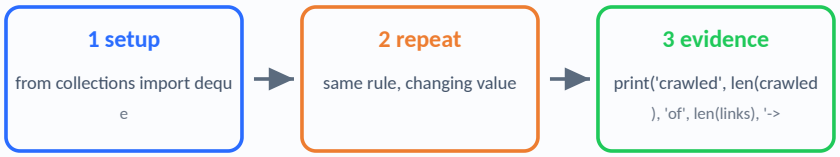
What You'll Build & Learn

Crawl breadth-first until a budget of four fetches is spent, then report coverage against the total.

- Crawl budget caps fetches per pass
- BFS order picks the lucky pages
- Coverage is crawled over total

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 9: resolve relative links against a base. Project 11 changes the surface problem while preserving the underlying method.



progress check

Reading target: spend a crawl budget of k fetches is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('crawled', len(crawled), 'of', len(links), '->', crawled)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('crawled', len(crawled), 'of', len(links), '->', crawled)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in seen:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Spend a Crawl Budget of K Fetches: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, budget. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if nxt not in seen: | Evidence: print('crawled', len(crawled), 'of', len(links), '->', crawled)

🛠️ Reader to Writer Bridge

1. Read: explain spend a crawl budget of k fetches in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 9.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 11 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('crawled', len(crawled), 'of', len(links), '->', crawled)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spend a crawl budget of k fetches and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Stopping the BFS once `len(crawled)` hits the budget means the shallowest, earliest-discovered pages win the limited fetches, which mirrors how crawl budget favours well-linked pages.

```
from collections import deque

links = {
    'home': ['a', 'b', 'c'],
    'a': ['d'], 'b': ['e'], 'c': ['f'],
    'd': [], 'e': [], 'f': [],
```

```
}
budget = 4
crawled, seen, q = [], {'home'}, deque(['home'])
while q and len(crawled) < budget:
    page = q.popleft()
    crawled.append(page)
    for nxt in links[page]:
        if nxt not in seen:
            seen.add(nxt)
            q.append(nxt)
print('crawled', len(crawled), 'of', len(links), '->', crawled)
```

```
output
crawled 4 of 7 -> ['home', 'a', 'b', 'c']
```

How it works:

1. crawled, seen, and the queue initialise with home as the seed.
2. The loop continues while the queue holds pages and crawled is below the budget.
3. Each popped page is appended and its unseen children enqueued for later.
4. The print reports crawled 4 of 7, naming home, a, b, c.

Try it:

1. Compute and print the percentage of pages crawled.
2. Raise the budget until full coverage is reached.
3. Switch to a stack and see which pages the budget catches.
4. Raise the budget to 7 and confirm the whole site is crawled.

⚠ Common Mistakes

- Checking the budget after appending lets the crawl overshoot by one.
- Counting discovered links against the budget instead of actual fetches.
- Using a stack so the budget is spent diving one branch instead of spreading wide.

Skills gained budget capping | BFS traversal | coverage reporting

→ Where You'll Use This: Crawl-budget thinking guides large-site SEO: you prioritise high-value URLs near the homepage because the engine will not reach everything each visit.

Mental Model

Crawl budget is a shopping trip with a fixed cart: you grab the nearest aisles first and leave the back of the store for next time.

Project 11 Count Inbound Links per Page

The Idea Behind It

In-degree, the count of pages linking to a given URL, is the simplest popularity signal and the seed idea behind PageRank: more inbound links usually means a more important page. This code walks every target list in the graph and increments a Counter for each link's destination. Iterating the sorted pages then prints each one's inbound tally, turning raw links into a ranking input.

What You'll Build & Learn

Count how many internal links point to each page and print the in-degree per URL.

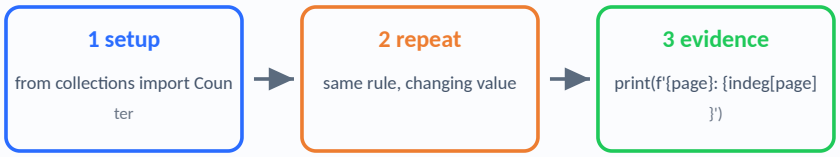
- In-degree counts inbound links
- It is a basic popularity signal
- Counter tallies destinations cleanly

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 10: spend a crawl budget of k fetches. Project 12 changes the surface problem while preserving the underlying method.

progress check

Reading target: count inbound links per page is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{page}: {indeg[page]}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`for targets in links.values():`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{page}: {indeg[page]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for targets in links.values():`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Inbound Links per Page: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, Counter, links, home, about. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: for targets in links.values(): | Evidence: print(f'{page}: {indeg[page]}')

🛠️ Reader to Writer Bridge

1. Read: explain count inbound links per page in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 10.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 12 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page}: {indeg[page]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count inbound links per page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Iterating every link target and incrementing a `Counter` tallies in-degree; sorting the page keys before printing keeps the output deterministic.

```
from collections import Counter

links = {
    'home': ['about', 'blog'],
    'about': ['home'],
    'blog': ['home', 'post1'],
    'post1': ['blog'],
```

```
}
indeg = Counter()
for targets in links.values():
    for t in targets:
        indeg[t] += 1
for page in sorted(links):
    print(f'{page}: {indeg[page]}')
```

```
output
about: 1
blog: 2
home: 2
post1: 1
```

How it works:

1. An empty Counter named indeg will accumulate inbound counts.
2. The outer loop iterates the target lists, the inner loop each linked page.
3. indeg[t] += 1 credits one inbound link to every destination t.
4. Iterating sorted pages prints each name with its inbound count.

Try it:

1. Also compute and print each page's out-degree.
2. Find pages with zero inbound links automatically.
3. Sort the output by in-degree instead of by name.
4. Print out-degree alongside in-degree for each page.

⚠ Common Mistakes

- Counting `len(links[page])` measures out-degree, not in-degree.
- Skipping pages with zero inbound links because they never appear as a target.
- Iterating `links.keys()` for targets instead of the value lists.

Skills gained in-degree counting | Counter accumulation | nested iteration

→ Where You'll Use This: Internal-link counts feed link-equity audits, helping you confirm that money pages receive more internal links than peripheral ones.

Mental Model

In-degree is counting how many friends mention your name: the more shout-outs, the more the room assumes you matter.

Project 12 Find the Most-Linked Page

The Idea Behind It

If in-degree measures popularity, the page with the highest in-degree is the site's link hub, the spot where internal authority pools. This code first tallies inbound links into a Counter, then uses max over the sorted keys with a key function reading the count, so ties break deterministically by name. The winner is surfaced as the most-linked page along with its inbound total.

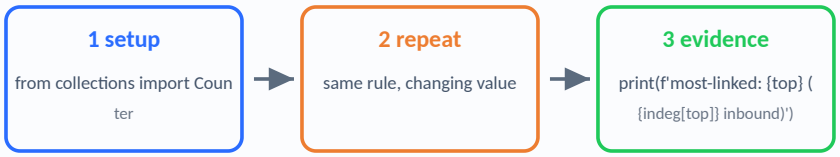
What You'll Build & Learn

Tally inbound links and surface the single most-linked page along with its in-degree.

- The link hub has the highest in-degree
- max with a key selects the winner
- Sorting first makes ties deterministic

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 11: count inbound links per page. Project 13 changes the surface problem while preserving the underlying method.



progress check

Reading target: find the most-linked page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'most-linked: {top} ({indeg[top]} inbound)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Evidence	Entry: from collections import Counter | Core: for targets in links.values(): | Evidence: print(f'most-linked: {top} ({indeg[top]} inbound)')

🛠️ Reader to Writer Bridge

1. Read: explain find the most-linked page in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 11.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 13 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'most-linked: {top} ({indeg[top]} inbound)')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find the most-linked page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

After tallying in-degree, `max` over the sorted keys with an in-degree key function returns the most-linked page, with sorting making ties break alphabetically and deterministically.

```
from collections import Counter

links = {
    'home': ['about', 'blog'],
    'about': ['home', 'blog'],
    'blog': ['home'],
```

```
    'post1': ['blog'],
}
indeg = Counter()
for targets in links.values():
    for t in targets:
        indeg[t] += 1
top = max(sorted(indeg), key=lambda p: indeg[p])
print(f'most-linked: {top} ({indeg[top]} inbound)')
```

```
output
most-linked: blog (3 inbound)
```

How it works:

1. The Counter loop credits each destination an inbound link, as before.
2. sorted(indeg) orders candidate pages so equal counts break alphabetically.
3. max with key=lambda reading indeg[p] picks the highest-scoring page.
4. The f-string reports blog with three inbound links as the hub.

Try it:

1. Print the top three most-linked pages instead of one.
2. Break ties by out-degree when in-degrees are equal.
3. Report the least-linked page as the weakest spot.
4. Print the top two pages by slicing a sorted list instead of one `max`.

⚠ Common Mistakes

- Calling `max` over the unsorted dict makes ties resolve unpredictably.
- Passing `indeg.values()` to `max` loses which page the count belongs to.
- Forgetting pages with zero in-degree are absent from the Counter entirely.

Skills gained max with key | deterministic tie-break | Counter usage

→ Where You'll Use This: Spotting the internal link hub tells you where authority concentrates and whether it lands on a page you actually want to rank.

Mental Model

The most-linked page is the town square: every street eventually points there, so it is where the crowd gathers.

Project 13 Tokenize an HTML Body into Terms

The Idea Behind It

Before an engine can index a page it must strip the HTML and reduce the visible text to lowercase word tokens, the bridge from raw markup to indexable terms. This code uses one regular expression to replace every tag with a space and another to pull out runs of lowercase letters, then a Counter tallies them. The three most common terms reveal what the page is plausibly about.

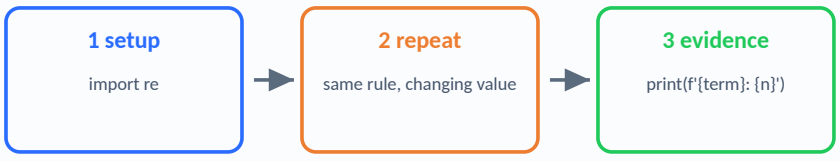
What You'll Build & Learn

Strip HTML tags, tokenize the visible text into lowercase words, and report the top terms.

- Indexing starts by stripping HTML tags
- Regex extracts lowercase word tokens
- Term counts hint at page topic

🧭 Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 12: find the most-linked page. Project 14 changes the surface problem while preserving the underlying method.



progress check

`Reading target:` tokenize an html body into terms is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- `Writing move:` this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- `Evidence:` `print(f'{term}: {n}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: `setup` creates the facts, `repeat` applies the chapter idea, and `evidence` proves your trace against the output. *visual trace*

3. Transfer: change one small part of tokenize an html body into terms and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A regex removes `<...>` tags, then `findall` over lowercased text extracts alphabetic word tokens, which a `Counter` tallies into term frequencies.

```python
import re
from collections import Counter

body = '<h1>Best Running Shoes</h1><p>Running shoes for fast runners. Shoes!
</p>'
text = re.sub(r'<[^>]+>', ' ', body)
tokens = re.findall(r'[a-z]+', text.lower())
counts = Counter(tokens)
for term, n in counts.most_common(3):
    print(f'{term}: {n}')
```

```
output
shoes: 3
running: 2
```

```
best: 1
```

How it works:

1. re.sub replaces every angle-bracket tag with a space, leaving plain text.
2. Lowercasing then re.findall pulls out runs of letters as tokens.
3. A Counter tallies how many times each token appears.
4. most_common(3) prints shoes, running, best with their counts.

Try it:

1. Remove stop words like for and the before counting.
2. Keep digits in tokens for product codes and prices.
3. Weight words inside an h1 tag more heavily.
4. Strip a stop-word list so `for` and `the` do not dominate.

⚠ Common Mistakes

- A greedy `<.*>` would swallow text between two tags; `<[^>]+>` stops at the first `>`.
- Counting before lowercasing makes `Shoes` and `shoes` distinct terms.
- Splitting on whitespace instead of a regex keeps trailing punctuation glued to words.

Skills gained regex tokenizing | HTML stripping | Counter most_common

→ Where You'll Use This: This is the front end of any indexer or on-page SEO tool that needs to know which terms a page actually emphasises.

Mental Model

Tokenizing is shredding a magazine into individual word cards so you can count which topics fill the page.

Project 14 Build an Inverted Index and Query It

The Idea Behind It

An inverted index flips documents inside out, mapping each term to the set of pages containing it, which is what makes search feel instant. This code iterates the document bodies, splits each into words, and adds the page id to that term's set in a defaultdict. A query then becomes a single dictionary lookup returning the matching page ids rather than a scan of every document.

What You'll Build & Learn

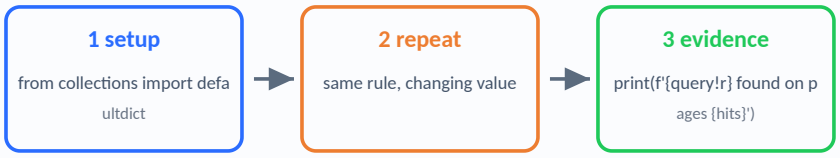
Build an inverted index from a few documents and answer a one-word query with a single lookup.

- An inverted index maps terms to pages

- It makes lookups instant
- defaultdict(set) avoids missing-key checks

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 13: tokenize an html body into terms. Project 15 changes the surface problem while preserving the underlying method.



progress check

Reading target: build an inverted index and query it is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{query!r} found on pages {hits}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build an Inverted Index and Query It: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, defaultdict, docs, cheap, red. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: for pid, body in docs.items(): | Evidence: print(f'{query!r} found on pages {hits}')

Reader to Writer Bridge

1. Read: explain build an inverted index and query it in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 13.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 15 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{query!r} found on pages {hits}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build an inverted index and query it and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For each document, every term gains the page id in a `defaultdict(set)`; answering a query is then just reading that term's posting set, sorted for stable output.

```
from collections import defaultdict

docs = {
    1: 'cheap red shoes',
    2: 'red running shoes',
    3: 'blue running socks',
}
index = defaultdict(set)
for pid, body in docs.items():
    for term in body.split():
        index[term].add(pid)
query = 'running'
hits = sorted(index.get(query, set()))
print(f'{query!r} found on pages {hits}')
```

```
output
'running' found on pages [2, 3]
```

How it works:

1. index is a defaultdict of sets, one entry per term.
2. For each document, splitting the body yields its terms.
3. index[term].add(pid) records that this page contains the term.
4. Querying running returns pages 2 and 3 from one lookup.

Try it:

1. Support a two-word AND query by intersecting term sets.
2. Store term positions so you can match exact phrases.
3. Lowercase and de-punctuate tokens before indexing them.
4. Query a term in only one document and confirm a single-page result.

⚠ Common Mistakes

- Using a list instead of a set lets a repeated term add the same page id twice.
- Looking up a missing term with `index[query]` mutates the defaultdict; `.get` avoids that.
- Indexing on raw case so `Shoes` and `shoes` land in different postings.

Skills gained inverted index | defaultdict(set) | query lookup

→ Where You'll Use This: The inverted index is the core data structure of every search engine and site-search feature, turning queries into fast set lookups.

⚡ Mental Model

An inverted index is a book's back-of-book index: instead of reading every page, you jump straight to the pages a word appears on.

Project 15 Rank Pages by Term Frequency

💡 The Idea Behind It

Once you know which pages match a query you must order them, and the crudest ranking simply counts how often the query term appears, rewarding more mentions with a higher position. This code builds a scores dict via str.count for each body, then sorts by negative score with the page id as a tiebreaker so output is stable. The most repetitive page lands on top.

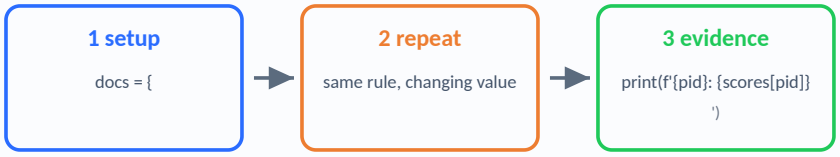
What You'll Build & Learn

Score each page by how many times the query term appears and rank them from most to least.

- Term frequency is a naive ranking
- More mentions means higher rank
- Negative-score sort orders descending

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 14: build an inverted index and query it. Project 16 changes the surface problem while preserving the underlying method.



progress check

Reading target: rank pages by term frequency is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `docs = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{pid}: {scores[pid]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`docs = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`'p2': 'running shoes for runners',`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{pid}: {scores[pid]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Rank Pages by Term Frequency: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: docs, p1, shoes, running, p2. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: docs = { | Core: 'p2': 'running shoes for runners', | Evidence: print(f'{pid}: {scores[pid]}')

🛠️ Reader to Writer Bridge

1. Read: explain rank pages by term frequency in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 14.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 16 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{pid}: {scores[pid]}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `docs = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank pages by term frequency and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting the query term per document gives a score, and sorting by negative score with the page id as a tiebreaker yields a deterministic ranked list.

```
docs = {
    'p1': 'shoes shoes running shoes',
    'p2': 'running shoes for runners',
    'p3': 'running running running gear',
}
query = 'running'
scores = {pid: body.split().count(query) for pid, body in docs.items()}
ranked = sorted(scores, key=lambda p: (-scores[p], p))
for pid in ranked:
    print(f'{pid}: {scores[pid]}')
```

```
output
p3: 3
p1: 1
p2: 1
```

How it works:

1. A dict comprehension counts the query word in each document body.
2. sorted ranks pages by negative score, then page id to break ties.
3. p3 with three mentions of running ranks first.
4. p1 and p2 tie at one and order alphabetically.

Try it:

1. Normalise frequency by document length to be fairer.
2. Rank by total occurrences of two query words combined.
3. Print the matching pages with zero hits excluded.
4. Normalize by document length to favour focused pages over long ones.

⚠ Common Mistakes

- Sorting by `scores[p]` ascending puts the worst match first.
- Omitting the page-id tiebreaker makes equal-score ties order unpredictably.

- Using `in` instead of `.count` treats one mention the same as ten.

Skills gained term frequency | sort by key | tie-break ordering

→ Where You'll Use This: Raw term frequency is the baseline ranking that later signals like TF-IDF and BM25 improve upon, and it explains why keyword stuffing once worked.

⚡ Mental Model

Term-frequency ranking is judging relevance by how loudly each page shouts the keyword, with no regard for substance.

Project 16 Classify a User-Agent as Bot or Human

💡 The Idea Behind It

Servers distinguish crawlers from browsers by inspecting the User-Agent header, and spotting marker substrings is the practical test. This code lowercases each agent string and checks whether any of the markers bot, spider, or crawl appears using any() over a tuple. Googlebot and bingbot are flagged as bots while the Firefox and Safari strings pass as human, exactly how a site profiles incoming traffic.

What You'll Build & Learn

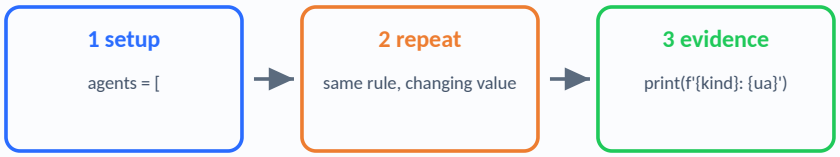
Classify each User-Agent string as a bot or a human by scanning for crawler marker substrings.

- User-Agent strings reveal the client
- Marker substrings flag crawlers
- any() tests several markers at once

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 15: rank pages by term frequency. Project 17 changes the surface problem while preserving the underlying method. *progress check*

Reading target: classify a user-agent as bot or human is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `agents = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are

discovered.

- Evidence: `print(f'{kind}: {ua}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`agents = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`kind = 'BOT' if any(m in low for m in markers) else 'human'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{kind}: {ua}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `kind = 'BOT' if any(m in low for m in markers) else 'human'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Classify a User-Agent as Bot or Human: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: agents, Mozilla, compatible, Googlebot, Windows. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: agents = [| Core: kind = 'BOT' if any(m in low for m in markers) else 'human' | Evidence: print(f'{kind}: {ua}')

🛠️ Reader to Writer Bridge

1. Read: explain classify a user-agent as bot or human in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 15.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 17 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{kind}: {ua}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `agents = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify a user-agent as bot or human and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Lowercasing the User-Agent and testing for any crawler marker substring (`bot`, `spider`, `crawl`) classifies each visitor with a simple membership check.

```
agents = [
    'Mozilla/5.0 (compatible; Googlebot/2.1)',
    'Mozilla/5.0 (Windows NT 10.0) Gecko Firefox/120',
    'Mozilla/5.0 (compatible; bingbot/2.0)',
    'Mozilla/5.0 (Macintosh) Safari/605',
]
markers = ('bot', 'spider', 'crawl')
for ua in agents:
    low = ua.lower()
    kind = 'BOT' if any(m in low for m in markers) else 'human'
    print(f'{kind}: {ua}')
```

```
output
BOT: Mozilla/5.0 (compatible; Googlebot/2.1)
human: Mozilla/5.0 (Windows NT 10.0) Gecko Firefox/120
BOT: Mozilla/5.0 (compatible; bingbot/2.0)
human: Mozilla/5.0 (Macintosh) Safari/605
```

How it works:

1. markers is a tuple of crawler giveaway substrings.
2. Each agent string is lowercased for case-insensitive matching.
3. any(m in low for m in markers) returns true if any marker appears.
4. Googlebot and bingbot print as BOT, the browser strings as human.

Try it:

1. Identify which specific bot matched, not just BOT.
2. Add fake-bot detection by checking the source IP.
3. Count how many requests came from bots versus humans.
4. Add `'AhrefsBot'` and confirm it is flagged.

⚠ Common Mistakes

- Matching case-sensitively misses `Googlebot` if you only check `googlebot`.
- Checking `== 'bot'` instead of substring membership never matches a real User-Agent.
- A browser string containing 'bot' in a product token would be a false positive to watch for.

Skills gained substring matching | any() predicate | user-agent parsing

→ Where You'll Use This: User-Agent sniffing drives log-file analysis, bot management, and serving crawlers the same content as users to avoid cloaking penalties.

Mental Model

Reading a User-Agent is checking a visitor's badge at the door: the lanyard says whether a robot or a person walked in.

Project 17 Enforce a Per-Minute Crawl Rate Cap

The Idea Behind It

Polite crawlers throttle themselves so they never hammer a server, and you can verify politeness by checking whether any rolling 60-second window breaks a request cap. This code, for each fetch timestamp, counts how many other timestamps fall inside the trailing window, tracking the worst such count. Comparing that peak against the cap of five yields a verdict, and here six fetches in one window flag the crawler as too fast.

What You'll Build & Learn

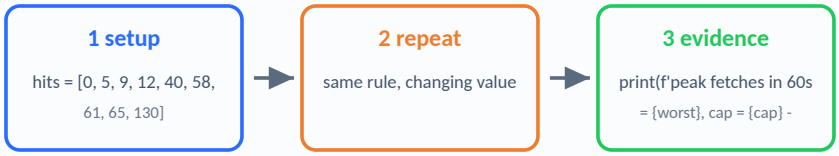
Scan fetch timestamps for the busiest 60-second window and judge it against a per-minute cap.

- Crawlers throttle to stay polite
- Rolling windows measure request rate
- Peak count tested against the cap

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 16: classify a user-agent as bot or human. Project 18 changes the surface problem while preserving the underlying method.

progress check



Reading target: enforce a per-minute crawl rate cap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `hits = [0, 5, 9, 12, 40, 58, 61, 65, 130]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'peak fetches in 60s = {worst}, cap = {cap} -> {verdict}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`hits = [0, 5, 9, 12, 40, 58, 61, 65, 130]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`count = sum(1 for u in hits if t - window < u <= t)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'peak fetches in 60s = {worst}, cap = {cap} -> {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `count = sum(1 for u in hits if t - window < u <= t)`

Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Enforce a Per-Minute Crawl Rate Cap: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: hits, cap, window, worst, enumerate. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: hits = [0, 5, 9, 12, 40, 58, 61, 65, 130] | Core: count = sum(1 for u in hits if t - window < u <= t) | Evidence: print(f'peak fetches in 60s = {worst}, cap = {cap} -> {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain enforce a per-minute crawl rate cap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 16.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 18 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'peak fetches in 60s = {worst}, cap = {cap} -> {verdict}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `hits = [0, 5, 9, 12, 40, 58, 61, 65, 130]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of enforce a per-minute crawl rate cap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

For every timestamp, counting how many fetches fall in the trailing 60-second window finds the busiest moment; if that peak exceeds the cap the crawl was impolite.

```
hits = [0, 5, 9, 12, 40, 58, 61, 65, 130]
cap = 5
window = 60
worst = 0
for i, t in enumerate(hits):
```

```
    count = sum(1 for u in hits if t - window < u <= t)
    worst = max(worst, count)
verdict = 'OK' if worst <= cap else 'TOO FAST'
print(f'peak fetches in 60s = {worst}, cap = {cap} -> {verdict}')
```

```
output
peak fetches in 60s = 6, cap = 5 -> TOO FAST
```

How it works:

1. For each timestamp t, count fetches within the trailing 60-second window.
2. The condition t - window < u <= t selects hits ending at t.
3. worst keeps the maximum window count seen across all timestamps.
4. Six exceeds the cap of five, so the verdict prints TOO FAST.

Try it:

1. Change the window to 30 seconds and recheck the peak.
2. Report the timestamp where the busiest window occurs.
3. Slow the schedule until every window obeys the cap.
4. Lower `cap` to 6 and watch the verdict flip to OK.

⚠ Common Mistakes

- Counting fetches per fixed calendar minute misses bursts that straddle a boundary.
- Using `<=` on both window ends double-counts the edge timestamp.
- Comparing the total fetch count to the cap instead of the per-window peak.

Skills gained sliding window | rate limiting | peak tracking

→ Where You'll Use This: Crawl-rate analysis underlies both crawl-delay settings you configure and the server logs you inspect when a bot overloads a site.

Mental Model

It is a bouncer counting how many people entered in the last minute and shouting stop when the door gets too busy.

Project 18 Merge Sitemap and Link Discovery

The Idea Behind It

Crawlers discover URLs two ways, by following links and by reading the sitemap, and the full discovery set is the union of both sources. This code unions a set of link-found URLs with a set of sitemap URLs, then subtracts

links from sitemap to expose URLs the sitemap alone surfaced. Those sitemap-only pages, contact and pricing, would be invisible to a pure link crawl.

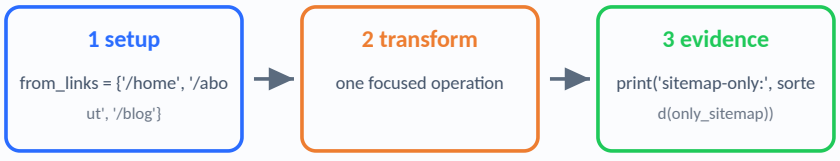
What You'll Build & Learn

Combine link-discovered and sitemap URLs, then identify which pages only the sitemap revealed.

- URLs come from links and sitemaps
- Union gives the full discovery set
- Difference finds sitemap-only pages

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 17: enforce a per-minute crawl rate cap. Project 19 changes the surface problem while preserving the underlying method.



progress check

Reading target: merge sitemap and link discovery is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from_links = {'/home', '/about', '/blog'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('sitemap-only:', sorted(only_sitemap))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from_links = {'/home', '/about', '/blog'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`from_sitemap = {'/home', '/blog', '/pricing', '/contact'}`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print('sitemap-only:', sorted(only_sitemap))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `from_sitemap = {'/home', '/blog', '/pricing', '/contact'}`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Merge Sitemap and Link Discovery: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: from_links, home, about, blog, from_sitemap. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from_links = {'/home', '/about', '/blog'} | Core: from_sitemap = {'/home', '/blog', '/pricing', '/contact'} | Evidence: print('sitemap-only:', sorted(only_sitemap))

Reader to Writer Bridge

1. Read: explain merge sitemap and link discovery in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 17.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 19 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('sitemap-only:', sorted(only_sitemap))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `from_links = {'/home', '/about', '/blog'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of merge sitemap and link discovery and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Set union combines both discovery channels, while subtracting the link set from the sitemap set reveals the pages only the sitemap could have surfaced.

```
from_links = {'/home', '/about', '/blog'}
from_sitemap = {'/home', '/blog', '/pricing', '/contact'}
discovered = from_links | from_sitemap
only_sitemap = from_sitemap - from_links
print('total URLs:', len(discovered))
print('sitemap-only:', sorted(only_sitemap))
```

```
output
total URLs: 5
sitemap-only: ['/contact', '/pricing']
```

How it works:

1. from_links and from_sitemap are two sets of discovered paths.
2. The union operator merges them into the complete discovered set.
3. from_sitemap minus from_links isolates sitemap-only URLs.
4. Output reports five total URLs and names contact and pricing as sitemap-only.

Try it:

1. Find URLs in links but absent from the sitemap.
2. Add a third source such as a referral log set.

3. Report the percentage of URLs unique to each source.
4. Add a URL found only by links and confirm it is not sitemap-only.

⚠ Common Mistakes

- Using list concatenation instead of set union leaves duplicate URLs.
- Subtracting in the wrong order (`from_links - from_sitemap`) answers a different question.
- Forgetting to sort the difference makes the printed order nondeterministic.

Skills gained set union | set difference | discovery merging

→ Where You'll Use This: A well-built sitemap surfaces pages that internal links miss, which is exactly how you rescue orphan pages from never being crawled.

Mental Model

Links are word-of-mouth, the sitemap is the official directory: combining both gives you every address in town.

Project 19 Detect a Crawl Trap Cycle

The Idea Behind It

A crawl trap is a loop of links that sends a crawler round forever, and detecting a cycle in the link graph lets you spot the trap before it burns budget. This recursive function carries the path taken so far and returns the looping slice the moment it revisits a node already on that path. Following home through a, b, c uncovers the a, b, c, a cycle.

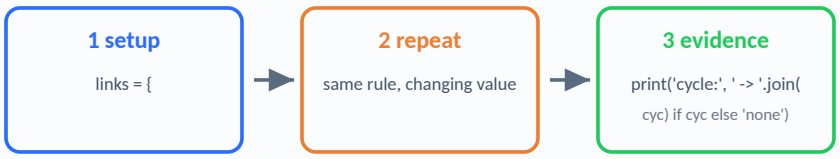
What You'll Build & Learn

Recursively search the link graph for a cycle and print the looping sequence of pages.

- Crawl traps are link cycles
- Cycles waste crawl budget
- Path tracking detects revisits

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 18: merge sitemap and link discovery. Project 20 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a crawl trap cycle is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('cycle:', ' -> '.join(cyc) if cyc else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if node in path:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('cycle:', ' -> '.join(cyc) if cyc else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if node in path:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Detect a Crawl Trap Cycle: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: links, home, find_cycle, node, path. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: links = { | Core: if node in path: | Evidence: print('cycle:', ' -> '.join(cyc) if cyc else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain detect a crawl trap cycle in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 18.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 20 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('cycle:', ' -> '.join(cyc) if cyc else 'none')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect a crawl trap cycle and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A depth-first walk that carries its current path detects a cycle the moment it revisits a node already on that path, returning the looping segment.

```
links = {
    'home': ['a'],
    'a': ['b'],
    'b': ['c'],
    'c': ['a'],
}

def find_cycle(node, path):
    if node in path:
        return path[path.index(node):] + [node]
    for nxt in links[node]:
        res = find_cycle(nxt, path + [node])
        if res:
            return res
    return None

cyc = find_cycle('home', [])
print('cycle:', ' -> '.join(cyc) if cyc else 'none')
```

```
output
cycle: a -> b -> c -> a
```

How it works:

1. find_cycle takes the current node and the path of ancestors.
2. If the node is already in path, it returns the loop slice from that point.
3. Otherwise it recurses into each child with the node appended to path.
4. Starting at home, it surfaces the cycle a -> b -> c -> a.

Try it:

1. Make the function find all cycles, not the first.
2. Convert it to an iterative search using an explicit stack.
3. Add a branch with no cycle and confirm none is reported.
4. Break the loop by pointing `c` to a dead-end and confirm 'none'.

⚠ Common Mistakes

- Checking a global `visited` set instead of the current path reports a diamond as a false cycle.
- Building `path + [node]` is essential; mutating one shared list corrupts the recursion.
- Deep or wide graphs can hit Python's recursion limit with this naive approach.

Skills gained cycle detection | recursion | path tracking

→ Where You'll Use This: Cycle detection flags infinite loops from calendar widgets, faceted filters, or redirect chains that quietly drain a site's crawl budget.

Mental Model

A crawl trap is a hall of revolving doors: keep pushing forward and you end up exactly where you started, forever.

Project 20 Compute Each Page's Crawl Depth

The Idea Behind It

Crawl depth is the shortest number of clicks from the seed to a page, and BFS computes it naturally because it reaches each page by the fewest hops first. This code seeds a depth dict at zero for home and, during the breadth-first sweep, records each newly discovered child as one deeper than its parent. The result assigns every reachable page a shortest-path distance from the homepage.

What You'll Build & Learn

Compute and print the shortest click-depth from the seed to every reachable page.

- Crawl depth is shortest clicks from seed
- BFS yields shortest-path distances
- Deep pages are crawled less often

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 19: detect a crawl trap cycle. Project 21 changes the surface problem while preserving the underlying method. *progress check*

Reading target: compute each page's crawl depth is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{page}: depth {depth[page]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in depth:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{page}: depth {depth[page]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in depth:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute Each Page's Crawl Depth: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: collections, deque, links, home, depth. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import deque | Core: if nxt not in depth: | Evidence: print(f'{page}: depth {depth[page]}')

🛠️ Reader to Writer Bridge

1. Read: explain compute each page's crawl depth in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 19.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 21 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page}: depth {depth[page]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of compute each page's crawl depth and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

BFS naturally discovers each node by its shortest path, so recording `depth[neighbour] = depth[current] + 1` on first sight gives every page its true crawl depth.

```
from collections import deque

links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c', 'd'],
    'c': ['e'],
    'd': [], 'e': [],
}
depth = {'home': 0}
q = deque(['home'])
while q:
    page = q.popleft()
    for nxt in links[page]:
        if nxt not in depth:
            depth[nxt] = depth[page] + 1
            q.append(nxt)
for page in sorted(depth):
    print(f'{page}: depth {depth[page]}')
```

```
output
a: depth 1
b: depth 1
c: depth 2
d: depth 2
e: depth 3
home: depth 0
```

How it works:

1. depth starts with home at zero and the queue holds home.
2. Each child not yet in depth gets its parent's depth plus one.
3. Because BFS reaches pages by fewest hops, the first depth recorded is shortest.
4. Sorted output shows home at zero rising to e at depth three.

Try it:

1. Flag every page deeper than two clicks.
2. Report the average depth across all pages.
3. Add a shortcut link and watch a page's depth drop.

4. Add a shortcut link from `home` to `e` and watch its depth drop.

⚠ Common Mistakes

- Using DFS instead of BFS records a path length, not the shortest one.
- Overwriting a depth when a page is reached again by a longer route inflates it.
- Seeding the queue without putting the seed in `depth` at depth 0 desynchronises the two.

Skills gained BFS shortest path | depth labelling | graph distance

→ Where You'll Use This: Click depth is a practical SEO health metric: keeping important pages within three clicks of the homepage helps them get crawled and indexed.

Mental Model

Crawl depth is how many doors you open from the lobby to reach a room: the deeper it is, the less often anyone visits.

Project 21 Apply Robots Allow and Disallow Rules

The Idea Behind It

A robots file tells crawlers which paths they may fetch, and when rules overlap the longest-matching prefix wins, letting a specific Disallow carve a hole out of a broad Allow. This code scans every rule, keeping the one whose prefix both matches the path and is at least as long as the current best. The final rule's action decides whether each URL is crawlable.

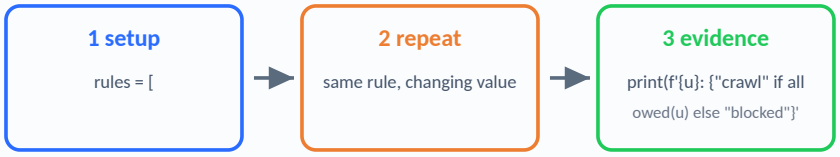
What You'll Build & Learn

Apply robots Allow and Disallow rules by longest-prefix match to decide if each URL is crawlable.

- Robots rules gate crawlable paths
- The longest matching prefix wins
- Specific Disallow beats broad Allow

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 20: compute each page's crawl depth. Project 22 changes the surface problem while preserving the underlying method.



progress check

Reading target: apply robots allow and disallow rules is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `rules = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{u}: {"crawl" if allowed(u) else "blocked"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`rules = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if path.startswith(prefix) and len(prefix) >= len(best[1]):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{u}: {"crawl" if allowed(u) else "blocked"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if path.startswith(prefix) and len(prefix) >= len(best[1]):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Apply Robots Allow and Disallow Rules: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: rules, Disallow, admin, cart, Allow. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: rules = [| Core: if path.startswith(prefix) and len(prefix) >= len(best[1]): | Evidence: print(f'{u}: {"crawl" if allowed(u) else "blocked"}')

🛠️ Reader to Writer Bridge

1. Read: explain apply robots allow and disallow rules in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 20.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 22 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{u}: {"crawl" if allowed(u) else "blocked"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `rules = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of apply robots allow and disallow rules and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

For each URL the rule with the longest matching prefix decides access, mirroring the real longest-match precedence of robots directives.

```
rules = [
    ('Disallow', '/admin'),
    ('Disallow', '/cart'),
    ('Allow', '/'),
]
urls = ['/', '/blog', '/admin/login', '/cart', '/products']

def allowed(path):
    best = ('Allow', '')
    for action, prefix in rules:
        if path.startswith(prefix) and len(prefix) >= len(best[1]):
            best = (action, prefix)
    return best[0] == 'Allow'

for u in urls:
    print(f'{u}: {"crawl" if allowed(u) else "blocked"}')
```

```
output
/: crawl
/blog: crawl
/admin/login: blocked
/cart: blocked
/products: crawl
```

How it works:

1. allowed starts with a default Allow on an empty prefix.
2. It scans rules, keeping any whose prefix matches and is at least as long.
3. The longest-matching rule's action becomes the verdict for the path.
4. /admin/login and /cart hit Disallow rules and print as blocked.

Try it:

1. Add wildcard pattern support like /private/*.
2. Handle a path matched by no rule at all.
3. Report which rule won for each tested URL.

4. Add `('Allow', '/cart/gift')` and confirm that sub-path becomes crawlable.

⚠ Common Mistakes

- First-match-wins instead of longest-match gives wrong verdicts when rules overlap.
- Comparing prefix length without `startswith` matches unrelated paths.
- Treating an empty default as Disallow blocks everything not explicitly allowed.

Skills gained longest-prefix match | robots rules | access control

→ Where You'll Use This: This is the exact precedence logic behind robots.txt parsing, which determines whether Googlebot is even permitted to request a given URL.

Mental Model

Robots rules are zoning laws: a broad allow covers the whole city, but a precise no-entry sign overrides it on one street.

Project 22 Fold Duplicates with Canonical Tags

The Idea Behind It

Tracking parameters and trailing slashes spawn many URLs for one page, and a canonical tag tells the engine the single address to index while folding the rest away. This code reads each page's declared canonical, builds a set of those canonicals to find the truly unique pages, and subtracts that from the total to count how many duplicates were absorbed. Five URLs collapse to three indexable pages.

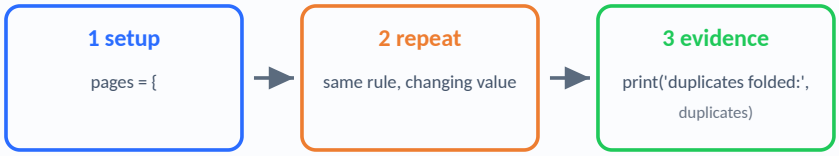
What You'll Build & Learn

Use declared canonical tags to find the unique indexable pages and count the duplicates folded away.

- Many URLs can map to one page
- Canonical tags pick the index URL
- Set of canonicals counts unique pages

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 21: apply robots allow and disallow rules. Project 23 changes the surface problem while preserving the underlying method.



progress check

Reading target: fold duplicates with canonical tags is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('duplicates folded:', duplicates)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`indexable = sorted({p['canonical'] for p in pages.values()})`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('duplicates folded:', duplicates)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `indexable = sorted({p['canonical'] for p in pages.values()})`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Fold Duplicates with Canonical Tags: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: pages, home, canonical, ref, ad. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: indexable = sorted({p['canonical'] for p in pages.values()}) | Evidence: print('duplicates folded:', duplicates)

🛠️ Reader to Writer Bridge

1. Read: explain fold duplicates with canonical tags in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 21.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 23 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('duplicates folded:', duplicates)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of fold duplicates with canonical tags and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Collecting the distinct canonical values gives the set of pages actually indexed; the gap between total URLs and canonicals is the count of duplicates folded.

```
pages = {
    '/home': {'canonical': '/home'},
    '/home?ref=ad': {'canonical': '/home'},
    '/blog': {'canonical': '/blog'},
    '/blog/': {'canonical': '/blog'},
    '/about': {'canonical': '/about'},
}
indexable = sorted({p['canonical'] for p in pages.values()})
duplicates = len(pages) - len(indexable)
print('unique pages indexed:', indexable)
print('duplicates folded:', duplicates)
```

```
output
unique pages indexed: ['/about', '/blog', '/home']
duplicates folded: 2
```

How it works:

1. Each page in the dict declares a canonical URL.
2. A set comprehension collects the distinct canonical values.
3. len(pages) minus that set's length counts folded duplicates.
4. Three unique pages are indexed and two duplicates are folded.

Try it:

1. Group every source URL under its canonical target.
2. Flag a page whose canonical points elsewhere unexpectedly.
3. Detect a canonical that points to a noindexed page.
4. Point `/blog/`'s canonical at `/home` and watch `/blog` vanish.

⚠ Common Mistakes

- Counting raw URLs as indexed pages over-reports the index size.
- Forgetting to dedupe canonicals double-counts a page reachable by two URLs.
- A page pointing its canonical at a different page would silently disappear from the index.

Skills gained canonicalization | set comprehension | duplicate folding

→ Where You'll Use This: Canonical handling decides which of many parameterised or paginated URLs Google indexes, a constant concern on e-commerce and faceted sites.

Mental Model

Canonical tags are mail forwarding: many addresses can reach one person, but the engine only ever delivers to the home address.

Project 23 Route Pages by HTTP Status Code

The Idea Behind It

A crawler's next move hinges on the HTTP status a URL returns: 200 means index, a 3xx means follow the redirect, and 4xx or 5xx means drop. This code iterates page-and-code pairs and uses an if/elif chain to assign each a verdict, with the 300-to-399 range explicitly tested for redirects. The status code, not the content, drives the entire indexing decision here.

What You'll Build & Learn

Route each page to index, follow-redirect, or drop based purely on its HTTP status code.

- Status code drives indexing decisions
- 200 indexes, 3xx redirects, 4xx and 5xx drop
- A range test classifies redirects

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 22: fold duplicates with canonical tags. Project 24 changes the surface problem while preserving the underlying method.

progress check

Reading target: route pages by http status code is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print(f'{code} {path}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if code == 200:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{code} {path}: {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Route Pages by HTTP Status Code: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: pages, home, old, missing, blog. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: pages = [| Core: if code == 200: | Evidence: print(f'{code} {path}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain route pages by http status code in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 22.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 24 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code} {path}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of route pages by http status code and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Bucketing each status into 200, the 300 range, or everything else maps the numeric code to the crawler's action, exactly as a real fetch pipeline branches.

```
pages = [
    ('/home', 200),
    ('/old', 301),
    ('/missing', 404),
    ('/blog', 200),
    ('/down', 503),
]
for path, code in pages:
    if code == 200:
        verdict = 'index'
    elif 300 <= code < 400:
        verdict = 'follow redirect'
    else:
        verdict = 'drop'
    print(f'{code} {path}: {verdict}')
```

```
output
200 /home: index
301 /old: follow redirect
404 /missing: drop
200 /blog: index
503 /down: drop
```

How it works:

1. The loop unpacks each path and its HTTP status code.
2. A code of 200 sets the verdict to index.
3. A code in the 300-399 range sets follow redirect.
4. Everything else, including 404 and 503, sets drop.

Try it:

1. Split 4xx from 5xx with distinct verdicts.
2. Treat 503 as retry-later instead of drop.
3. Count how many pages fall into each bucket.
4. Add a `410` (gone) and decide whether to drop it permanently.

⚠ Common Mistakes

- Testing `code == 300` instead of the `300 <= code < 400` range misses 301 and 302.
- Treating a 5xx server error like a 4xx not-found ignores that it may recover later.
- Indexing a 204 (no content) as if it were a 200 with a body.

Skills gained status routing | if/elif chain | range testing

→ Where You'll Use This: Status-code triage is the heart of crawl-error reporting: it explains why pages get indexed, redirected, or dropped from search results.

Mental Model

The status code is a traffic light at each URL: green go, amber detour, red stop and turn back.

Project 24 Honour the Noindex Directive

The Idea Behind It

A page can be crawled yet explicitly asked not to be indexed through a noindex meta directive, so search-result and print pages typically carry it to stay out of the index. This code reads each page's noindex flag and partitions the URLs with two list comprehensions: one keeps pages where the flag is false, the other collects the blocked ones. Crawlability and indexability are clearly separated.

What You'll Build & Learn

Split pages into indexable and noindexed sets based on each page's noindex meta directive.

- Noindex blocks indexing, not crawling
- Crawlable is not the same as indexable
- List comprehensions partition the pages

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 23: route pages by http status code. Project 25 changes the surface problem while preserving the underlying method.

progress check

Reading target: honour the noindex directive is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('noindex:', sorted(blocked))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`indexable = [p for p, m in pages.items() if not m['noindex']]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('noindex:', sorted(blocked))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `indexable = [p for p, m in pages.items() if not m['noindex']]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Honour the Noindex Directive: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: pages, home, noindex, search, results. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: indexable = [p for p, m in pages.items() if not m['noindex']] | Evidence: print('noindex:', sorted(blocked))

🛠️ Reader to Writer Bridge

1. Read: explain honour the noindex directive in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 23.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 25 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('noindex:', sorted(blocked))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of honour the noindex directive and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Partitioning pages on their `noindex` flag separates the indexable set from the deliberately excluded one, with sorting keeping both lists deterministic.

```
pages = {
    '/home': {'noindex': False},
    '/search-results': {'noindex': True},
    '/blog': {'noindex': False},
    '/print-view': {'noindex': True},
}
indexable = [p for p, m in pages.items() if not m['noindex']]
blocked = [p for p, m in pages.items() if m['noindex']]
print('indexable:', sorted(indexable))
print('noindex:', sorted(blocked))
```

```
output
indexable: ['/blog', '/home']
noindex: ['/print-view', '/search-results']
```

How it works:

1. Each page maps to a metadata dict carrying a noindex boolean.
2. One comprehension keeps pages where noindex is false.
3. Another collects the pages where noindex is true.
4. Sorted output lists blog and home as indexable, the rest as noindex.

Try it:

1. Add a nofollow flag and handle it separately.
2. Warn when a noindexed page still receives internal links.
3. Count what share of pages carry the noindex directive.
4. Flip `/blog` to noindex and watch it move lists.

⚠ Common Mistakes

- Confusing noindex (keep crawling, do not index) with a robots Disallow (do not crawl).
- Treating a missing `noindex` key as truthy and dropping good pages.
- Printing unsorted sets so the two lists vary run to run.

Skills gained list comprehension directive handling set partitioning

→ Where You'll Use This: Honouring noindex keeps thin or duplicate pages like search results and filters out of the index without blocking crawlers from reaching them.

Mental Model

Noindex is a guest who attends the party but asks not to appear in any photos: present, yet absent from the album.

Project 25 Follow a Redirect Chain to the Target

The Idea Behind It

URLs often redirect through several hops before landing on the real page, so a crawler walks the chain to find the final destination and counts the steps. This code follows a redirect dict from a start URL, appending each new target to a chain list and incrementing a hop counter, with a guard of ten to prevent runaway loops. The chain resolves cleanly to /final after three hops.

What You'll Build & Learn

Follow a redirect chain from a start URL to its final target and count the number of hops.

- Redirects can chain several hops
- Crawlers follow to the final URL
- A hop cap guards against loops

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 24: honour the noindex directive. Project 26 changes the surface problem while preserving the underlying method. *progress check*

Reading target: follow a redirect chain to the target is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `redirects = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

- Evidence: `print('hops:', hops)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirects = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`while cur in redirects and hops < 10:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('hops:', hops)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `while cur in redirects and hops < 10:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Follow a Redirect Chain to the Target: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: redirects, start, chain, cur, hops. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: redirects = { | Core: while cur in redirects and hops < 10: | Evidence: print('hops:', hops)

🛠️ Reader to Writer Bridge

1. Read: explain follow a redirect chain to the target in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 24.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 26 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('hops:', hops)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `redirects = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of follow a redirect chain to the target and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Walking the redirect map until a URL has no further target, with a hop guard, resolves the chain and counts how many redirects were traversed.

```
redirects = {
    '/a': '/b',
    '/b': '/c',
    '/c': '/final',
}
start = '/a'
chain, cur, hops = [start], start, 0
while cur in redirects and hops < 10:
    cur = redirects[cur]
    chain.append(cur)
    hops += 1
print(' -> '.join(chain))
print('hops:', hops)
```

```
output
/a -> /b -> /c -> /final
hops: 3
```

How it works:

1. chain begins with the start URL and hops starts at zero.
2. While the current URL has a redirect and hops is under ten, follow it.
3. Each new target is appended to chain and hops increments.
4. The loop ends at /final after three hops, both printed.

Try it:

1. Flag chains longer than two hops as inefficient.
2. Print the destination only, hiding the intermediate URLs.
3. Distinguish 301 permanent from 302 temporary redirects.
4. Add another hop `/final -> /home` and watch the chain lengthen.

⚠ Common Mistakes

- No hop limit means a looping chain spins forever.
- Recording the chain before appending the next hop drops the final URL.
- Counting visited URLs instead of redirects overstates the hop count by one.

Skills gained chain following | loop guard | hop counting

→ Where You'll Use This: Tracing redirect chains diagnoses crawl waste and lost link equity, since long chains slow crawlers and dilute the signal that reaches the target.

Mental Model

Following redirects is forwarded mail that gets forwarded again: you keep chasing the new address until a letter finally arrives.

Project 26 Detect a Redirect Loop

The Idea Behind It

If redirects form a cycle a crawler would loop forever fetching the same URLs, so tracking visited addresses lets you stop and flag the loop. This code follows the redirect dict but adds each URL to a seen set first; the moment it revisits a URL already in seen it sets a loop flag and breaks. The /x, /y, /z cycle is caught after three hops rather than spinning endlessly.

What You'll Build & Learn

Detect a redirect cycle by tracking visited URLs, stopping and flagging the loop instead of looping forever.

- Redirect cycles trap crawlers
- A seen set detects revisits
- break stops the infinite loop

Skill Roadmap

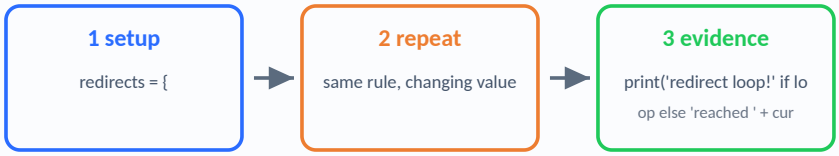
Skill step: pushes the same idea into a less automatic situation. It builds on Project 25: follow a redirect chain to the target. Project 27 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a redirect loop is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `redirects = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('redirect loop!' if loop else 'reached ' + cur, 'after', hops, 'hops')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirects = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if cur in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('redirect loop!' if loop else 'reached ' + cur, 'after', hops, 'hops')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: redirects = { | Core: if cur in seen: | Evidence: print('redirect loop!' if loop else 'reached ' + cur, 'after', hops, 'h...

🛠️ Reader to Writer Bridge

1. Read: explain detect a redirect loop in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 25.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 27 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('redirect loop!' if loop else 'reached ' + cur, 'after', hops, 'hops')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `redirects = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a redirect loop and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Adding each URL to a `seen` set before stepping to its target means re-encountering a seen URL proves a loop, which the code reports rather than looping.

```
redirects = {
    '/x': '/y',
    '/y': '/z',
    '/z': '/x',
}
```

```
start, cur = '/x', '/x'
seen, hops = set(), 0
loop = False
while cur in redirects:
    if cur in seen:
        loop = True
        break
    seen.add(cur)
    cur = redirects[cur]
    hops += 1
print('redirect loop!' if loop else 'reached ' + cur, 'after', hops, 'hops')
```

```
output
redirect loop! after 3 hops
```

How it works:

1. start and cur begin at /x with an empty seen set.
2. Before following, the loop checks if cur is already in seen.
3. A revisit sets loop True and breaks out immediately.
4. Otherwise cur is recorded, the redirect is followed, and hops increments.

Try it:

1. Print the exact URL where the loop closes.
2. Combine the cap guard with the seen-set check.
3. Add a chain that resolves cleanly and confirm no loop.
4. Break the loop by pointing `/z` to `/done` and confirm a clean finish.

⚠ Common Mistakes

- Checking `seen` after advancing misses the URL that closes the loop.
- Using the hop counter alone as a guard hides the fact that it is a loop, not just a long chain.
- Resetting `seen` inside the loop defeats the detection entirely.

Skills gained cycle detection | visited set | loop guard

→ Where You'll Use This: Redirect-loop detection catches the misconfigurations that return ERR_TOO_MANY_REDIRECTS to users and silently waste a crawler's budget.

Mental Model

A redirect loop is a roundabout with no exit: tracking where you have been is the only way to notice you keep passing the same sign.

Project 27 Rank Pages with a PageRank Iteration

The Idea Behind It

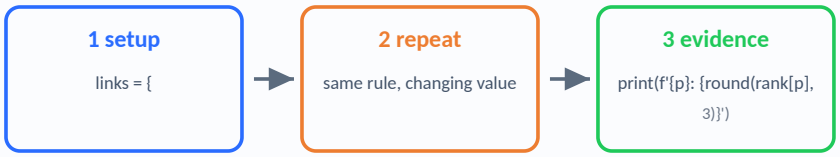
PageRank treats each link as a vote and spreads importance around the graph until the scores settle, and a few damped iterations approximate that steady state. This code seeds every page with equal rank, then repeatedly distributes each page's rank across its outbound links, scaled by a 0.85 damping factor with a 0.15 teleport baseline. After twenty rounds the ranks converge, with the well-linked pages scoring highest.

What You'll Build & Learn

Approximate PageRank by iterating link-vote distribution with damping until scores stabilise.

- Links are votes that spread importance
- Damping models random teleportation
- Iteration converges to steady ranks

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 26: detect a redirect loop. Project 28 changes the surface problem while preserving the underlying method. *progress check*

Reading target: rank pages with a pagerank iteration is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `links = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{p}: {round(rank[p], 3)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`links = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`rank = {p: 1.0 / N for p in links}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{p}: {round(rank[p], 3)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `rank = {p: 1.0 / N for p in links}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Rank Pages with a PageRank Iteration: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: links, home, len, rank, range. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: links = { | Core: rank = {p: 1.0 / N for p in links} | Evidence: print(f'{p}: {round(rank[p], 3)}')

🛠️ Reader to Writer Bridge

1. Read: explain rank pages with a pagerank iteration in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 26.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 28 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{p}: {round(rank[p], 3)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `links = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank pages with a pagerank iteration and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each round redistributes 85% of every page's rank evenly across its out-links plus a 15% uniform teleport; repeating converges toward the stationary PageRank values.

```
links = {
    'home': ['a', 'b'],
    'a': ['c'],
    'b': ['c'],
    'c': ['home'],
}
N = len(links)
```

```
rank = {p: 1.0 / N for p in links}
for _ in range(20):
    nxt = {p: 0.15 / N for p in links}
    for p, outs in links.items():
        share = rank[p] / len(outs)
        for t in outs:
            nxt[t] += 0.85 * share
    rank = nxt
for p in sorted(rank):
    print(f'{p}: {round(rank[p], 3)}')
```

```
output
a: 0.172
b: 0.172
c: 0.33
home: 0.326
```

How it works:

1. Every page starts with rank 1/N, an equal share.
2. Each iteration seeds nxt with the 0.15/N teleport baseline.
3. A page's rank, split across its outbound links, is added scaled by 0.85.
4. After twenty rounds, c and home score highest as central pages.

Try it:

1. Print the rank after each iteration to watch it converge.
2. Handle a dangling page with no outbound links.
3. Change the damping factor and observe the effect.
4. Run only 2 iterations and watch the ranks before they settle.

⚠ Common Mistakes

- Updating `rank` in place mid-round uses half-new values and breaks convergence.
- A page with zero out-links (a dangling node) would leak rank and needs special handling.
- Printing raw floats without `round` gives noisy, nondeterministic-looking output.

Skills gained PageRank iteration | damping factor | rank distribution

→ Where You'll Use This: PageRank's link-vote model still underlies how authority flows through internal links and backlinks, shaping which pages an engine trusts most.

Mental Model

PageRank is reputation by endorsement: you are trusted in proportion to how much trusted people vouch for you, settling over many rounds.

Project 28 Score Pages by Query-Term Coverage

The Idea Behind It

A multi-word query rewards pages that contain more of its words, so coverage, the fraction of query terms present, is a sharper relevance signal than raw frequency. This code splits the query into a term set, then for each document builds a set of its words and intersects the two, scoring by how many query terms overlap. Sorting by coverage ranks the pages that match more of the query higher.

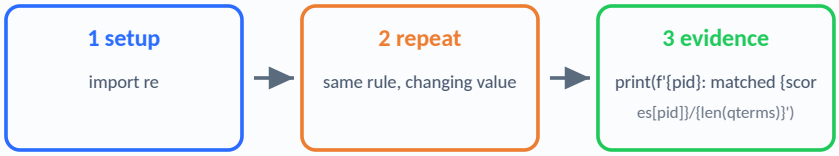
What You'll Build & Learn

Score each page by how many distinct query terms it contains and rank by that coverage.

- Coverage counts query terms present
- Set intersection measures overlap
- More terms matched ranks higher

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 27: rank pages with a pagerank iteration. Project 29 changes the surface problem while preserving the underlying method.



progress check

Reading target: score pages by query-term coverage is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated library calls.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{pid}: matched {scores[pid]}/{len(qterms)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`for pid, body in docs.items():`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. slow line
3. Check the evidence	`print(f'{pid}: matched {scores[pid]}/{len(qterms)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for pid, body in docs.items():`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Pages by Query-Term Coverage: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: re, docs, p1, red, running. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: for pid, body in docs.items(): | Evidence: print(f'{pid}: matched {scores[pid]}/{len(qterms)}')

🛠️ Reader to Writer Bridge

1. Read: explain score pages by query-term coverage in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 27.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 29 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{pid}: matched {scores[pid]}/{len(qterms)}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score pages by query-term coverage and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Intersecting each document's term set with the query's term set counts how many query words a page covers; ranking by that coverage orders the most-on-topic pages first.

```
import re

docs = {
    'p1': 'red running shoes',
```

```
    'p2': 'red shoes sale',
    'p3': 'blue running shoes',
}
query = 'running shoes'
qterms = set(query.split())
scores = {}
for pid, body in docs.items():
    terms = set(re.findall(r'[a-z]+', body))
    scores[pid] = len(qterms & terms)
ranked = sorted(scores, key=lambda p: (-scores[p], p))
for pid in ranked:
    print(f'{pid}: matched {scores[pid]}/{len(qterms)}')
```

```
output
p1: matched 2/2
p3: matched 2/2
p2: matched 1/2
```

How it works:

1. The query splits into qterms, a set of its words.
2. Each document body becomes a set via re.findall of letter runs.
3. Intersecting qterms with the document's words and taking len gives the score.
4. p1 and p3 match both terms and outrank p2's single match.

Try it:

1. Break coverage ties using term frequency.
2. Report each page's matched terms, not just the count.
3. Lowercase and de-duplicate the query terms first.
4. Add a page containing both query words once each and confirm full coverage.

⚠ Common Mistakes

- Using term frequency instead of set intersection rewards repetition over coverage.
- Forgetting to lowercase or regex-tokenize lets punctuation hide a match.
- Omitting the page-id tiebreaker makes equal-coverage ties nondeterministic.

Skills gained set intersection | coverage scoring | query matching

→ Where You'll Use This: Term-coverage scoring reflects why pages addressing more of a query's intent rank above pages that merely repeat one keyword many times.

Mental Model

Coverage is grading an answer by how many of the question's points it addresses, not by how often it repeats one of them.

Project 29 Weight a Term with TF-IDF

The Idea Behind It

Counting a term is not enough because a word in every page tells you nothing, so TF-IDF multiplies term frequency by inverse document frequency to reward rare, distinctive words. This code first builds a document-frequency table, then computes the idf for apple as the log of N over its df, and finally scores each page by tf times idf. Pages where apple is both frequent and distinctive score highest.

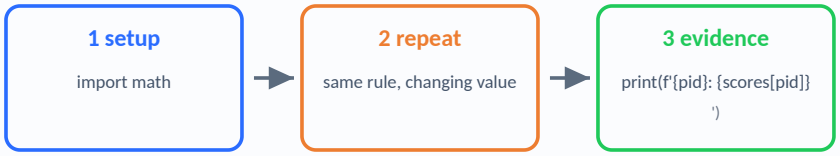
What You'll Build & Learn

Weight a term per page with TF-IDF and rank the pages by the resulting score.

- Common words carry little signal
- IDF rewards rare distinctive terms
- TF-IDF is frequency times inverse document frequency

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 28: score pages by query-term coverage. Project 30 changes the surface problem while preserving the underlying method.



progress check

Reading target: weight a term with tf-idf is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import math` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print(f'{pid}: {scores[pid]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import math`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`for body in docs.values():`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{pid}: {scores[pid]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for body in docs.values():`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Weight a Term with TF-IDF: connect the surface task to the chapter skill, crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
Names	Watch these names first: math, docs, p1, apple, banana. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import math | Core: for body in docs.values(): | Evidence: print(f'{pid}: {scores[pid]}')

🛠️ Reader to Writer Bridge

1. Read: explain weight a term with tf-idf in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 28.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 30 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{pid}: {scores[pid]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import math` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of weight a term with tf-idf and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

IDF is `log(N / document_frequency)`, so a term in fewer documents weighs more; multiplying by per-document term frequency ranks pages by distinctive relevance.

```
import math

docs = {
    'p1': 'apple apple banana',
    'p2': 'banana cherry cherry cherry',
    'p3': 'apple cherry',
}
N = len(docs)
```

```
df = {}
for body in docs.values():
    for term in set(body.split()):
        df[term] = df.get(term, 0) + 1
term = 'apple'
idf = math.log(N / df[term])
scores = {}
for pid, body in docs.items():
    tf = body.split().count(term)
    scores[pid] = round(tf * idf, 3)
for pid in sorted(scores, key=lambda p: (-scores[p], p)):
    print(f'{pid}: {scores[pid]}')
```

```
output
p1: 0.811
p3: 0.405
p2: 0.0
```

How it works:

1. df counts how many documents contain each unique term.
2. idf for apple is the log of N divided by its document frequency.
3. Each page's tf is its count of apple, multiplied by idf for the score.
4. p1 scores highest, p3 lower, and p2 zero since it lacks apple.

Try it:

1. Compute TF-IDF for every term, not just apple.
2. Add smoothing so a term in all docs is not exactly zero.
3. Normalise term frequency by document length first.
4. Score `"banana"` (in two docs) and compare its weight to `"apple"`.

⚠ Common Mistakes

- Computing document frequency from raw tokens (not a per-doc set) overcounts repeats.
- A term present in every document gives IDF 0, zeroing its score, which surprises beginners.
- Using `log10` versus natural `log` silently changes every score.

Skills gained TF-IDF weighting | inverse document frequency | log scaling

→ Where You'll Use This: TF-IDF is the classic relevance weighting behind on-page optimisation and content-gap analysis, favouring distinctive terms over ubiquitous filler.

Mental Model

TF-IDF is valuing a fingerprint: a feature shared by everyone identifies no one, but a rare distinctive trait pins down the page.

Project 30 Run the Full Crawl Pipeline Report

The Idea Behind It

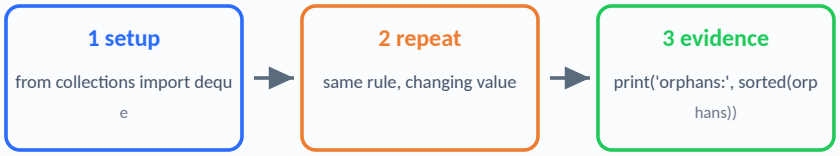
This capstone ties the chapter together by running a miniature crawl audit in one pass: from a seed it crawls the link graph with BFS, records every page's depth, and reports coverage, deepest page, and orphans. The depth dict doubles as both the visited set and the distance map, while the full page inventory minus the crawled set exposes the orphan ghost. It is the skeleton of a real audit.

What You'll Build & Learn

Run a combined crawl pipeline that reports coverage, maximum depth, and orphan pages in a single pass.

- A crawl audit fuses several signals
- Depth dict doubles as the visited set
- Coverage, depth, and orphans in one pass

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 29: weight a term with tf-idf. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run the full crawl pipeline report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import deque` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
- Evidence: `print('orphans:', sorted(orphans))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import deque`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.
2. Apply the rule	`if nxt not in depth:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('orphans:', sorted(orphans))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: How Search Engines Work becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if nxt not in depth:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('orphans:', sorted(orphans))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import deque` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run the full crawl pipeline report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One BFS produces the depth map, and set arithmetic over all known pages yields coverage and orphans, summarising crawl health from a single traversal.

```
from collections import deque

links = {
    'home': ['blog', 'shop'],
    'blog': ['post1', 'post2'],
    'shop': ['item1'],
    'post1': [], 'post2': [], 'item1': [],
```

```
    'ghost': [],
}
seed = 'home'
depth, q = {seed: 0}, deque([seed])
while q:
    p = q.popleft()
    for nxt in links[p]:
        if nxt not in depth:
            depth[nxt] = depth[p] + 1
            q.append(nxt)
crawled = set(depth)
orphans = set(links) - crawled
print('seed:', seed)
print('crawled:', len(crawled), 'of', len(links))
print('max depth:', max(depth.values()))
print('orphans:', sorted(orphans))
```

```
output
seed: home
crawled: 6 of 7
max depth: 2
orphans: ['ghost']
```

How it works:

1. A BFS from the seed fills depth with each page's distance from home.
2. crawled is the set of keys in depth, the pages actually reached.
3. set(links) minus crawled exposes the orphan ghost.
4. The report prints coverage 6 of 7, max depth 2, and the orphan list.

Try it:

1. Add average depth to the report alongside the maximum.
2. Include each crawled page's depth in the output.
3. Feed orphans back in via a sitemap and re-audit.
4. Link `ghost` from `shop` and watch coverage hit 100%.

⚠ Common Mistakes

- Computing orphans before the BFS finishes reports pages still in the queue as unreachable.
- Calling `max` on an empty depth map (no pages) would raise; the seed guarantees one entry here.
- Counting `len(depth)` as total pages instead of crawled pages hides the orphans.

Skills gained crawl audit | BFS pipeline | orphan detection

→ **Where You'll Use This:** This is the blueprint of a production site-crawl tool: one traversal yields the coverage, depth, and orphan metrics that drive technical-SEO reports.

Mental Model

It is a one-walk building inspection: you tour from the entrance, note how deep each room sits, and list any room no hallway reaches.

Chapter Progress Checkpoint

What this chapter added: after 30 mini-projects, How Search Engines Work should feel like a reusable Python move: crawl, index and rank — what a bot sees, crawl budget, and how urls are discovered.

chapter checkpoint

1 Read
Open any project from Projects 1-30 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 2 (robots.txt and Crawl Directives) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall | 3 Meaning | 2 Structure | 1 Transfer

1.1.Q1 Recall MEDIUM — Turn back to Project 22 (Fold Duplicates with Canonical Tags). Without running it, what exactly does it print?

1.1.Q2 Meaning MEDIUM — Turn back to Project 1 (Model a Tiny Web as a Link Graph). Without running it, what exactly does it print?

1.1.Q3 Structure MEDIUM — Turn back to Project 18 (Merge Sitemap and Link Discovery). Without running it, what exactly does it print?

1.1.Q4 Transfer MEDIUM — Turn back to Project 24 (Honour the Noindex Directive). Without running it, what exactly does it print?

1.1.Q5 Recall EASY A search engine performs three phases in order. What are they?

- A Rank, crawl, index
- B Crawl, index, rank
- C Index, crawl, rank
- D Crawl, rank, index

1.1.Q6 Meaning MEDIUM A page exists and has great content but no other page links to it and it is not in any sitemap. What is most likely true?

- A It will rank #1
- B It may never be crawled or indexed (orphan page)
- C It is automatically indexed
- D It is a duplicate

1.1.Q7 Structure EASY Why does wasting crawl budget on duplicate URLs hurt SEO?

- A Duplicates are illegal
- B Fetches spent re-crawling duplicates are not spent on unique, important pages, delaying their indexing
- C It uses more disk on your server
- D It changes your domain authority

1.1.Q8 Meaning EASY In an inverted index, what does the entry for the term "audit" store?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 1 – How Search Engines Work

1.1.Q1. `unique pages indexed: ['/about', '/blog', '/home']` then `duplicates folded: 2`

1.1.Q2. `pages=5 links=6`

1.1.Q3. `total URLs: 5` then `sitemap-only: ['/contact', '/pricing']`

1.1.Q4. `indexable: ['/blog', '/home']` then `noindex: ['/print-view', '/search-results']`

1.1.Q5. **B** crawl (discover), index (store/understand), then rank (order for a query).

1.1.Q6. **B** with no inbound edge and no sitemap entry, the crawler has no way to discover it.

1.1.Q7. **B** the budget is finite, so junk fetches steal from valuable ones.

1.1.Q8. The set of pages (documents) that contain the term "audit" — so a query for "audit" is a fast lookup, not a scan.

Chapter 2 · robots.txt and Crawl Directives

Parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

Chapter Skill Map

What this chapter adds: In robots.txt and Crawl Directives, the focus is parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay. You practise it across 40 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples.

chapter arc

What it builds on: Chapter 2 assumes the reading habits from Chapter 1: How Search Engines Work. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 3, XML Sitemaps and URL Discovery, reuses this chapter's discipline with a new kind of problem.

1 **Projects 31-43**	2 **Projects 44-56**	3 **Projects 57-70**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

robots.txt is not a wall — it is a rulebook the crawler reads to itself.

groups, then longest match, then allow-wins ties

Every well-behaved bot, before it fetches anything from `example.com`, requests `https://example.com/robots.txt` and reads it as instructions about where it may go. The file looks like a flat list of lines, but a crawler does not read it flat. It reads it as a set of groups: a `User-agent:` line opens a block, and every `Allow:` / `Disallow:` line beneath it belongs to that block until the next `User-agent:` appears. Parsing the file into those groups is step zero — nothing else works until you have it.

Once the file is grouped, answering a question takes three moves in a fixed order. First, pick the group: a bot obeys *only* the block that names it, and falls back to the `*` block if it has no named block of its own. Second, within that one group, find every rule whose pattern matches the path. Third, apply precedence — the matching rule with the *longest* pattern wins, and if an Allow and a Disallow tie on length, Allow wins. Everything in this chapter is an implementation of those three moves.

The single operation underneath it all is a prefix test: a path is governed by a rule when the path *starts with* the rule's value. `Disallow: /admin` matches `/admin`, `/admin/login`, and `/administrator` alike, because all three begin with `/admin`. Here is that core test, the thing a crawler runs before every fetch:

```
disallow = ['/admin', '/cart']
paths = ['/admin/login', '/blog', '/cart', '/products']
for path in paths:
```

```
    blocked = any(path.startswith(rule) for rule in disallow)
    print(f'{path}: {"blocked" if blocked else "crawl"}')
```

```
output
/admin/login: blocked
/blog: crawl
/cart: blocked
/products: crawl
```

Read that loop and you have read the heart of robots.txt enforcement: a prefix test against a list of forbidden starts. Everything else — Allow overrides, wildcards, per-bot groups — is added precision layered on top of `startswith`.

startswith is the whole engine; the rest is tie-breaking

Two things robots.txt is *not*. It does not hide a page from the index — a disallowed URL can still appear in results if other sites link to it; it only stops the *fetch*. And it is advisory: honest crawlers obey it, but it enforces nothing. Keeping secrets out of robots.txt (which is publicly readable) is itself a classic mistake.

ROBOTS.TXT

A plain-text file at the site root (`/robots.txt`) that tells crawlers which paths they may or may not fetch. It controls **crawling**, not indexing, and is honoured voluntarily.

USER-AGENT GROUP

A `User-agent:` line plus all the `Allow`/`Disallow` lines beneath it, up to the next `User-agent:`. A bot obeys exactly one group: its own named block, or `*` if it has none.

DISALLOW

A rule naming a path prefix the bot must not fetch. `Disallow: /admin` blocks every URL starting with `/admin`. An empty `Disallow:` (no value) blocks nothing — it permits everything.

ALLOW

A rule that carves an exception out of a broader Disallow. `Allow: /blog/public` re-permits a sub-path under `Disallow: /blog` by matching more characters.

LONGEST-MATCH PRECEDENCE

When several rules match a path, the one whose pattern matches the most characters wins; an Allow and a Disallow of equal length are broken in favour of Allow. This — not file order — decides the verdict.

WILDCARD (`*` AND `$`)

In a pattern, ∗ means "any sequence of characters" and a trailing `0` or `/*?sort=`.

Step zero: split the flat file into groups

A crawler cannot reason about robots.txt until it has carved the lines into groups keyed by user-agent. Walk the file top to bottom; a `User-agent:` line opens (or re-opens) a group, and each `Allow`/`Disallow` line is filed under the currently open agent. Split each line on its first colon into a *field* and a *value* — field names are case-insensitive, so lower-case them.

```
robots = """User-agent: Googlebot
Disallow: /no-google

User-agent: *
Disallow: /private
"""
groups, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    field, _, value = line.partition(':')
    field, value = field.strip().lower(), value.strip()
    if field == 'user-agent':
        agent = value
        groups.setdefault(agent, [])
    elif agent is not None:
        groups[agent].append((field, value))
for ua in sorted(groups):
    print(f'{ua}: {groups[ua]}')
```

```
output
*: [('disallow', '/private')]
Googlebot: [('disallow', '/no-google')]
```

Two subtleties live in this loop. A rule that appears *before* any `User-agent:` belongs to no group and is silently ignored. And if the same bot is named twice, its blocks are merged, not replaced — `setdefault` keeps the existing list and appends to it.

Pick the one group that applies to a bot

A bot does not obey the whole file — it obeys a single group. The selection rule: if the file names the bot, use that block and ignore the * block entirely; otherwise fall back to *; and if there is no * either, the bot has no rules and may crawl everything. Matching is case-insensitive and picks the *most specific* (longest) matching name, so `Googlebot-Image` obeys its own block rather than the generic `Googlebot` one.

```
groups = {'googlebot': ['/a'], 'googlebot-image': ['/b'], '*': ['/c']}
def pick(bot):
    bot = bot.lower()
    best = None
    for ua in groups:
        if ua != '*' and ua in bot:
            if best is None or len(ua) > len(best):
                best = ua
    return best or '*'
for bot in ['Googlebot', 'Googlebot-Image', 'Bingbot']:
    print(f'{bot} -> group {pick(bot)!r}')
```

```
output
Googlebot -> group 'googlebot'
Googlebot-Image -> group 'googlebot-image'
Bingbot -> group '*'
```

`Bingbot` has no block of its own, so it falls through to *. `Googlebot-Image` is the longest name contained in its user-agent string, so it wins over the shorter `googlebot`. *specificity, not file order, chooses the group*

Allow vs Disallow: longest match wins, Allow breaks ties

Inside the chosen group, a path can match several rules at once. The verdict is decided by longest-match precedence: among all matching rules, the one with the longest pattern wins. A short `Disallow` is therefore *punched through* by a longer `Allow` that names a sub-path. Track the best length seen and the action that owns it:

```
rules = [('disallow', '/'), ('allow', '/public'), ('disallow', '/public/secret')]
paths = ['/', '/public', '/public/page', '/public/secret', '/other']
for path in paths:
    best_len, action = -1, 'allow'
    for act, pattern in rules:
        if path.startswith(pattern) and len(pattern) > best_len:
            best_len, action = len(pattern), act
    print(f'{path}: {"crawl" if action == "allow" else "blocked"}')
```

```
output
/: blocked
/public: crawl
/public/page: crawl
```

```
/public/secret: blocked
/other: blocked
```

`Disallow: /` blocks everything, but `Allow: /public` (7 chars) out-matches it for any `/public…` path, and the longer `Disallow: /public/secret` (15 chars) re-blocks just that branch. One subtlety the loop above glosses over: when an Allow and a Disallow match with exactly equal length, the tie goes to **Allow**, so an `Allow: /folder` defeats a same-length `Disallow: /folder`.

Wildcards: translate the pattern to a regex

Real rules use `*` ("any run of characters") and a trailing `$` anchor the end. Then matching is one `re` call.

```
import re
def to_rx(pat):
    rx = ['^']
    for ch in pat:
        rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))
    return re.compile(''.join(rx))
rx = to_rx('/*.pdf$')
for path in ['/report.pdf', '/report.pdf?v=2', '/dir/a.pdf', '/a.pdf.html']:
    print(f'{path}: {"match" if rx.match(path) else "no"}')
```

```
output
/report.pdf: match
/report.pdf?v=2: no
/dir/a.pdf: match
/a.pdf.html: no
```

The `$` stripped out — so `/folder/*.html` (13 effective chars) can out-rank a shorter literal Allow.

Beyond robots.txt: meta robots and X-Robots-Tag

robots.txt governs the *fetch*; a separate family of directives governs whether a fetched page may be *indexed*. An HTML page can carry `<meta name="robots" content="noindex, nofollow">` in its head, and non-HTML files (like PDFs) carry the same controls in an `X-Robots-Tag` HTTP header. When both speak, the most restrictive wins — a header `noindex` overrides a page that says `index`.

```
import re
html = '<meta name="robots" content="index, follow">'
headers = {'X-Robots-Tag': 'noindex'}
def parse(text):
    return {d.strip().lower() for d in text.split(',') if d.strip()}
meta = parse(re.search(r'content="([^"]+)"', html).group(1))
hdr = parse(headers.get('X-Robots-Tag', ''))
combined = meta | hdr
print('meta:', sorted(meta))
```

```
print('header:', sorted(hdr))
print('effective noindex:', 'noindex' in combined)
```

```
output
meta: ['follow', 'index']
header: ['noindex']
effective noindex: True
```

So a URL can be perfectly crawlable in robots.txt yet still kept out of results by a `noindex` — and, conversely, a `Disallow` in robots.txt can stop the bot from ever seeing a `noindex` tag, which is why disallowing a page you want de-indexed is self-defeating.

crawl control and index control are two different switches

Example 1

A robots.txt has `Disallow: /` then `Allow: /public` then `Disallow: /public/secret`, all under `User-agent: *`. For Bingbot, is `/public/page` crawlable, and is `/public/secret`?

SOLUTION

1. Bingbot has no named block, so it falls back to the * group and obeys these three rules.
2. For `/public/page`: it matches `Disallow: /` (1 char) and `Allow: /public` (7 chars). Longest match is the Allow → crawl.
3. For `/public/secret`: it matches `/` (1), `/public` (7) and `Disallow: /public/secret` (15). The longest is the Disallow → blocked.

`/public/page` is crawlable; `/public/secret` is blocked. Longest-match precedence, not file order, decides each one.

more characters matched = higher authority

Example 2

The file has a `Googlebot` block (`Disallow: /no-google`) and a * block (`Disallow: /private`). May Googlebot fetch `/private`? May it fetch `/no-google`?

SOLUTION

1. Googlebot has its own named block, so it obeys *only* that block and ignores the * block entirely.
2. In the Googlebot block the only rule is `Disallow: /no-google`. `/private` does not start with `/no-google`, and no rule blocks it → crawl.
3. `/no-google` does start with `/no-google`, so it is blocked for Googlebot.

Googlebot MAY fetch `/private` (its block never mentions it) and may NOT fetch `/no-google`. The * block's `/private` rule does not apply to a bot that has its own group.

a named bot reads only its own block

Example 3

A rule `Disallow: /*.pdf$` is in force. Which of `/a.pdf`, `/a.pdf?dl=1`, `/dir/b.pdf`, `/a.pdf.html` are blocked?

SOLUTION

1. Compile the pattern: `*` → `.*`, the trailing `0` .
2. `/a.pdf` ends in `.pdf` → match → blocked. `/dir/b.pdf` also ends in `.pdf` → blocked.
3. `/a.pdf?dl=1` continues past `.pdf` with `?dl=1`, so the $ anchor fails → not matched → crawl. `/a.pdf.html` ends in `.html`, not `.pdf` → crawl.

Blocked: `/a.pdf` and `/dir/b.pdf`. Allowed: `/a.pdf?dl=1` and `/a.pdf.html`. The `0` means "and nothing after"))

Mental-Math Shortcut

Group, match, longest wins (Allow on ties). To predict any verdict, run it in that order: pick the one group for the bot (its own name beats *, and a named bot ignores *), find every rule that matches the path as a prefix, then keep the rule with the most matched characters — and if an Allow and a Disallow tie on length, Allow wins. If no rule matches at all, the answer is *crawl*: robots.txt is permissive by default.

⚠ Common Mistakes

- Reading robots.txt as ordered rules where "last wins" or "first wins". Crawlers use longest-match precedence; line order does not decide the verdict.
- Assuming `Disallow` keeps a URL out of Google. It only blocks the fetch — a disallowed URL can still be indexed from external links. Use `noindex` (meta or X-Robots-Tag) to keep a page out of results.
- Confusing `Disallow: /` (blocks the whole site) with `Disallow:` (empty value, allows the whole site). A shipped staging file with `Disallow: /` silently hides everything.
- Disallowing `/css/` or `/js/`, which stops Google from rendering the page as users see it; or putting secret paths in robots.txt, which is publicly readable and just advertises them.

This chapter contains 40 hands-on mini-projects (Projects 31–70). Type each one out, run it, and experiment.

Project 31 Parse robots.txt into User-Agent Rule Groups

The Idea Behind It

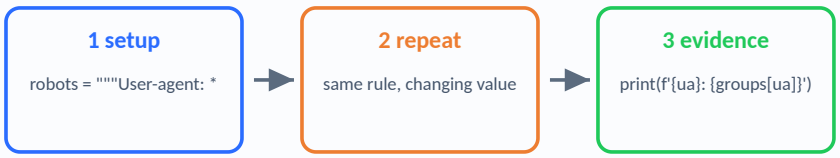
Crawlers do not read robots.txt as loose text; they fold it into groups where each User-agent line opens a block owning the Allow and Disallow lines beneath it. This project walks the lines, partitions each on the colon, lowercases the field, and uses setdefault to start a fresh rule list whenever a new agent appears, building the structure every later check depends on.

What You'll Build & Learn

Turn a flat robots.txt string into a dictionary keyed by user-agent, each holding its ordered Allow and Disallow rules.

- robots.txt is grouped by user-agent
- partition splits a field from its value
- setdefault seeds a fresh rule list

🧭 Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 32 changes the surface problem while preserving the underlying method. *progress check*

Reading target: parse robots.txt into user-agent rule groups is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{ua}: {groups[ua]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: *`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{ua}: {groups[ua]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Parse robots.txt into User-Agent Rule Groups: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Disallow, admin. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: * | Core: if not line: | Evidence: print(f'{ua}: {groups[ua]}')

🛠️ Reader to Writer Bridge

1. Read: explain parse robots.txt into user-agent rule groups in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 32 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{ua}: {groups[ua]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse robots.txt into user-agent rule groups and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting each line on the first colon yields a `field: value` pair; a `user-agent` line opens a new group and following allow/disallow lines append to whichever group is currently open.

```
robots = """User-agent: *
Disallow: /admin
Disallow: /cart
Allow: /
"""
groups = {}
agent = None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    field, _, value = line.partition(':')
    field = field.strip().lower()
    value = value.strip()
    if field == 'user-agent':
        agent = value
        groups.setdefault(agent, [])
    elif field in ('allow', 'disallow') and agent is not None:
        groups[agent].append((field, value))
```

```
    for ua in sorted(groups):
        print(f'{ua}: {groups[ua]}')
```

```
output
*: [('disallow', '/admin'), ('disallow', '/cart'), ('allow', '/')]
```

How it works:

1. A triple-quoted robots string holds one wildcard block; groups starts empty and agent is None.
2. Each line is stripped, blanks are skipped, and partition(':') splits it into field and value.
3. When field equals user-agent the value becomes the current agent and setdefault opens an empty list for it.
4. Allow and Disallow lines append a (field, value) tuple to the active agent's list.
5. Sorting the keys, the final loop prints each agent with its captured rules.

Try it:

1. Add a second User-agent block for Googlebot and confirm both keys appear in the printed dictionary
2. Track the source line number with each rule so you can report where a directive came from
3. Preserve directive order across blocks and print the rules without sorting the agent keys
4. Add a second `User-agent: Googlebot` block and confirm a new key appears.

⚠ Common Mistakes

- Splitting on every colon breaks `Sitemap: https://...` lines whose value itself contains a colon; `partition(':')` splits only on the first.
- Appending allow/disallow rules while `agent` is still None (no User-agent seen yet) silently drops or misattributes them.
- Forgetting to lowercase the field name misses `DISALLOW` or `User-Agent`, since directive names are case-insensitive.

Skills gained string parsing | dict grouping | robots.txt structure

→ Where You'll Use This: Every robots.txt linter, crawler, and SEO audit tool starts by parsing the file into per-agent groups before it can answer any crawlability question.

Mental Model

Think of the file as a filing cabinet: each User-agent line is a drawer label, and the Allow/Disallow lines drop into whichever drawer is currently open.

Project 32 Match a Path Against Disallow Prefixes

The Idea Behind It

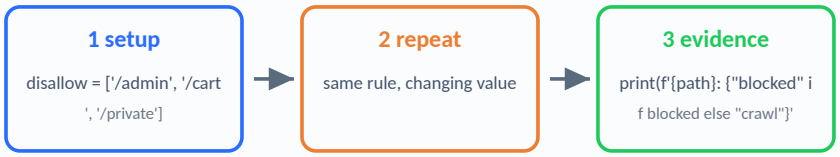
The atomic robots.txt operation is a prefix test: a URL path is blocked when it begins with any Disallow value. This project keeps a list of disallowed prefixes and, for each candidate path, uses any() with str.startswith to decide blocked or crawl. It is the exact comparison a crawler runs before deciding whether to fetch a given URL.

What You'll Build & Learn

Classify each path as blocked or crawlable by testing whether it starts with any disallowed prefix.

- a Disallow match is a prefix test
- any() short-circuits over a rule list
- startswith drives the verdict

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 31: parse robots.txt into user-agent rule groups. Project 33 changes the surface problem while preserving the underlying method. *progress check*

Reading target: match a path against disallow prefixes is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `disallow = ['/admin', '/cart', '/private']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

2. Explain: point to `disallow = ['/admin', '/cart', '/private']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of match a path against disallow prefixes and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`str.startswith` over each Disallow value implements robots' prefix matching, so `/admin` blocks `/admin/login` but a path only sharing a prefix-of-a-word like `/privacy` vs `/private` is not blocked.

```
disallow = ['/admin', '/cart', '/private']
paths = ['/admin/login', '/blog', '/cart', '/products', '/privacy']
for path in paths:
    blocked = any(path.startswith(rule) for rule in disallow)
    print(f'{path}: {"blocked" if blocked else "crawl"}')
```

```
output
/admin/login: blocked
/blog: crawl
/cart: blocked
```

```
/products: crawl
/privacy: crawl
```

How it works:

1. disallow lists three blocked prefixes and paths lists five candidate URLs.
2. For each path, any(path.startswith(rule) for rule in disallow) returns True if a prefix matches.
3. The conditional expression prints blocked when the generator finds a match and crawl otherwise.
4. /admin/login and /cart match prefixes and print blocked; /privacy does not match /private so it crawls.

Try it:

1. Add /search to the disallow list and verify a /search?q=x style path becomes blocked
2. Return the specific rule that matched instead of a plain blocked label for easier debugging
3. Make /privacy correctly crawlable even if you add a /priv prefix by testing for a path separator boundary
4. Add `/cartoon` to the paths and confirm `/cart` still blocks it (prefix match).

⚠ Common Mistakes

- Assuming `/private` blocks `/privacy`; it does not, because `/privacy` does not start with the full string `/private` (they differ at the 8th character).
- Using `in` instead of `startswith` would wrongly block any path that merely contains the rule text anywhere.
- Forgetting that an empty Disallow value matches every path because every string starts with the empty string.

Skills gained prefix matching | startswith | any()

→ Where You'll Use This: Prefix testing is the inner loop of any crawl-budget audit that flags which of a site's URLs a robots.txt would keep search engines from fetching.

Mental Model

It works like a bouncer scanning the start of each name on a guest list: if the path's opening characters match a banned prefix, the door stays shut.

Project 33 Let Allow Override a Broader Disallow

The Idea Behind It

Allow and Disallow lines live together, and conflicts resolve by specificity: the longer matching rule wins. This project computes, per path, the longest Allow prefix length and the longest Disallow prefix length using max with a default, then crawls when the Allow match is at least as long. A narrow Allow can therefore punch a hole through a broad Disallow.

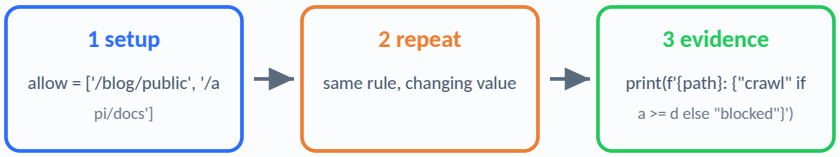
What You'll Build & Learn

Let a longer Allow prefix override a shorter Disallow so a permitted sub-path stays crawlable inside a blocked folder.

- longer matching rule wins
- max with default guards empty matches
- Allow can override Disallow

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 32: match a path against disallow prefixes. Project 34 changes the surface problem while preserving the underlying method.



progress check

Reading target: let allow override a broader disallow is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `allow = ['/blog/public', '/api/docs']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"crawl" if a >= d else "blocked"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"crawl" if a >= d else "blocked"}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `allow = ['/blog/public', '/api/docs']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of let allow override a broader disallow and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

For each path the longest matching Allow length is compared to the longest matching Disallow length; the longer match decides, so a specific `/blog/public` Allow beats a broad `/blog` Disallow.

```
allow = ['/blog/public', '/api/docs']
disallow = ['/blog', '/api']
paths = ['/blog/public/post', '/blog/draft', '/api/docs', '/api/keys']
for path in paths:
    a = max((len(r) for r in allow if path.startswith(r)), default=-1)
    d = max((len(r) for r in disallow if path.startswith(r)), default=-1)
    print(f'{path}: {"crawl" if a >= d else "blocked"}')
```

```
output
/blog/public/post: crawl
/blog/draft: blocked
/api/docs: crawl
/api/keys: blocked
```

How it works:

1. allow holds two specific sub-paths and disallow holds two broad parent paths.

2. For each path, a is the longest matching Allow length and d the longest matching Disallow length, defaulting to -1.
3. The ternary prints crawl when a >= d, meaning the Allow match is at least as specific.
4. /blog/public/post crawls because /blog/public is longer than /blog; /blog/draft stays blocked.

Try it:

1. Add an Allow for /api/keys/help and check it overrides the broader /api Disallow
2. Print both the winning length and the action so a tie at -1 versus -1 is visible
3. Change the comparison to strict greater-than and observe which equal-length paths flip to blocked
4. Add `('Allow', '/api/keys/public')` and watch that one sub-path open up.

⚠ Common Mistakes

- Using `>` instead of `>=` flips the tie toward Disallow; Google's rule is that Allow wins ties of equal length.
- Forgetting the `default=-1` makes `max` raise on a path that matches no rule of one kind.
- Comparing the number of matching rules instead of the matched prefix length gives the wrong winner.

Skills gained longest-match | max default | rule precedence

→ Where You'll Use This: Specificity resolution is what lets SEO teams open a single public folder inside an otherwise disallowed section without rewriting the whole robots.txt.

Mental Model

Picture two highlighters over the same URL: the one that colours more characters of the path is the one whose verdict sticks.

Project 34 Select the Rule Group for a Named Bot

The Idea Behind It

When robots.txt holds both a named Googlebot block and a wildcard block, Googlebot follows only its own block and ignores the star entirely. This project parses every group, then selects the bot's block if it exists and falls back to the star otherwise, printing the chosen group and its rules. Picking the correct group is what makes per-bot targeting actually work.

What You'll Build & Learn

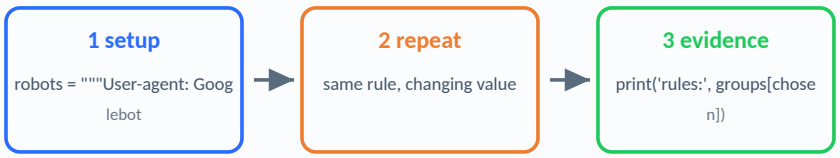
Choose the rule group a named bot must obey, preferring its own block over the wildcard fallback.

- a named bot ignores the star block
- group selection precedes rule evaluation

- fallback to wildcard when unnamed

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 33: let allow override a broader disallow. Project 35 changes the surface problem while preserving the underlying method.



progress check

Reading target: select the rule group for a named bot is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: Googlebot` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('rules:', groups[chosen])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: Googlebot`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print('rules:', groups[chosen])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Select the Rule Group for a Named Bot: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Googlebot, Disallow. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: Googlebot | Core: if not line: | Evidence: print('rules:', groups[chosen])

Reader to Writer Bridge

1. Read: explain select the rule group for a named bot in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 33.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 35 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('rules:', groups[chosen])`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: Googlebot` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of select the rule group for a named bot and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A bot uses its most specific matching group; if a group names the bot exactly it wins outright, and the `*` group is used only as a fallback when no named group matches.

```
robots = """User-agent: Googlebot
Disallow: /no-google

User-agent: *
Disallow: /private
"""
groups, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    field, _, value = line.partition(':')
    field, value = field.strip().lower(), value.strip()
    if field == 'user-agent':
        agent = value
        groups.setdefault(agent, [])
    elif agent is not None:
        groups[agent].append((field, value))
bot = 'Googlebot'
chosen = bot if bot in groups else '*'
print(f'group for {bot}: {chosen}')
print('rules:', groups[chosen])
```

```
output
group for Googlebot: Googlebot
rules: [('disallow', '/no-google')]
```

How it works:

1. The robots string defines a Googlebot block and a separate wildcard block, separated by a blank line.
2. The parser groups rules per agent exactly as before, skipping blanks and lowercasing fields.
3. chosen is set to bot when 'Googlebot' is a key, else to the wildcard '*'.
4. Because Googlebot has its own block, it prints that group's single /no-google rule, not the wildcard's /private.

Try it:

1. Change bot to Bingbot and confirm it falls back to the wildcard group's rules
2. Add a /no-google/exception Allow to Googlebot's block and reprint the chosen rules
3. Report which group was used so a fallback to the star is explicit in the output
4. Set `bot = 'Bingbot'` and watch it fall back to the `*` group.

⚠ Common Mistakes

- Merging the named group with the `*` group doubles up rules; a bot must obey one group only.
- Falling back to `*` when a named group exists but is empty wrongly applies the wildcard rules.
- Treating the blank line between groups as optional; it is what separates one User-agent block from the next.

Skills gained group selection | wildcard fallback | dict lookup

→ Where You'll Use This: Correct group selection underpins any tool that answers crawlability per crawler, since Googlebot, Bingbot, and AdsBot each obey only their own most-specific block.

Mental Model

It is like a memo addressed to one person: if your name is on the envelope you read only that copy and disregard the all-staff notice pinned to the wall.

Project 35 Resolve Verdicts by Longest-Match Precedence

The Idea Behind It

With overlapping Allow and Disallow lines, the rule whose pattern matches the most characters decides the verdict. This project scans a flat rule list, tracking the longest prefix that the path starts with and remembering its action, then translates allow to crawl and disallow to blocked. This longest-match precedence is the core of how Google evaluates robots.txt.

What You'll Build & Learn

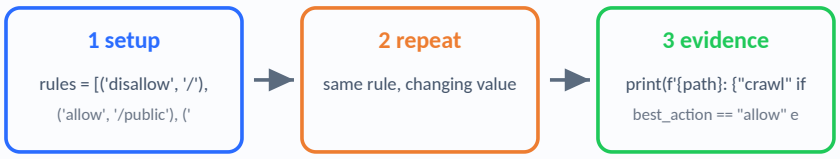
Resolve each path to crawl or blocked by keeping the action of the longest matching rule pattern.

- longest pattern sets the verdict
- track best length while scanning
- Google uses longest-match

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 34: select the rule group for a named bot. Project 36 changes the surface problem while preserving the underlying method.

progress check



Reading target: resolve verdicts by longest-match precedence is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `rules = [('disallow', '/'), ('allow', '/public'), ('disallow', '/public/secret')]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"crawl" if best_action == "allow" else "blocked"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Reader to Writer Bridge

1. Read: explain resolve verdicts by longest-match precedence in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 34.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 36 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"crawl" if best_action == "allow" else "blocked"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `rules = [('disallow', '/'), ('allow', '/public'), ('disallow', '/public/secret')]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of resolve verdicts by longest-match precedence and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Scanning every rule and keeping the action of the longest matching prefix means a deep `/public/secret` Disallow overrides a shorter `/public` Allow, while `/other` matches only the site-wide `/` Disallow and stays blocked.

```
rules = [('disallow', '/'), ('allow', '/public'), ('disallow',
'/public/secret')]
paths = ['/', '/public', '/public/page', '/public/secret', '/other']
for path in paths:
    best_len, best_action = -1, 'allow'
    for action, pattern in rules:
        if path.startswith(pattern) and len(pattern) > best_len:
            best_len, best_action = len(pattern), action
    print(f'{path}: {"crawl" if best_action == "allow" else "blocked"}')
```

```
output
/: blocked
/public: crawl
/public/page: crawl
/public/secret: blocked
/other: blocked
```

How it works:

1. rules holds a root Disallow, a /public Allow, and a deeper /public/secret Disallow.
2. For each path, best_len starts at -1 and best_action defaults to allow.
3. Every rule whose pattern the path starts with, and that is longer than best_len, updates both trackers.
4. /public/secret is blocked by the 14-character rule, while /public crawls thanks to its 7-character Allow.

Try it:

1. Add an Allow for /public/secret/ok and confirm the deepest rule now permits that path
2. Print the winning pattern alongside the verdict to make the longest match visible
3. Reverse the rule list order and verify the result is unchanged because length, not order, decides
4. Add `('allow', '/public/secret/ok')` and confirm that deepest path opens again.

⚠ Common Mistakes

- First-match-wins instead of longest-match gives the wrong answer the moment two rules overlap.
- Initialising `best_action` to 'disallow' makes unmatched paths blocked instead of the default allow.
- Comparing `len(pattern)` without the `startswith` guard counts non-matching rules.

Skills gained longest-match | precedence loop | verdict mapping

→ Where You'll Use This: Longest-match resolution is the engine behind robots.txt testers, so an SEO can predict exactly how Google ranks competing Allow and Disallow lines on a single URL.

⚡ Mental Model

Think of competing claims on a plot of land: the surveyor sides with whoever's boundary line covers the most ground.

Project 36 Break a Specificity Tie in Allow's Favour

💡 The Idea Behind It

When an Allow and a Disallow match a path with identical pattern lengths, the tie goes to Allow. This project tracks the longest match but, on an exact length tie, flips allow_wins to True whenever the tying rule is an Allow. That single tie-break keeps a hesitant Disallow: /folder from blocking a path that an equally specific Allow: /folder was meant to open.

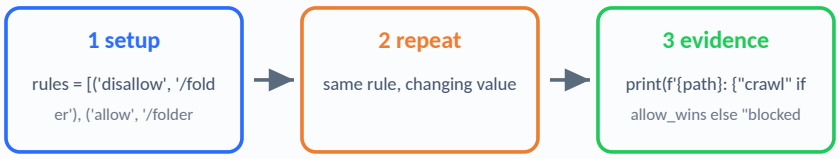
What You'll Build & Learn

Break an exact-length tie between Allow and Disallow in favour of Allow so the path stays crawlable.

- equal-length ties favour Allow
- track allow_wins alongside length

- tie-break overrides Disallow

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 35: resolve verdicts by longest-match precedence. Project 37 changes the surface problem while preserving the underlying method. *progress check*

Reading target: break a specificity tie in allow's favour is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `rules = [('disallow', '/folder'), ('allow', '/folder')]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 37 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"crawl" if allow_wins else "blocked"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `rules = [('disallow', '/folder'), ('allow', '/folder')]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of break a specificity tie in allow's favour and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

When a new match equals the current best length, the code only flips the verdict if the new rule is an Allow, encoding Google's 'Allow wins equal-length ties' rule.

```
rules = [('disallow', '/folder'), ('allow', '/folder')]
paths = ['/folder', '/folder/page', '/other']
for path in paths:
    best_len, allow_wins = -1, True
    for action, pattern in rules:
        if path.startswith(pattern):
            if len(pattern) > best_len:
                best_len, allow_wins = len(pattern), (action == 'allow')
            elif len(pattern) == best_len and action == 'allow':
                allow_wins = True
    print(f'{path}: {"crawl" if allow_wins else "blocked"}')
```

```
output
/folder: crawl
/folder/page: crawl
/other: crawl
```

How it works:

1. rules pairs a Disallow and an Allow on the identical pattern /folder.
2. For each path, best_len starts at -1 and allow_wins starts True.
3. A strictly longer match resets allow_wins to whether that rule is an Allow.
4. On an equal-length match, allow_wins flips to True only when the tying rule is an Allow, so every path crawls.

Try it:

1. Make the Disallow pattern one character longer and watch the verdict flip to blocked
2. Add a print of allow_wins per rule iteration to trace how the tie resolves
3. Introduce a third rule at the same length and confirm an Allow still wins the group
4. Swap the two rules' order and confirm the verdict does not change.

⚠ Common Mistakes

- Letting the last-seen rule win the tie makes the order of lines change the verdict.
- Initialising `allow_wins` to False would block `/other`, which no rule even matches.
- Forgetting the equal-length branch makes Disallow win ties whenever it is listed first.

Skills gained tie-breaking | Allow precedence | match tracking

→ Where You'll Use This: The equal-length Allow-wins rule matters whenever a config has mirror-image directives, and getting it right prevents an audit from falsely reporting a permitted folder as blocked.

⚡ Mental Model

Like a referee's call on an even play, the benefit of the doubt goes to the side that lets the action continue, so Allow carries a tied decision.

Project 37 Convert a Wildcard Pattern to a Regex

💡 The Idea Behind It

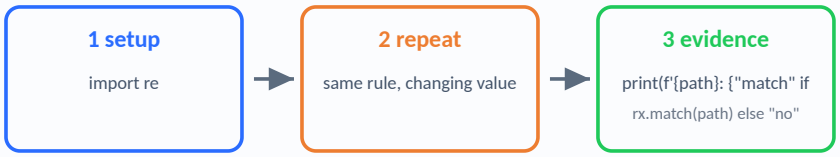
robots.txt patterns let an asterisk stand for any run of characters, which is more than plain prefix matching can express. This project compiles a pattern into a regex by escaping every literal character with re.escape and turning each star into .*, then anchors it with a leading caret. Matching a path against that compiled regex brings full wildcard support using only the standard library.

What You'll Build & Learn

Translate a robots wildcard pattern into an anchored regex so star segments match any characters.

- star means any character sequence
- re.escape protects literals
- anchor patterns with a caret

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 36: break a specificity tie in allow's favour. Project 38 changes the surface problem while preserving the underlying method. *progress check*

Reading target: convert a wildcard pattern to a regex is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"match" if rx.match(path) else "no"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if ch == '*':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {"match" if rx.match(path) else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if ch == '*':`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Reader to Writer Bridge

1. Read: explain convert a wildcard pattern to a regex in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 36.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 38 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"match" if rx.match(path) else "no"}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of convert a wildcard pattern to a regex and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Building the regex character by character, escaping every literal and expanding `*` to `.*`, turns a robots pattern like `/*.php` into a safe, anchored regular expression.

```
import re
def to_regex(pattern):
    out = ['^']
    for ch in pattern:
        if ch == '*':
            out.append('.*')
        else:
            out.append(re.escape(ch))
    return ''.join(out)
pattern = '/*.php'
rx = re.compile(to_regex(pattern))
paths = ['/index.php', '/dir/page.php', '/about.html', '/x.php?id=1']
for path in paths:
    print(f'{path}: {"match" if rx.match(path) else "no"}')
```

```
output
/index.php: match
/dir/page.php: match
/about.html: no
/x.php?id=1: match
```

How it works:

1. to_regex builds a list starting with '^' and walks each character of the pattern.
2. A star appends '.*' while any other character is passed through re.escape and appended.
3. The joined string compiles into rx, and */.php becomes ^/.\.php.*
4. /index.php and /x.php?id=1 match because .* absorbs the leading and trailing text; /about.html does not.

Try it:

1. Add a pattern /admin/* and confirm it matches nested admin paths but not /administrator

2. Print the generated regex string to inspect how each character was escaped
3. Use fullmatch instead of match and observe which trailing-text paths stop matching
4. Change the pattern to `/admin*` and test it against `/administrator`.

⚠ Common Mistakes

- Skipping `re.escape` lets pattern characters like `.` or `?` act as regex metacharacters and over-match.
- Forgetting the leading `^` anchor lets the pattern match anywhere in the path, not from the start.
- Expecting `/*.php` to require a directory; the leading `*` can match the empty string, so `/index.php` matches too.

Skills gained wildcard to regex | re.escape | pattern anchoring

→ Where You'll Use This: Wildcard translation is essential for any robots checker that must honour patterns like */.php or /?*, which appear constantly in real e-commerce and CMS robots files.

Mental Model

The asterisk is a blank tile in a word game: it fills in for any letters, and re.escape keeps the real letters from being misread as game rules.

Project 38 Anchor a Pattern to the Path End with $

The Idea Behind It

A trailing dollar sign in a robots pattern means the path must end exactly there. This project extends the wildcard-to-regex translator to map a literal $ onto a regex end-anchor, so /*.pdf$ matches a bare PDF but rejects one carrying a query string. It is precisely how you block .pdf files while letting .pdf?download=1 URLs slip through.

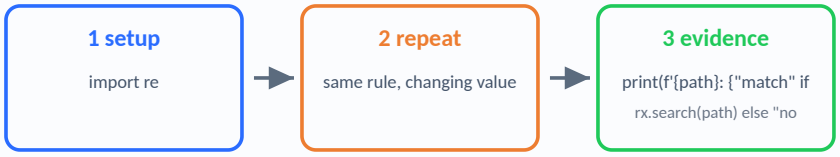
What You'll Build & Learn

Add end-anchoring so a pattern can match a file extension exactly and reject anything appended after it.

- trailing $ anchors the path end
- map $ to a regex end-anchor
- queries defeat an exact-end match

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 37: convert a wildcard pattern to a regex. Project 39 changes the surface problem while preserving the underlying method.



progress check

Reading target: anchor a pattern to the path end with $ is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"match" if rx.search(path) else "no"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if ch == '*':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {"match" if rx.search(path) else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if ch == '*':`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Anchor a Pattern to the Path End with $: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, to_regex, pattern, ch, append. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if ch == '*': | Evidence: print(f'{path}: {"match" if rx.search(path) else "no"}')

🛠️ Reader to Writer Bridge

1. Read: explain anchor a pattern to the path end with $ in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 37.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 39 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"match" if rx.search(path) else "no"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of anchor a pattern to the path end with $ and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Mapping `$` to the regex end-anchor `$` means `/*.pdf$` matches a path ending in `.pdf` but not one with a query string after it, since the characters after `.pdf` break the anchor.

```
import re
def to_regex(pattern):
    out = ['^']
    for ch in pattern:
        if ch == '*':
            out.append('.*')
        elif ch == '$':
            out.append('$')
        else:
            out.append(re.escape(ch))
    return ''.join(out)
pattern = '/*.pdf$'
rx = re.compile(to_regex(pattern))
paths = ['/report.pdf', '/report.pdf?v=2', '/dir/a.pdf', '/a.pdf.html']
for path in paths:
    print(f'{path}: {"match" if rx.search(path) else "no"}')
```

```
output
/report.pdf: match
/report.pdf?v=2: no
/dir/a.pdf: match
/a.pdf.html: no
```

How it works:

1. to_regex now has a branch that appends a regex '$' when it meets a literal $ in the pattern.
2. */.pdf$ compiles to* ^/.\.pdf$, demanding the path finish at .pdf.
3. Using rx.search, /report.pdf matches but /report.pdf?v=2 fails because text follows .pdf.
4. /a.pdf.html also fails since the path does not end at .pdf despite containing it.

Try it:

1. Add a /*.json$ pattern and verify /data.json blocks while /data.json?cb=1 does not
2. Switch rx.search back to rx.match and check whether mid-path matches still behave
3. Allow a single optional trailing slash before the end-anchor and retest the PDF cases

4. Remove the `$` from the pattern and watch `/report.pdf?v=2` start matching.

⚠ Common Mistakes

- Treating `$` as a literal dollar sign blocks the wrong URLs and never anchors.
- Forgetting that the query string `?v=2` is part of the path string here, so `$` correctly rejects it.
- Using `rx.match` here still works, but dropping the `^` from the builder would let `.pdf` match mid-path.

Skills gained end anchoring | regex $ | extension matching

→ Where You'll Use This: End-anchored patterns are how sites block indexable file types like PDFs or .json exactly, a frequent directive in robots files protecting downloads and APIs.

⚡ Mental Model

The dollar sign is a full stop on the URL sentence: the path has to finish right there, so anything written after it breaks the match.

Project 39 Extract Sitemap Lines from robots.txt

💡 The Idea Behind It

Sitemap directives stand outside any user-agent group and point crawlers at the site's URL inventory. This project ignores group structure entirely, scanning every line, partitioning on the colon, and collecting the value whenever the field is sitemap. It prints the count and each URL, mirroring the first thing a crawler does after fetching robots.txt: harvest the sitemaps.

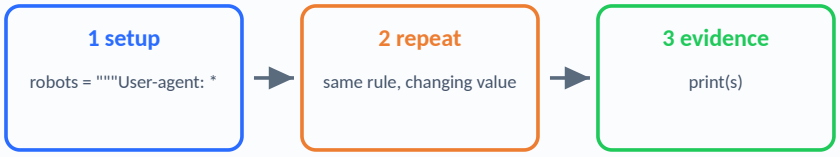
What You'll Build & Learn

Pull every Sitemap URL out of robots.txt regardless of which user-agent group surrounds it.

- Sitemap lines are group-independent
- scan all lines for one field
- collect values into a list

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 38: anchor a pattern to the path end with $. Project 40 changes the surface problem while preserving the underlying method. *progress check*



Reading target: extract sitemap lines from robots.txt is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(s)` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of extract sitemap lines from robots.txt and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A `Sitemap` line is global, so it is collected regardless of the current group; `partition(':')` keeps the `https://` URL intact because it splits only on the first colon.

```
robots = """User-agent: *
Disallow: /admin
Sitemap: https://example.com/sitemap.xml
Sitemap: https://example.com/news-sitemap.xml
"""
sitemaps = []
for line in robots.splitlines():
    field, _, value = line.partition(':')
    if field.strip().lower() == 'sitemap':
        sitemaps.append(value.strip())
print('found', len(sitemaps), 'sitemaps')
for s in sitemaps:
    print(s)
```

```
output
found 2 sitemaps
https://example.com/sitemap.xml
https://example.com/news-sitemap.xml
```

How it works:

1. The robots string mixes a wildcard block with two Sitemap lines.
2. Each line is partitioned on ':' and its field is stripped and lowercased.
3. When the field equals sitemap, the cleaned value is appended to the sitemaps list.
4. The code prints found 2 sitemaps, then each captured sitemap URL on its own line.

Try it:

1. Add a third Sitemap line and confirm the printed count updates to three
2. Validate that each captured value starts with https before adding it to the list
3. Deduplicate the sitemaps list so a repeated URL is only reported once
4. Add a third Sitemap line and confirm the count rises.

⚠ Common Mistakes

- Splitting on all colons truncates the URL right after `https`; partition on the first colon avoids that.

- Scoping sitemaps to the current user-agent group; sitemap directives apply site-wide, not per-bot.
- Forgetting to `.strip()` the value leaves a leading space on every captured URL.

Skills gained sitemap extraction | line scanning | field filtering

→ Where You'll Use This: Harvesting Sitemap directives is step one of crawl discovery, feeding the URL set that sitemap validators and index-coverage audits then crawl and verify.

Mental Model

Sitemap lines are the address book stapled to the front of the rulebook: whoever reads the file copies down those addresses before doing anything else.

Project 40 Read Crawl-Delay into a Request Budget

The Idea Behind It

Crawl-delay asks bots to pause a set number of seconds between fetches. This project scans for the crawl-delay field, parses its integer value, and when present converts it into a per-minute fetch ceiling with 60 divided by the delay. Turning the raw directive into a concrete fetch budget makes the politeness rule actionable for a scheduler instead of a number on a page.

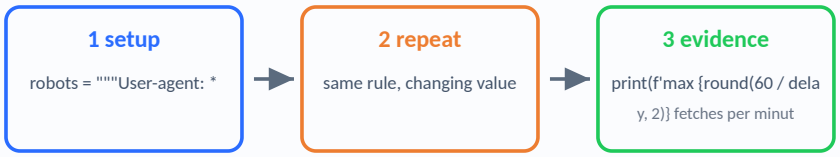
What You'll Build & Learn

Read a Crawl-delay value and convert it into a maximum fetches-per-minute politeness budget.

- Crawl-delay sets seconds between fetches
- absent delay means crawl freely
- convert delay to a rate ceiling

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 39: extract sitemap lines from robots.txt. Project 41 changes the surface problem while preserving the underlying method. *progress check*



Reading target: read crawl-delay into a request budget is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'max {round(60 / delay, 2)} fetches per minute')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Evidence	Entry: robots = """User-agent: * | Core: if field.strip().lower() == 'crawl-delay': | Evidence: print(f'max {round(60 / delay, 2)} fetches per minute')

🛠️ Reader to Writer Bridge

1. Read: explain read crawl-delay into a request budget in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 39.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 41 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'max {round(60 / delay, 2)} fetches per minute')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of read crawl-delay into a request budget and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Parsing the integer after `Crawl-delay:` gives the inter-fetch gap, and `60 / delay` converts that gap into the maximum number of fetches a polite crawler makes per minute.

```
robots = """User-agent: *
Crawl-delay: 10
Disallow: /tmp
"""
delay = None
for line in robots.splitlines():
    field, _, value = line.partition(':')
    if field.strip().lower() == 'crawl-delay':
        delay = int(value.strip())
if delay is None:
    print('no crawl-delay set (crawl freely)')
else:
    print(f'wait {delay}s between fetches')
    print(f'max {round(60 / delay, 2)} fetches per minute')
```

```
output
wait 10s between fetches
max 6.0 fetches per minute
```

How it works:

1. delay starts as None and each line is partitioned and checked for the crawl-delay field.
2. A matching line parses its value with int into delay.
3. When delay is None the code prints a crawl-freely message.
4. Otherwise it prints the wait time and round(60 / delay, 2), giving 6.0 fetches per minute for a 10-second delay.

Try it:

1. Change the delay to 5 and verify the ceiling rises to twelve fetches per minute
2. Guard against a zero delay so the division does not raise an error
3. Accept a fractional delay like 0.5 by parsing with float instead of int
4. Change the delay to 5 and watch the per-minute ceiling double.

⚠ Common Mistakes

- Leaving the value as a string makes `60 / delay` raise a TypeError.
- Dividing by a zero crawl-delay raises ZeroDivisionError; real parsers treat 0 as no delay.
- Assuming every crawler honours Crawl-delay; Googlebot ignores it and uses its own rate logic.

Skills gained crawl-delay parsing | rate conversion | int casting

→ Where You'll Use This: Crawl-delay budgeting feeds polite crawler schedulers and helps SEOs reason about how slowly a directive forces a bot to traverse a large site.

⚡ Mental Model

Crawl-delay is a turnstile timer: it spaces visitors out by N seconds, and dividing a minute by that spacing tells you how many can pass through.

Project 41 Detect a Site-Wide Disallow Block

💡 The Idea Behind It

A Disallow: / blocks the entire site for the matched user-agent, because every path begins with a slash. This project gathers all Disallow values and tests whether a bare slash is among them, flagging a full-site block. Spotting it warns you that a deploy may have shipped a staging robots.txt that quietly hides every page from search engines.

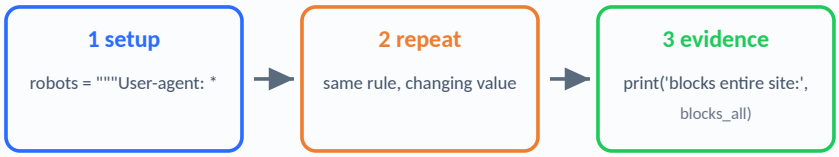
What You'll Build & Learn

Detect a site-wide block by checking whether a lone slash appears among the collected Disallow values.

- Disallow: / blocks the whole site
- every path starts with a slash
- watch for leaked staging rules

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 40: read crawl-delay into a request budget. Project 42 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect a site-wide disallow block is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

Evidence	Entry: robots = """User-agent: * | Core: if field.strip().lower() == 'disallow': | Evidence: print('blocks entire site:', blocks_all)

🛠️ Reader to Writer Bridge

1. Read: explain detect a site-wide disallow block in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 40.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 42 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('blocks entire site:', blocks_all)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. `Transfer:` change one small part of detect a site-wide disallow block and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Because every URL path begins with `/`, a single `Disallow: /` rule matches everything; detecting that exact value flags a total block.

```
robots = """User-agent: *
Disallow: /
"""
disallows = []
for line in robots.splitlines():
    field, _, value = line.partition(':')
    if field.strip().lower() == 'disallow':
        disallows.append(value.strip())
blocks_all = '/' in disallows
print('disallow rules:', disallows)
print('blocks entire site:', blocks_all)
```

```
output
disallow rules: ['/']
blocks entire site: True
```

How it works:

1. The robots string contains a single Disallow: / under the wildcard agent.
2. Each line is partitioned, and disallow values are appended into the disallows list.
3. blocks_all is True when '/' is a member of that list.
4. The code prints the disallow rules and the boolean confirming the entire site is blocked.

Try it:

1. Add a real Allow: / alongside the Disallow and decide how your check should treat the conflict
2. Exit with a nonzero status code when a full-site block is detected for CI use
3. Report which user-agent owns the blanket Disallow rather than just a boolean
4. Change the rule to `Disallow: /admin` and confirm it no longer blocks the whole site.

⚠ Common Mistakes

- Confusing `Disallow: /` (block all) with `Disallow:` empty (allow all); the slash is the only difference.
- Checking `'/' in line` instead of the parsed value matches any rule containing a slash.
- Assuming `Disallow: /*` is needed for a full block; the bare `/` already blocks everything.

Skills gained site-wide block detection membership test value collection

→ Where You'll Use This: A lone Disallow: / is the single most damaging robots mistake, so deploy checks and SEO monitors specifically watch for it to prevent a site vanishing from search.

⚡ Mental Model

Disallow: / is pulling the master breaker: one line cuts power to every room, which is exactly why a leaked staging file is so dangerous.

Project 42 Treat an Empty Disallow as Allow-All

💡 The Idea Behind It

A Disallow with no value is the mirror opposite of Disallow: /: it explicitly opens the whole site to a bot. This project collects Disallow values and, when every entry is an empty string, reports that the entire site is allowed; otherwise it lists the real blocked prefixes. The empty value is a common, deliberate way to grant a crawler unrestricted access.

What You'll Build & Learn

Recognise that an empty Disallow value permits the whole site rather than blocking anything.

- empty Disallow means allow everything
- it is the opposite of Disallow: /
- filter out blank values

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 41: detect a site-wide disallow block. Project 43 changes the surface problem while preserving the underlying method.

progress check

Reading target: treat an empty disallow as allow-all is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

- Evidence: `print('blocked prefixes:', [r for r in rules if r])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: *`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if field.strip().lower() == 'disallow':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('blocked prefixes:', [r for r in rules if r])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if field.strip().lower() == 'disallow':`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Treat an Empty Disallow as Allow-All: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Disallow, rules. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: * | Core: if field.strip().lower() == 'disallow': | Evidence: print('blocked prefixes:', [r for r in rules if r])

🛠️ Reader to Writer Bridge

1. Read: explain treat an empty disallow as allow-all in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 41.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 43 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('blocked prefixes:', [r for r in rules if r])`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of treat an empty disallow as allow-all and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

An empty Disallow value matches nothing, so a group whose only rule is `Disallow:` imposes no restriction at all, the canonical allow-everything signal.

```
robots = """User-agent: *
Disallow:
"""
rules = []
for line in robots.splitlines():
    field, _, value = line.partition(':')
    if field.strip().lower() == 'disallow':
        rules.append(value.strip())
if rules == [''] or all(r == '' for r in rules):
    print('empty Disallow -> entire site allowed')
else:
    print('blocked prefixes:', [r for r in rules if r])
```

```
output
empty Disallow -> entire site allowed
```

How it works:

1. The robots string has a Disallow line with nothing after the colon.
2. Each Disallow value is stripped and appended to rules, so the empty line yields an empty string.
3. The check rules == [''] or all values being empty triggers the allow-all message.
4. Otherwise the code would print the non-empty blocked prefixes instead.

Try it:

1. Add a real Disallow: /admin and confirm the code now lists blocked prefixes
2. Mix an empty and a non-empty Disallow and decide which message should win
3. Print a count of empty versus non-empty Disallow lines for clarity
4. Add a non-empty `Disallow: /admin` line and watch the verdict change.

⚠ Common Mistakes

- Treating an empty Disallow as a blank line and dropping it loses the explicit allow-all intent.
- Comparing the value to `'/'` mistakes allow-all for block-all.

- Forgetting that an empty Disallow next to real Disallow lines does not undo them.

Skills gained empty-value handling | allow-all detection | list filtering

→ Where You'll Use This: Distinguishing an empty Disallow from a missing one keeps an audit from misreporting a deliberately open robots block as either broken or restrictive.

Mental Model

An empty Disallow is an open gate with the sign still hanging: the gate names a rule but lets everyone walk straight through.

Project 43 Strip Comments Before Parsing Rules

The Idea Behind It

A hash starts a comment that runs to the end of its line, whether the line is all comment or a directive with a trailing note. This project splits each line on its first hash, keeps the part before it, strips whitespace, and discards lines that become empty. Cleaning comments first stops directive parsing from choking on human annotations mixed into the file.

What You'll Build & Learn

Strip whole-line and trailing comments so only clean directive text survives for later parsing.

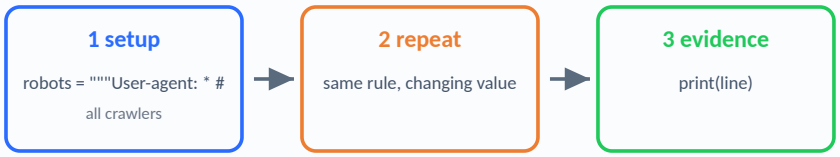
- a hash begins a comment
- comments run to line end
- clean before parsing directives

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 42: treat an empty disallow as allow-all. Project 44 changes the surface problem while preserving the underlying method.

progress check

Reading target: strip comments before parsing rules is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `robots = """User-agent: * # all crawlers` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(line)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: * # all crawlers`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(line)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Strip Comments Before Parsing Rules: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, all, crawlers. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: * # all crawlers | Core: if line: | Evidence: print(line)

🛠️ Reader to Writer Bridge

1. Read: explain strip comments before parsing rules in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 42.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 44 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(line)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: * # all crawlers` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of strip comments before parsing rules and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Cutting each line at its first `#` and stripping whitespace removes both full-line and trailing comments, leaving only the directive text to parse.

```
robots = """User-agent: *  # all crawlers
Disallow: /admin  # back office
# whole-line comment
Allow: /public
"""
cleaned = []
for line in robots.splitlines():
    line = line.split('#', 1)[0].strip()
    if line:
        cleaned.append(line)
for line in cleaned:
    print(line)
```

```
output
User-agent: *
Disallow: /admin
Allow: /public
```

How it works:

1. The robots string carries inline comments after directives and one whole-line comment.
2. Each line is split on its first '#' and only the portion before it is kept.
3. That portion is stripped, and non-empty results are appended to cleaned.
4. The whole-line comment vanishes and the trailing notes are trimmed, printing three bare directives.

Try it:

1. Feed a line that is only whitespace before a comment and confirm it is dropped
2. Preserve a hash that appears inside a quoted value rather than treating it as a comment
3. Count how many comment lines were removed and print that total
4. Add a path that legitimately contains `#fragment` and see it get truncated.

⚠ Common Mistakes

- Splitting on `#` without `maxsplit=1` is harmless here but discards the rest if you later need it.
- A `#` inside a quoted value would be cut too; robots.txt has no quoting, so this is safe but worth knowing.
- Dropping the empty-after-strip check keeps blank lines that the parser must then skip anyway.

Skills gained comment stripping | str.split limit | line cleaning

→ Where You'll Use This: Comment removal is a mandatory preprocessing step in robots parsers, since real files routinely document their rules with hash comments a naive parser would mishandle.

Mental Model

The hash is an editor's red pen: everything to the right of it on the line is struck out before the document goes to the parser.

Project 44 Index Every User-Agent Group Separately

The Idea Behind It

A robots.txt can name many bots, each carrying its own block of rules. This project parses the file into a dictionary keyed by user-agent, skipping blanks and attaching rules to whichever agent is currently open. It then prints the sorted set of agents and the rule count under each, so you can answer questions per bot rather than treating the file as one undifferentiated list.

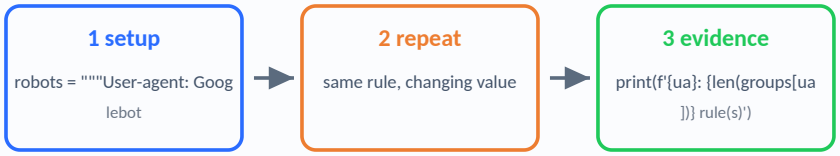
What You'll Build & Learn

Index every user-agent block into its own dictionary entry and report how many rules each bot has.

- one file can target many bots
- key rules by user-agent
- count rules per group

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 43: strip comments before parsing rules. Project 45 changes the surface problem while preserving the underlying method.



progress check

Reading target: index every user-agent group separately is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: Googlebot` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{ua}: {len(groups[ua])} rule(s)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: Googlebot`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

🛠️ Reader to Writer Bridge

1. Read: explain index every user-agent group separately in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 43.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 45 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{ua}: {len(groups[ua])} rule(s)')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `robots = """User-agent: Googlebot` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of index every user-agent group separately and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each `User-agent` line starts a fresh keyed list and the directives below it accumulate into that list, so the dict ends up holding one rule group per bot.

```
robots = """User-agent: Googlebot
Disallow: /no-google

User-agent: Bingbot
Disallow: /no-bing
```

```
User-agent: *
Disallow: /private
"""
groups, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    field, _, value = line.partition(':')
    field, value = field.strip().lower(), value.strip()
    if field == 'user-agent':
        agent = value
        groups.setdefault(agent, [])
    elif agent:
        groups[agent].append((field, value))
print('groups found:', sorted(groups))
for ua in sorted(groups):
    print(f'{ua}: {len(groups[ua])} rule(s)')
```

```
output
groups found: ['*', 'Bingbot', 'Googlebot']
*: 1 rule(s)
Bingbot: 1 rule(s)
Googlebot: 1 rule(s)
```

How it works:

1. The robots string defines Googlebot, Bingbot, and wildcard blocks separated by blank lines.
2. Lines are stripped, blanks skipped, and fields partitioned and lowercased.
3. A user-agent line opens a new dictionary key; other lines append to the current agent's list.
4. The code prints the sorted agent names and then each agent with its rule count of one.

Try it:

1. Add a second Disallow under Bingbot and confirm its rule count rises to two
2. Report the total rule count across all groups in addition to the per-bot counts
3. Detect and warn when a user-agent name appears with no rules beneath it
4. Add a second block for `Googlebot` and watch its rule count grow.

⚠ Common Mistakes

- Resetting the group dict on every blank line wipes earlier blocks.
- Using a plain dict without `setdefault` raises KeyError on the first rule of a new group.
- Sorting bots by insertion order instead of name makes the printed list nondeterministic.

Skills gained multi-bot indexing dict grouping rule counting

→ Where You'll Use This: Indexing per bot is the data model behind comparing how a site treats Googlebot versus aggressive scrapers, a routine part of crawl-management audits.

Mental Model

Think of a hotel front desk with one mail slot per guest: each bot has its own slot, and you check the slot that belongs to the bot you care about.

Project 45 Answer Can Googlebot Fetch This Path

The Idea Behind It

The practical question is binary: may this bot fetch this URL? This project parses groups, then defines can_fetch, which scans the active rules and keeps the action of the longest matching pattern, favouring Allow on ties via its combined length check. Wrapping group selection and longest-match precedence into one helper turns the whole file into a yes-or-no answer per path.

What You'll Build & Learn

Wrap parsing and precedence into a can_fetch helper that returns whether a bot may crawl a given path.

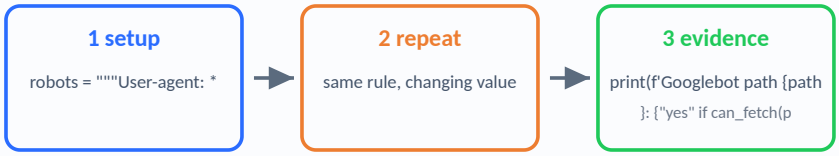
- crawlability reduces to yes or no
- longest match selects the action
- Allow wins on a tie

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 44: index every user-agent group separately. Project 46 changes the surface problem while preserving the underlying method.

progress check

Reading target: answer can googlebot fetch this path is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

- Evidence: `print(f'Googlebot path {path}: {"yes" if can_fetch(path, rules) else "no"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: *`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'Googlebot path {path}: {"yes" if can_fetch(path, rules) else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

   same idea, new surface

🔍 From Concept to Code (Python)

`can_fetch` finds the longest matching rule (Allow winning equal-length ties) and returns whether that rule allows the path, giving a clean per-URL crawl decision.

```
robots = """User-agent: *
Disallow: /admin
Disallow: /cart
Allow: /cart/wishlist
"""
groups, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent':
        agent = v; groups.setdefault(agent, [])
    elif agent:
        groups[agent].append((f, v))
def can_fetch(path, rules):
    best_len, action = -1, 'allow'
    for a, p in rules:
        if p and path.startswith(p) and len(p) >= best_len:
            if len(p) > best_len or a == 'allow':
                best_len, action = len(p), a
    return action == 'allow'
rules = groups.get('Googlebot', groups['*'])
for path in ['/blog', '/admin', '/cart', '/cart/wishlist']:
    print(f'Googlebot path {path}: {"yes" if can_fetch(path, rules) else
"no"}')
```

```
output
Googlebot path /blog: yes
Googlebot path /admin: no
Googlebot path /cart: no
Googlebot path /cart/wishlist: yes
```

How it works:

1. The file is parsed into groups with the now-familiar partition loop.
2. can_fetch scans rules, and a non-empty pattern the path starts with updates best_len when it is longer or an equal-length Allow.
3. rules is taken from the Googlebot group if present, else the wildcard.
4. /cart is blocked but /cart/wishlist crawls because its longer Allow beats the /cart Disallow.

Try it:

1. Pass a list of paths and print a crawlable count alongside each verdict

2. Add an early return when rules is empty so unrestricted bots short-circuit to yes
3. Extend the patterns with a wildcard and confirm can_fetch still resolves correctly
4. Add `Allow: /admin/help` and confirm that one sub-path becomes fetchable.

⚠ Common Mistakes

- Skipping the `if p` guard lets an empty rule string match every path with length 0.
- Using `groups['Googlebot']` directly raises KeyError when only a `*` group exists; `.get` with a fallback avoids that.
- Returning on the first matching rule instead of the longest gives wrong answers for nested paths.

Skills gained can_fetch helper | longest-match | Allow tie-break

→ Where You'll Use This: A can_fetch function is the public API of a robots library, called by crawlers and SEO tools to gate every URL fetch before a request goes out.

Mental Model

can_fetch is a turnstile that swallows the whole rulebook and lights up green or red for each URL you push through it.

Project 46 Count Allowed Versus Blocked URLs

The Idea Behind It

An audit over a URL list should summarise the damage: how many URLs stay crawlable and how many a Disallow set hides. This project counts allowed and blocked URLs with the same prefix test, then computes a block rate as a percentage of the total. That single number is a quick health signal for how aggressively a robots.txt is pruning the crawlable surface.

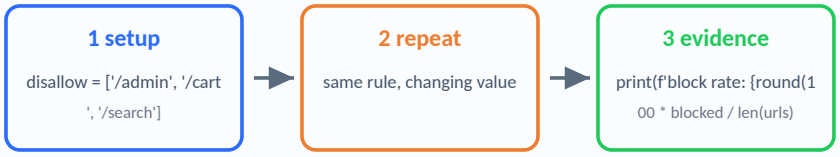
What You'll Build & Learn

Tally allowed and blocked URLs against a Disallow set and report the resulting block-rate percentage.

- audits summarise crawl coverage
- tally allowed versus blocked
- block rate as one signal

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 45: answer can googlebot fetch this path. Project 47 changes the surface problem while preserving the underlying method.



progress check

Reading target: count allowed versus blocked urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `disallow = ['/admin', '/cart', '/search']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'block rate: {round(100 * blocked / len(urls), 1)}%')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`disallow = ['/admin', '/cart', '/search']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if any(u.startswith(r) for r in disallow):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'block rate: {round(100 * blocked / len(urls), 1)}%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(u.startswith(r) for r in disallow):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Allowed Versus Blocked URLs: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: disallow, admin, cart, search, urls. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: disallow = ['/admin', '/cart', '/search'] | Core: if any(u.startswith(r) for r in disallow): | Evidence: print(f'block rate: {round(100 * blocked / len(urls), 1)}%')

🛠️ Reader to Writer Bridge

1. Read: explain count allowed versus blocked urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 45.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 47 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'block rate: {round(100 * blocked / len(urls), 1)}%')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `disallow = ['/admin', '/cart', '/search']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count allowed versus blocked urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Tallying each URL against the Disallow prefixes splits the list into allowed and blocked counts, and the ratio gives a block-rate percentage.

```
disallow = ['/admin', '/cart', '/search']
urls = ['/', '/blog', '/admin/users', '/products', '/cart', '/search?q=x',
'/about']
allowed = blocked = 0
for u in urls:
    if any(u.startswith(r) for r in disallow):
        blocked += 1
    else:
        allowed += 1
print(f'allowed: {allowed}')
print(f'blocked: {blocked}')
print(f'block rate: {round(100 * blocked / len(urls), 1)}%')
```

```
output
allowed: 4
blocked: 3
block rate: 42.9%
```

How it works:

1. disallow lists three blocked prefixes and urls lists seven candidate paths.
2. allowed and blocked counters start at zero.
3. For each URL, any() with startswith increments blocked on a match and allowed otherwise.
4. The code prints both counts and round(100 * blocked / total, 1), yielding a 42.9% block rate.

Try it:

1. Print the list of blocked URLs so the report names them, not just a count
2. Add an Allow override and account for it before tallying each URL
3. Guard against an empty URL list so the percentage does not divide by zero
4. Add `/search/help` to an Allow list and exclude it from the blocked tally.

⚠ Common Mistakes

- Counting URLs that merely contain a rule substring instead of starting with it inflates the blocked count.

- Dividing integers without `* 100` or floats gives 0 for the percentage in older code.
- Double-counting a URL matched by two rules; `any` short-circuits to count it once.

Skills gained block-rate metric counting loop percentage calc

→ **Where You'll Use This:** A block-rate summary is the headline number in a crawl-coverage report, flagging at a glance when a robots.txt is hiding far more of a site than intended.

Mental Model

It is a quick census of the site's doors: count how many are open versus locked, then quote the locked fraction as a one-line headline.

Project 47 Parse Meta Robots from an HTML Head

The Idea Behind It

Beyond robots.txt, a page can carry a meta robots tag whose content lists directives like noindex and nofollow. This project uses a regex to pull the content value out of the HTML head, splits it on commas into a lowercased set, and derives whether the page is indexable and whether its links are followed. It tells you if a crawlable page actually wants to be indexed.

What You'll Build & Learn

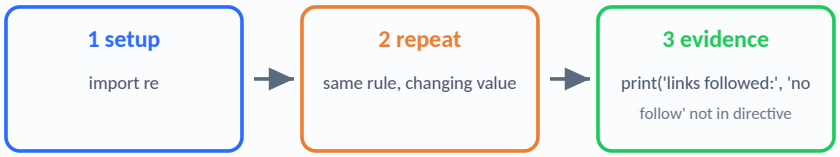
Extract meta robots directives from an HTML head and report indexability and link-following status.

- meta robots adds page-level control
- regex extracts the content value
- split directives into a set

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 46: count allowed versus blocked urls. Project 48 changes the surface problem while preserving the underlying method.

progress check



Reading target: parse meta robots from an html head is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('links followed:', 'nofollow' not in directives)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if m:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('links followed:', 'nofollow' not in directives)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Parse Meta Robots from an HTML Head: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, html, head, meta, name. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if m: | Evidence: print('links followed:', 'nofollow' not in directives)

🛠️ Reader to Writer Bridge

1. Read: explain parse meta robots from an html head in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 46.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 48 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('links followed:', 'nofollow' not in directives)`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of parse meta robots from an html head and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A regex pulls the `content` attribute of the robots meta tag, then splitting on commas and lowercasing yields the directive set used to answer index/follow questions.

```
import re
html = '<head><meta name="robots" content="noindex, nofollow"><title>X</title>
</head>'
m = re.search(r'<meta\s+name=["\']robots["\']\s+content=["\']([^"\']+)["\']',
html, re.I)
directives = set()
if m:
    directives = {d.strip().lower() for d in m.group(1).split(',')}
print('directives:', sorted(directives))
print('indexable:', 'noindex' not in directives)
print('links followed:', 'nofollow' not in directives)
```

```
output
directives: ['nofollow', 'noindex']
indexable: False
links followed: False
```

How it works:

1. html holds a head with a meta robots tag whose content is noindex, nofollow.
2. re.search with a case-insensitive flag captures the content attribute value.
3. The captured string is split on commas into a lowercased directives set.
4. indexable is 'noindex' not in directives and links followed is 'nofollow' not in directives, both False here.

Try it:

1. Handle a content value of index, follow and confirm both derived flags become True
2. Capture a googlebot-scoped meta tag separately from the generic robots tag
3. Detect a noarchive or nosnippet directive and print its status too
4. Add `noarchive` to the content and report it separately.

⚠ Common Mistakes

- A greedy or unanchored regex can grab the wrong meta tag when several exist.
- Not lowercasing leaves `NoIndex` unmatched against the literal `noindex` check.

- Confusing meta robots (page must be crawled to read it) with robots.txt (blocks the crawl entirely).

Skills gained meta robots parsing | regex capture | set membership

→ Where You'll Use This: Meta robots extraction is core to page-level SEO audits, catching pages set to noindex that still appear in sitemaps or internal links by mistake.

Mental Model

If robots.txt is the doorman deciding who enters, the meta robots tag is a note on the page itself saying whether it wants its photo in the directory.

Project 48 Read Index Rules from an X-Robots-Tag Header

The Idea Behind It

Non-HTML files such as PDFs cannot carry a meta tag, so their indexing rules ride in the X-Robots-Tag HTTP header instead. This project reads that header from a headers dict, splits its value into a lowercased set, and checks a list of common directives against it. Parsing the header gives the same noindex and noarchive controls a meta tag would for HTML pages.

What You'll Build & Learn

Parse the X-Robots-Tag response header into a directive set and report which index controls are active.

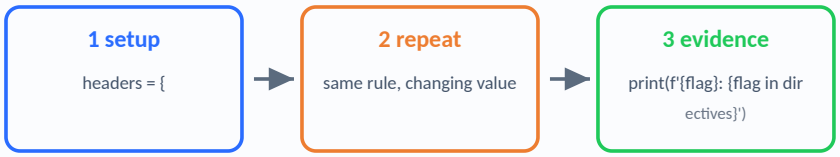
- headers control non-HTML indexing
- X-Robots-Tag mirrors meta robots
- split a header into a set

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 47: parse meta robots from an html head. Project 49 changes the surface problem while preserving the underlying method.

progress check

Reading target: read index rules from an x-robots-tag header is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `headers = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{flag}: {flag in directives}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`headers = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`directives = {d.strip().lower() for d in tag.split(',') if d.strip()}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{flag}: {flag in directives}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Read Index Rules from an X-Robots-Tag Header: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: headers, Content, Type, application, pdf. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: headers = { | Core: directives = {d.strip().lower() for d in tag.split(',') if d.strip()} | Evidence: print(f'{flag}: {flag in directives}')

🛠️ Reader to Writer Bridge

1. Read: explain read index rules from an x-robots-tag header in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 47.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 49 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{flag}: {flag in directives}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `headers = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of read index rules from an x-robots-tag header and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The header value is a comma-separated directive list; splitting and lowercasing it into a set lets a simple membership test answer each indexing question.

```
headers = {
    'Content-Type': 'application/pdf',
    'X-Robots-Tag': 'noindex, noarchive',
}
tag = headers.get('X-Robots-Tag', '')
directives = {d.strip().lower() for d in tag.split(',') if d.strip()}
print('X-Robots-Tag directives:', sorted(directives))
for flag in ['noindex', 'nofollow', 'noarchive', 'nosnippet']:
    print(f'{flag}: {flag in directives}')
```

```
output
X-Robots-Tag directives: ['noarchive', 'noindex']
noindex: True
nofollow: False
noarchive: True
nosnippet: False
```

How it works:

1. headers includes a PDF content type and an X-Robots-Tag of noindex, noarchive.
2. tag reads the header value, defaulting to an empty string when absent.
3. The value is split on commas, stripped, lowercased, and emptied entries dropped, forming directives.
4. Looping over four candidate flags prints noindex and noarchive as True, nofollow and nosnippet as False.

Try it:

1. Add nosnippet to the header value and confirm its flag turns True
2. Handle a missing X-Robots-Tag header and print a sensible default state
3. Combine multiple header values, as some servers send the tag more than once
4. Add `nosnippet` to the header value and watch its flag flip True.

⚠ Common Mistakes

- Looking up the header with a case-sensitive key when real headers vary in case.
- Forgetting `if d.strip()` lets a trailing comma add an empty directive to the set.

- Assuming the header only carries one directive; it is a comma-separated list like the meta tag.

Skills gained X-Robots-Tag parsing | header dict | directive set

→ Where You'll Use This: X-Robots-Tag parsing matters whenever you audit PDFs, images, or API responses, where header directives are the only way to keep non-HTML assets out of the index.

Mental Model

A PDF has no margins to scribble in, so the noindex instruction is tucked into the delivery envelope's header rather than written on the page.

Project 49 Flag Rules That Block CSS and JS

The Idea Behind It

Blocking /css/ or /js/ stops Google from rendering a page the way users see it, which can hurt rankings. This project collects every Disallow value, then flags any whose path mentions css or js or ends in those extensions. Auditing the Disallow list for render-critical resources is a common and high-impact SEO fix that a quick scan can surface automatically.

What You'll Build & Learn

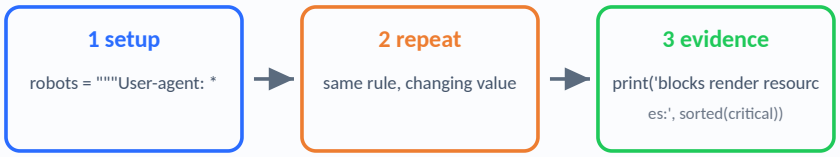
Scan the Disallow list for blocked CSS or JS paths that would stop Google rendering the page.

- blocking CSS or JS breaks rendering
- render gaps hurt rankings
- scan disallows for assets

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 48: read index rules from an x-robots-tag header. Project 50 changes the surface problem while preserving the underlying method.

progress check



Reading target: flag rules that block css and js is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('blocks render resources:', sorted(critical))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

3. Transfer: change one small part of flag rules that block css and js and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Scanning each Disallow value for `css`/`js` markers (or `.css`/`.js` suffixes) flags the rules that would starve the renderer of stylesheets and scripts.

```
robots = """User-agent: *
Disallow: /css/
Disallow: /js/
Disallow: /admin
"""
blocked = []
for line in robots.splitlines():
    f, _, v = line.partition(':')
    if f.strip().lower() == 'disallow':
        blocked.append(v.strip())
critical = []
for path in blocked:
    low = path.lower()
    if 'css' in low or 'js' in low or low.endswith('.css') or
low.endswith('.js'):
        critical.append(path)
print('blocked paths:', blocked)
print('blocks render resources:', sorted(critical))
```

```
output
blocked paths: ['/css/', '/js/', '/admin']
blocks render resources: ['/css/', '/js/']
```

How it works:

1. The robots string disallows /css/, /js/, and /admin under the wildcard agent.
2. Each Disallow value is collected into the blocked list.
3. For each path, a lowercased copy is tested for css or js substrings or matching extensions.
4. Matching paths go into critical, so the code reports /css/ and /js/ as render-blocking, leaving /admin out.

Try it:

1. Extend the check to fonts and images so /fonts/ and /img/ are also flagged
2. Avoid a false positive on a path like /jsmith by requiring a folder or extension boundary
3. Print a remediation hint suggesting an Allow override for each flagged resource
4. Add `/assets/app.js` and confirm the suffix branch catches it.

⚠ Common Mistakes

- Matching only file extensions misses directory blocks like `/css/` that contain no dot.
- A path like `/justice` contains 'js' and would false-positive; tighten the test for production.
- Forgetting to lowercase means `/CSS/` slips past the marker check.

Skills gained render-resource audit substring test extension check

→ **Where You'll Use This:** Flagging blocked CSS and JS is a staple of technical-SEO audits, since render-blocking robots rules are a recurring cause of mobile-usability and ranking issues.

⚡ Mental Model

Blocking the CSS and JS folders is like handing Google a page with the stylesheet torn out: it sees raw bones, not the page real visitors load.

Project 50 Flag Unknown robots.txt Directives

💡 The Idea Behind It

Crawlers silently ignore directives they do not recognise, so a typo like Craw-delay is simply dropped with no error. This project defines a set of known fields and prints every line whose field is not in it. Listing the unknown directives surfaces these dead lines, including misspellings and unsupported keywords, before they cause confusion about why a rule never takes effect.

What You'll Build & Learn

List robots.txt fields that are not recognised so typos and unsupported directives become visible.

- unknown directives are silently ignored
- a typo becomes a dead line
- validate fields against a known set

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 49: flag rules that block css and js. Project 51 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag unknown robots.txt directives is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

- Evidence: `print(f'unknown directive: {field}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: *`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'unknown directive: {field}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Unknown robots.txt Directives: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Disallow, admin. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: robots = """User-agent: * | Core: if not line: | Evidence: print(f'unknown directive: {field}')

🛠️ Reader to Writer Bridge

1. Read: explain flag unknown robots.txt directives in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 49.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 51 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'unknown directive: {field}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag unknown robots.txt directives and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing each line's field name against a set of standard directives reveals typos and non-standard extensions that Googlebot will skip.

```
robots = """User-agent: *
Disallow: /admin
Craw-delay: 5
Host: example.com
Allow: /public
Visit-time: 0600-0845
"""
known = {'user-agent', 'disallow', 'allow', 'sitemap', 'crawl-delay'}
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    field = line.partition(':')[0].strip().lower()
    if field not in known:
        print(f'unknown directive: {field}')
```

```
output
unknown directive: craw-delay
unknown directive: host
unknown directive: visit-time
```

How it works:

1. known holds the recognised field names like user-agent, disallow, and crawl-delay.
2. Each line is stripped, blanks skipped, and its field extracted, stripped, and lowercased.
3. When the field is not in the known set, the code prints it as an unknown directive.
4. The misspelled craw-delay plus host and visit-time are reported as unknown.

Try it:

1. Add the line number to each warning so the typo is easy to locate
2. Suggest the closest known field for an unknown one using a string-distance check
3. Treat host as known-but-deprecated and label it differently from a true typo
4. Add `Clean-param` (a Yandex directive) and decide whether to allow it.

⚠ Common Mistakes

- Treating non-standard but real directives (like `Host` for Yandex) as errors rather than warnings.
- Not lowercasing the field lets `Sitemap` register as unknown against a lowercase known-set.
- Flagging blank lines as unknown directives; skip empty lines first.

Skills gained directive validation | set membership | typo detection

→ Where You'll Use This: Flagging unknown directives is a core robots-linter feature, catching the silent typos and legacy fields that leave an intended rule doing nothing in production.

⚡ Mental Model

The parser is a customs officer with a fixed list of valid forms: hand it a misspelled one and it does not argue, it just sets it aside unread.

Project 51 Respect Case-Sensitive robots.txt Paths

💡 The Idea Behind It

Directive names in robots.txt are case-insensitive, but the path values are case-sensitive, so Disallow: /Admin does not block /admin. This project tests several differently-cased paths against a single capitalised prefix using startswith. Confusing the two causes either over-blocking or under-blocking, and seeing /admin crawl while /Admin blocks makes the distinction concrete.

What You'll Build & Learn

Show that Disallow paths are case-sensitive so only exactly-cased paths match the prefix.

- directive names are case-insensitive
- path values are case-sensitive
- case mismatches misblock URLs

🧭 Skill Roadmap

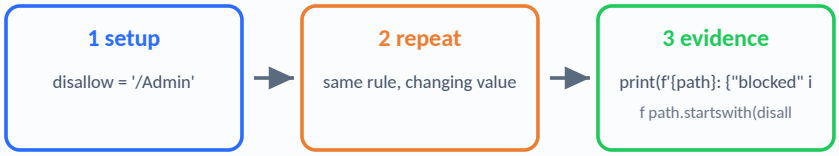
Skill step: moves you from recognition toward independent tracing. It builds on Project 50: flag unknown robots.txt directives. Project 52 changes the surface problem while preserving the underlying method.

progress check

Reading target: respect case-sensitive robots.txt paths is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens



- Setup: `disallow = '/Admin'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`disallow = '/Admin'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')`

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Respect Case-Sensitive robots.txt Paths: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: disallow, Admin, paths, admin, login. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: disallow = '/Admin' | Core: print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}') | Evidence: print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')

🛠️ Reader to Writer Bridge

1. Read: explain respect case-sensitive robots.txt paths in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 50.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 52 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `disallow = '/Admin'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of respect case-sensitive robots.txt paths and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Plain `str.startswith` is case-sensitive, so the `/Admin` rule blocks `/Admin` and `/Admin/users` but leaves the lowercase `/admin` and all-caps `/ADMIN/login` crawlable.

```
disallow = '/Admin'
paths = ['/Admin', '/admin', '/ADMIN/login', '/Admin/users']
```

```
    for path in paths:
        print(f'{path}: {"blocked" if path.startswith(disallow) else "crawl"}')
```

```
output
/Admin: blocked
/admin: crawl
/ADMIN/login: crawl
/Admin/users: blocked
```

How it works:

1. disallow holds the capitalised prefix /Admin.
2. paths lists four variants differing only in letter case.
3. Each path is tested with path.startswith(disallow) without any case folding.
4. /Admin and /Admin/users match and block, while lowercase /admin and uppercase /ADMIN/login crawl.

Try it:

1. Add a second rule for /admin and confirm both cases are now blocked
2. Implement a case-insensitive variant and discuss why it diverges from the spec
3. Test a mixed-case path like /Admin/Users to confirm only the prefix case matters
4. Lowercase both sides and watch every variant get blocked.

⚠ Common Mistakes

- Lowercasing the path before comparison wrongly blocks `/admin` and `/ADMIN/login`.
- Assuming the whole robots.txt is case-insensitive; only directive keywords are, not the paths.
- Expecting the rule to behave like a case-insensitive filter; `/admin` slips through while `/Admin/users` is correctly caught.

Skills gained case sensitivity | startswith | path matching

→ Where You'll Use This: Case sensitivity catches subtle robots bugs where a rule written in the wrong case fails to protect the intended URLs or accidentally blocks a different casing.

Mental Model

URL paths are like Unix filenames: Admin and admin are two different doors, so a rule guarding one leaves the other wide open.

Project 52 Handle Trailing Slashes in Disallow Rules

The Idea Behind It

Disallow: /blog and Disallow: /blog/ are not the same rule. This project tests four paths against both a slashless and a slashed prefix, printing each result. The slashless form also catches /blogger because the prefix matches, while the slashed form is confined to the directory and its children. The trailing slash narrows the match to a folder boundary.

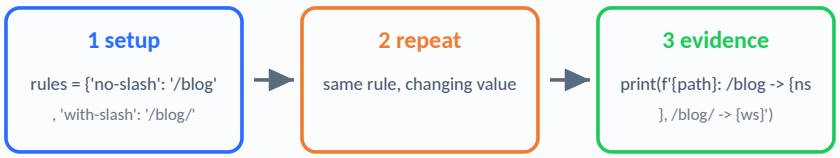
What You'll Build & Learn

Contrast a slashless and a slashed Disallow prefix to show how a trailing slash narrows the match.

- a trailing slash changes the match
- slashless catches sibling prefixes
- slashed confines to a directory

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 51: respect case-sensitive robots.txt paths. Project 53 changes the surface problem while preserving the underlying method.



progress check

Reading target: handle trailing slashes in disallow rules is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `rules = {'no-slash': '/blog', 'with-slash': '/blog/'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: /blog -> {ns}, /blog/ -> {ws}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`rules = {'no-slash': '/blog', 'with-slash': '/blog/'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`for path in paths:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: /blog -> {ns}, /blog/ -> {ws}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for path in paths:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Handle Trailing Slashes in Disallow Rules: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: rules, no, slash, blog, paths. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: rules = {'no-slash': '/blog', 'with-slash': '/blog/'} | Core: for path in paths: | Evidence: print(f'{path}: /blog -> {ns}, /blog/ -> {ws}')

🛠️ Reader to Writer Bridge

1. Read: explain handle trailing slashes in disallow rules in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 51.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 53 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: /blog -> {ns}, /blog/ -> {ws}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `rules = {'no-slash': '/blog', 'with-slash': '/blog/'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of handle trailing slashes in disallow rules and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Prefix matching means `/blog` matches anything starting with those five characters, including `/blogger`, whereas `/blog/` requires the slash and so excludes the unrelated `/blogger` path.

```
rules = {'no-slash': '/blog', 'with-slash': '/blog/'}
paths = ['/blog', '/blog/', '/blog/post', '/blogger']
for path in paths:
    ns = path.startswith(rules['no-slash'])
    ws = path.startswith(rules['with-slash'])
    print(f'{path}: /blog -> {ns}, /blog/ -> {ws}')
```

```
output
/blog: /blog -> True, /blog/ -> False
/blog/: /blog -> True, /blog/ -> True
```

```
/blog/post: /blog -> True, /blog/ -> True
/blogger: /blog -> True, /blog/ -> False
```

How it works:

1. rules maps 'no-slash' to /blog and 'with-slash' to /blog/.
2. paths includes /blog, /blog/, /blog/post, and the lookalike /blogger.
3. Each path is tested against both prefixes with startswith into ns and ws.
4. /blogger matches /blog but not /blog/, exposing how the slash blocks the false sibling match.

Try it:

1. Add /blog-archive to the paths and observe which prefix catches it
2. Decide and implement which form correctly blocks only the blog directory
3. Report a warning when a slashless rule would catch an unintended sibling
4. Add `/blog-archive` and see which rule catches it.

⚠ Common Mistakes

- Assuming `/blog` only blocks the blog section; it also blocks lookalikes like `/blogger`.
- Thinking `/blog/` blocks the bare `/blog` URL; it does not, since `/blog` lacks the trailing slash.
- Adding a trailing slash to normalize paths changes which rules match.

Skills gained trailing-slash semantics | prefix comparison | boundary matching

→ Where You'll Use This: Understanding the trailing slash prevents a common audit error where a folder rule unexpectedly blocks sibling pages whose names share the same opening characters.

Mental Model

Without the slash, /blog is a prefix net that scoops up /blogger too; adding the slash draws the boundary right at the folder wall.

Project 53 Default to Allow When No Rule Matches

The Idea Behind It

robots.txt is permissive by default: a path the file never mentions stays crawlable. This project tests each path against both a Disallow set and an Allow set, marking a URL blocked only when a Disallow matches and no Allow does. Modelling the default-allow rule explicitly stops an audit from wrongly flagging unlisted URLs, which crawlers are free to fetch, as blocked.

What You'll Build & Learn

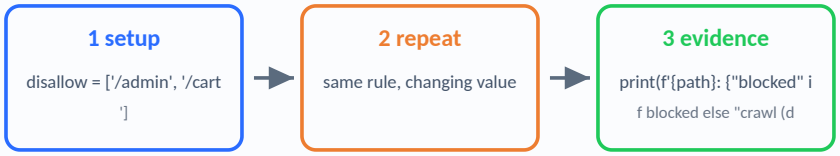
Apply default-allow so a path is blocked only when a Disallow matches and no Allow overrides it.

- unmentioned paths are crawlable
- default behaviour is allow
- Allow can override a Disallow

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 52: handle trailing slashes in disallow rules. Project 54 changes the surface problem while preserving the underlying method.

progress check



Reading target: default to allow when no rule matches is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `disallow = ['/admin', '/cart']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"blocked" if blocked else "crawl (default allow)"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`disallow = ['/admin', '/cart']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"blocked" if blocked else "crawl (default allow)"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `disallow = ['/admin', '/cart']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of default to allow when no rule matches and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A path is blocked only when a Disallow matches and no Allow rescues it; everything else, including unlisted paths, falls through to the default-allow.

```
disallow = ['/admin', '/cart']
allow = ['/cart/public']
paths = ['/blog', '/contact', '/admin', '/cart/public']
for path in paths:
    d = any(path.startswith(r) for r in disallow)
    a = any(path.startswith(r) for r in allow)
    blocked = d and not a
    print(f'{path}: {"blocked" if blocked else "crawl (default allow)"}')
```

```
output
/blog: crawl (default allow)
/contact: crawl (default allow)
/admin: blocked
/cart/public: crawl (default allow)
```

How it works:

1. disallow lists two blocked prefixes and allow lists one override sub-path.
2. For each path, d is whether any Disallow matches and a whether any Allow matches.

3. blocked is d and not a, so a matched Allow rescues the path.
4. /blog and /contact are never listed and crawl under default allow; /admin blocks; /cart/public crawls via its Allow.

Try it:

1. Add a /search URL and confirm it crawls because the file never mentions it
2. Switch to longest-match resolution and compare results against this simpler model
3. Label each verdict with whether it came from a rule or the default
4. Remove the Allow list and watch `/cart/public` flip to blocked.

⚠ Common Mistakes

- Defaulting unmatched paths to blocked inverts robots.txt's permissive model.
- Ignoring the Allow list lets `/cart/public` get blocked by the `/cart` Disallow.
- Using `d or not a` instead of `d and not a` blocks far too much.

Skills gained default-allow model | Allow override | boolean logic

→ Where You'll Use This: Encoding the default-allow rule keeps crawl audits honest, since most of a site's URLs are unlisted and must be reported as crawlable rather than uncertain.

Mental Model

Picture a park that is open unless a sign forbids entry: no sign means walk right in, so any path the file forgot to mention is fair game.

Project 54 Check robots.txt Against the Size Limit

The Idea Behind It

Google parses only the first 500 KiB of a robots.txt and ignores anything past that, so a bloated file can have later rules silently dropped. This project measures the byte size with utf-8 encoding, compares it against the limit, and reports whether the file fits, plus its line count. Measuring the size catches an oversized file whose tail-end directives stop applying.

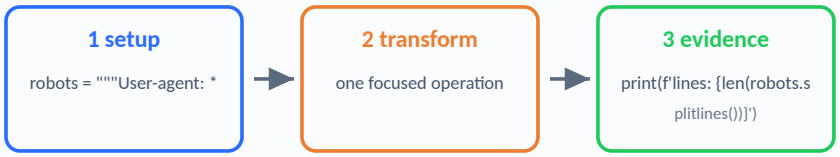
What You'll Build & Learn

Measure a robots.txt byte size against Google's 500 KiB limit and report whether it fits.

- Google parses only the first 500 KiB
- rules past the limit are ignored
- measure size in bytes not characters

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 53: default to allow when no rule matches. Project 55 changes the surface problem while preserving the underlying method.



progress check

Reading target: check robots.txt against the size limit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: *` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The logic is deliberately small: Python stores a value, applies one clear operation, and prints evidence. That tiny chain is the reading pattern larger programs still use.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'lines: {len(robots.splitlines())}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: *`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`Disallow: /admin`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print(f'lines: {len(robots.splitlines())}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `Disallow: /admin`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Check robots.txt Against the Size Limit: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Disallow, admin. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: robots = """User-agent: * | Core: Disallow: /admin | Evidence: print(f'lines: {len(robots.splitlines())}')

Reader to Writer Bridge

1. Read: explain check robots.txt against the size limit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 53.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 55 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'lines: {len(robots.splitlines())}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `robots = """User-agent: *` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check robots.txt against the size limit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Encoding the text to UTF-8 and taking its length gives the true byte size (not character count), which is what the 500 KiB parse limit applies to.

```
robots = """User-agent: *
Disallow: /admin
Disallow: /private
Sitemap: https://example.com/sitemap.xml
"""
size = len(robots.encode('utf-8'))
limit = 500000
print(f'robots.txt size: {size} bytes')
print(f'within {limit}-byte limit: {size <= limit}')
print(f'lines: {len(robots.splitlines())}')
```

```
output
robots.txt size: 91 bytes
within 500000-byte limit: True
lines: 4
```

How it works:

1. A small robots string holds two Disallow lines and a Sitemap.
2. size is len(robots.encode('utf-8')), the true byte length rather than the character count.
3. limit is 500000, and the code prints whether size is within it.
4. It also prints the line count, here 91 bytes across 4 lines, well within the cap.

Try it:

1. Build a large robots string and confirm the within-limit flag flips to False
2. Report the percentage of the limit consumed for an early-warning threshold
3. Account for multi-byte characters by adding non-ASCII text and rechecking the byte count
4. Multiply the robots text by 6000 and watch the limit check fail.

⚠ Common Mistakes

- Using `len(robots)` counts characters, not bytes; multibyte chars make the two differ.
- Confusing 500 KB (500000) with 500 KiB (512000); know which limit you are checking.
- Assuming rules past the limit error out; they are simply ignored, which is sneakier.

Skills gained byte-size check | utf-8 encoding | size limit

→ Where You'll Use This: A size check guards against generated robots files that grow past Google's limit, where the truncated tail quietly stops protecting or permitting URLs as intended.

⚡ Mental Model

Google reads robots.txt like a reader with a strict page budget: it stops at the 500 KiB mark, so anything written beyond that page is never seen.

Project 55 Merge Repeated Groups for the Same Bot

💡 The Idea Behind It

When a robots.txt names the same bot in two separate blocks, crawlers merge those rules into one group rather than letting the second block replace the first. This project parses the file with setdefault keyed by agent, so a repeated Googlebot key accumulates rules from both blocks. Merging is what makes split configurations behave, preserving every directive across the duplicated headers.

What You'll Build & Learn

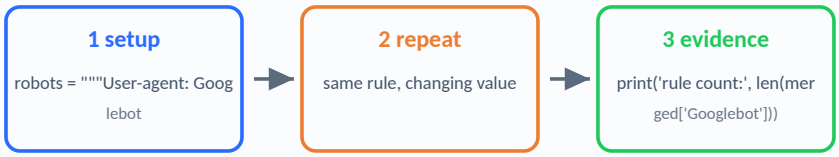
Merge rules from two blocks naming the same bot into a single combined rule group.

- repeated bot blocks are merged
- the second block does not replace
- setdefault accumulates rules

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 54: check robots.txt against the size limit. Project 56 changes the surface problem while preserving the underlying method.

progress check



Reading target: merge repeated groups for the same bot is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `robots = """User-agent: Googlebot` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('rule count:', len(merged['Googlebot']))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: Googlebot`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('rule count:', len(merged['Googlebot']))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Merge Repeated Groups for the Same Bot: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Googlebot, Disallow. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: Googlebot | Core: if not line: | Evidence: print('rule count:', len(merged['Googlebot']))

🛠️ Reader to Writer Bridge

1. Read: explain merge repeated groups for the same bot in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 54.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 56 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('rule count:', len(merged['Googlebot']))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `robots = """User-agent: Googlebot` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of merge repeated groups for the same bot and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Using `setdefault` keyed by bot name means a repeated `User-agent: Googlebot` reopens the existing list and appends to it, merging both blocks' rules.

```
robots = """User-agent: Googlebot
Disallow: /a

User-agent: Googlebot
Disallow: /b
Allow: /a/ok
"""
merged, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent':
        agent = v
        merged.setdefault(agent, [])
    elif agent:
        merged[agent].append((f, v))
print('Googlebot merged rules:', merged['Googlebot'])
print('rule count:', len(merged['Googlebot']))
```

```
output
Googlebot merged rules: [('disallow', '/a'), ('disallow', '/b'), ('allow', '/a/ok')]
rule count: 3
```

How it works:

1. The robots string has two Googlebot blocks separated by a blank line.
2. On each user-agent line, setdefault only creates the list if the key is new, never resetting it.
3. Rules from both blocks append to the same Googlebot list.
4. The merged group prints all three rules with a final count of three.

Try it:

1. Add a third Googlebot block and confirm all its rules join the merged group

2. Detect that the bot appears more than once and warn about a possibly unintended split
3. Compare merged behaviour against a replace model and print the difference
4. Add a third Googlebot block and confirm the rule count climbs.

⚠ Common Mistakes

- Reassigning `groups[agent] = []` on each block overwrites the earlier rules instead of merging.
- Assuming the last block wins; the spec merges all blocks for the same agent.
- Forgetting that case-insensitive agent names mean `googlebot` and `Googlebot` should merge too.

Skills gained group merging | setdefault | duplicate handling

→ Where You'll Use This: Merging duplicate groups reflects real crawler behaviour, so an audit of a config split across edits reports the bot's true effective ruleset rather than just the last block.

Mental Model

Two blocks for the same bot are like two pages of one shopping list: the crawler staples them together instead of throwing the first page away.

Project 56 Decide Wildcard Precedence by Effective Length

The Idea Behind It

When wildcard rules compete, Google compares pattern lengths with the asterisks and dollar signs stripped out. This project compiles each pattern to a regex, and for the rules that match a path computes an effective length by removing the wildcard characters, keeping the longer one and favouring Allow on a tie. That effective length decides which of two matching wildcard rules wins.

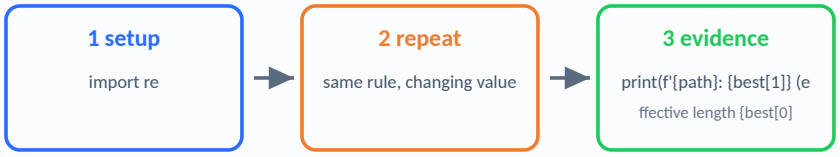
What You'll Build & Learn

Pick the winning wildcard rule by comparing pattern lengths with wildcard characters removed.

- wildcard winners use effective length
- strip stars and dollars before measuring
- Allow breaks an effective-length tie

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 55: merge repeated groups for the same bot. Project 57 changes the surface problem while preserving the underlying method.



progress check

Reading target: decide wildcard precedence by effective length is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {best[1]} (effective length {best[0]})')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if ch == '*':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {best[1]} (effective length {best[0]})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if ch == '*':`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Decide Wildcard Precedence by Effective Length: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, compile_rule, pattern, rx, ch. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if ch == '*': | Evidence: print(f'{path}: {best[1]} (effective length {best[0]})')

🛠️ Reader to Writer Bridge

1. Read: explain decide wildcard precedence by effective length in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 55.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 57 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {best[1]} (effective length {best[0]})')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of decide wildcard precedence by effective length and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Stripping `*` and `$` before measuring length gives each pattern a comparable specificity, so `/folder/*.html` (effective 13) beats the shorter `/folder/page` (12) Allow.

```
import re
def compile_rule(pattern):
    rx = ['^']
    for ch in pattern:
        if ch == '*':
            rx.append('.*')
        elif ch == '$':
            rx.append('$')
        else:
            rx.append(re.escape(ch))
    return re.compile(''.join(rx))
rules = [('allow', '/folder/page'), ('disallow', '/folder/*.html')]
path = '/folder/page.html'
best = None
for action, pat in rules:
    if compile_rule(pat).match(path):
        eff = len(pat.replace('*', '').replace('$', ''))
        if best is None or eff > best[0] or (eff == best[0] and action ==
'allow'):
            best = (eff, action)
print(f'{path}: {best[1]} (effective length {best[0]})')
```

```
output
/folder/page.html: disallow (effective length 13)
```

How it works:

1. compile_rule turns a pattern into an anchored regex, mapping star to .* and dollar to $.
2. rules pairs an Allow /folder/page with a Disallow /folder/*.html.
3. For the path /folder/page.html, each matching pattern's effective length removes * and $ characters.
4. The Disallow's effective length of 13 beats the Allow, so the path is disallowed.

Try it:

1. Add a longer Allow pattern and confirm it flips the verdict to allow
2. Print each rule's effective length to make the comparison transparent

3. Test a path that matches neither rule and ensure best stays None safely
4. Lengthen the Allow to `/folder/page.htmlx` and watch it win.

⚠ Common Mistakes

- Measuring the raw pattern length counts the `*`, distorting the comparison.
- Forgetting the Allow-wins-ties branch flips genuine ties the wrong way.
- Using the matched path length instead of the pattern length compares the wrong thing.

Skills gained effective length | wildcard precedence | regex compile

→ Where You'll Use This: Effective-length comparison is how Google resolves dueling wildcard rules, so a faithful robots tester must use it to predict verdicts on patterned directives.

Mental Model

Stripping the asterisks before measuring is like ignoring elastic in a tape measure: you compare the fixed, literal length each pattern actually pins down.

Project 57 Build a Full Per-Bot Allow Evaluator

The Idea Behind It

This project combines everything into a miniature robots engine. It compiles each pattern to regex, picks the bot's group or falls back to the wildcard, and applies effective-length precedence with an Allow tie-break to return a single allow or block per path. The allowed function answers the real question for any bot and URL, exercising group fallback, wildcards, and longest-match together.

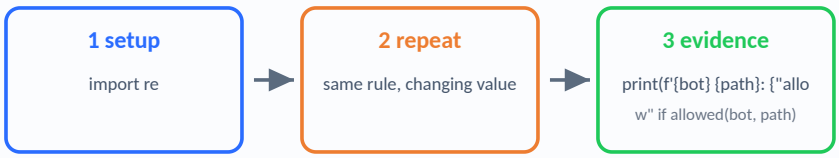
What You'll Build & Learn

Build a per-bot evaluator that selects a group, compiles patterns, and returns one allow-or-block verdict.

- a full engine combines all rules
- fall back to the wildcard group
- effective length plus Allow tie-break

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 56: decide wildcard precedence by effective length. Project 58 changes the surface problem while preserving the underlying method. *progress check*



Reading target: build a full per-bot allow evaluator is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{bot} {path}: {"allow" if allowed(bot, path) else "block"}')` exposes the result; match it against the output before changing the program.

output proves the trace

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a full per-bot allow evaluator and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Group selection plus regex matching plus effective-length precedence yields a per-bot decision, so Googlebot is freed for `/private/feed` while AhrefsBot inherits the `*` block-everything rule.

```
import re
def to_rx(pat):
    rx = ['^']
    for ch in pat:
        rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))
    return re.compile(''.join(rx))
groups = {
    'Googlebot': [('disallow', '/private'), ('allow', '/private/feed')],
    '*': [('disallow', '/')],
}
def allowed(bot, path):
    rules = groups.get(bot, groups.get('*', []))
    best_len, action = -1, 'allow'
    for a, pat in rules:
        if to_rx(pat).match(path):
            eff = len(pat.replace('*', '').replace('$', ''))
            if eff > best_len or (eff == best_len and a == 'allow'):
                best_len, action = eff, a
    return action == 'allow'
for bot, path in [('Googlebot', '/private'), ('Googlebot', '/private/feed'),
('AhrefsBot', '/home')]:
    print(f'{bot} {path}: {"allow" if allowed(bot, path) else "block"}')
```

```
output
Googlebot /private: block
Googlebot /private/feed: allow
AhrefsBot /home: block
```

How it works:

1. to_rx compiles a pattern to an anchored regex, mapping star and dollar.
2. groups defines a Googlebot block and a wildcard that disallows everything.

3. allowed picks the bot's rules or the wildcard, then keeps the longest effective-length match, favouring Allow on ties.
4. Googlebot reaches /private/feed via its Allow, but AhrefsBot falls to the wildcard Disallow: / and is blocked.

Try it:

1. Add a Bingbot group and confirm it is chosen ahead of the wildcard fallback
2. Return the winning rule with the verdict for easier debugging output
3. Cache compiled regexes so repeated paths do not recompile every pattern
4. Add a named `AhrefsBot` group and watch its verdict change.

⚠ Common Mistakes

- Forgetting the `*` fallback leaves unnamed bots with no rules and a wrong allow.
- Comparing raw pattern length instead of effective length mis-ranks wildcard rules.
- Recompiling the regex inside the loop is fine here but wasteful on large rule sets.

Skills gained robots engine | group fallback | longest-match

→ Where You'll Use This: A combined evaluator like this is the heart of a production robots library that crawlers and SEO platforms call to gate every fetch across many user-agents.

Mental Model

This is the whole assembly line in one machine: feed in a bot and a URL, and group selection, wildcard matching, and precedence stamp out a single green or red light.

Project 58 Trace Overlapping Rules to the Winner

The Idea Behind It

When several rules match one path, it helps to rank them by length before naming the winner. This project gathers every matching rule into tuples of length, action, and pattern, sorts them so the longest and Allow-favoured rule lands last, then reports the ranking and the winner. Making the order visible turns longest-match precedence from a black box into an explainable trace.

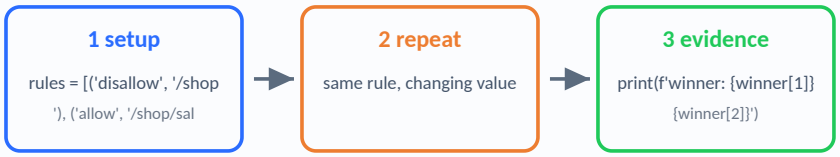
What You'll Build & Learn

List all rules matching a path ranked by length, then name the winner under longest-match precedence.

- rank matching rules by length
- sort surfaces the winner last
- make precedence explainable

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 57: build a full per-bot allow evaluator. Project 59 changes the surface problem while preserving the underlying method.



progress check

Reading target: trace overlapping rules to the winner is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `rules = [('disallow', '/shop'), ('allow', '/shop/sale'), ('disallow', '/shop/sale/expired')]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'winner: {winner[1]} {winner[2]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`rules = [('disallow', '/shop'), ('allow', '/shop/sale'), ('disallow', '/shop/sale/expired')]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`matches = [(len(p), a, p) for a, p in rules if path.startswith(p)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'winner: {winner[1]} {winner[2]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `matches = [(len(p), a, p) for a, p in rules if path.startswith(p)]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Trace Overlapping Rules to the Winner: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: rules, disallow, shop, allow, sale. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: rules = [('disallow', '/shop'), ('allow', '/shop/sale'), ('disallow', '... | Core: matches = [(len(p), a, p) for a, p in rules if path.startswith(p)] | Evidence: print(f'winner: {winner[1]} {winner[2]}')

Reader to Writer Bridge

1. Read: explain trace overlapping rules to the winner in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 57.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 59 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'winner: {winner[1]} {winner[2]}')`. Then compare punctuation, spacing, and order.
2. Explain: point to `rules = [('disallow', '/shop'), ('allow', '/shop/sale'), ('disallow', '/shop/sale/expired')]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of trace overlapping rules to the winner and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Collecting every matching rule with its length, sorting by length (Allow breaking ties), and taking the last element exposes exactly why the deepest Disallow wins.

```
rules = [('disallow', '/shop'), ('allow', '/shop/sale'), ('disallow',
'/shop/sale/expired')]
path = '/shop/sale/expired/item'
matches = [(len(p), a, p) for a, p in rules if path.startswith(p)]
matches.sort(key=lambda x: (x[0], x[1] == 'allow'))
winner = matches[-1]
print('matching rules (by length):')
for length, action, pat in matches:
    print(f'  {action} {pat} (len {length})')
print(f'winner: {winner[1]} {winner[2]}')
```

```
output
matching rules (by length):
  disallow /shop (len 5)
  allow /shop/sale (len 10)
  disallow /shop/sale/expired (len 18)
winner: disallow /shop/sale/expired
```

How it works:

1. rules has a /shop Disallow, a /shop/sale Allow, and a deeper /shop/sale/expired Disallow.
2. matches collects (len(p), action, pattern) for every rule the path starts with.
3. Sorting by length then by the Allow flag puts the strongest match last.
4. The code prints each matching rule with its length, then the winner: disallow /shop/sale/expired.

Try it:

1. Add an even deeper Allow and watch it move to the end of the ranking
2. Print the path itself in the header so multi-path output stays labelled
3. Handle the case of no matching rules by reporting a default-allow verdict

4. Add an equal-length Allow to force a tie and watch it win.

⚠ Common Mistakes

- Sorting only by length without the Allow tiebreaker makes equal-length winners arbitrary.
- Taking `matches[0]` returns the shortest match, the opposite of longest-match.
- Forgetting that an empty match list would make `matches[-1]` raise IndexError.

Skills gained rule tracing | tuple sort | precedence visibility

→ Where You'll Use This: An explainable trace of competing rules is exactly what robots-testing tools surface so an SEO can see why a URL was blocked, not just that it was.

⚡ Mental Model

It is like showing the bracket before the final: you see every contender ranked by reach, so the champion at the bottom of the list is no surprise.

Project 59 Allow Everything When No Group Applies

💡 The Idea Behind It

If a bot matches no named group and there is no wildcard group either, it has zero applicable rules and may crawl the whole site. This project parses a file containing only a Googlebot block, then resolves rules for Bingbot, which is absent. With no wildcard fallback, rules is empty and the bot is free to crawl. This edge case trips parsers that assume a star always exists.

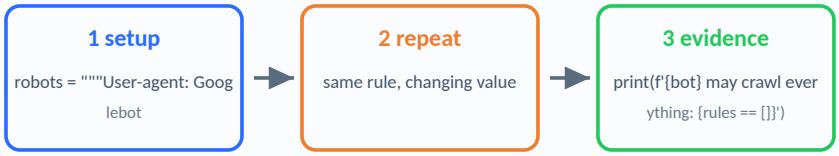
What You'll Build & Learn

Show a bot with no named group and no wildcard ends up with zero rules and full crawl access.

- no group means no rules
- absent wildcard grants full access
- do not assume a star block exists

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 58: trace overlapping rules to the winner. Project 60 changes the surface problem while preserving the underlying method.



progress check

Reading target: allow everything when no group applies is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = """User-agent: Googlebot` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{bot} may crawl everything: {rules == []}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: Googlebot`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{bot} may crawl everything: {rules == []}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Allow Everything When No Group Applies: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Googlebot, Disallow. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """User-agent: Googlebot | Core: if not line: | Evidence: print(f'{bot} may crawl everything: {rules == []}')

🛠️ Reader to Writer Bridge

1. Read: explain allow everything when no group applies in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 58.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 60 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{bot} may crawl everything: {rules == []}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `robots = """User-agent: Googlebot` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of allow everything when no group applies and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

With only a `Googlebot` block present, Bingbot finds neither its own group nor a `*` fallback, so its rule list is empty and nothing restricts it.

```
robots = """User-agent: Googlebot
Disallow: /no-google
"""
groups, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent':
        agent = v; groups.setdefault(agent, [])
    elif agent:
        groups[agent].append((f, v))
bot = 'Bingbot'
if bot in groups:
    rules = groups[bot]
elif '*' in groups:
    rules = groups['*']
else:
    rules = []
print(f'{bot} applicable rules: {rules}')
print(f'{bot} may crawl everything: {rules == []}')
```

```
output
Bingbot applicable rules: []
Bingbot may crawl everything: True
```

How it works:

1. The robots string defines only a Googlebot block.
2. Parsing fills groups with a single Googlebot key.
3. For Bingbot, the code checks its own key, then the wildcard, then falls to an empty list.
4. rules is empty, so it prints that Bingbot may crawl everything as True.

Try it:

1. Add a wildcard block and confirm Bingbot now inherits its rules instead of crawling freely
2. Test Googlebot and verify it still uses its own named block
3. Print which branch supplied the rules so the fallback path is explicit
4. Add a `User-agent: *` block and watch Bingbot inherit it.

⚠ Common Mistakes

- Defaulting to a block when no group matches contradicts robots.txt's allow-by-default model.
- Crashing on a missing `*` key instead of treating absence as no-rules.
- Assuming an empty rule list means blocked rather than fully allowed.

Skills gained empty-rules edge case | fallback chain | default crawl

→ Where You'll Use This: Handling the no-applicable-group case prevents a crawler or audit from crashing or wrongly blocking an unnamed bot when a file targets only specific crawlers.

Mental Model

No matching group is an unguarded gate: with neither your name nor an all-comers sign on it, you simply walk through unchallenged.

Project 60 Match the Most Specific User-Agent Token

The Idea Behind It

User-agent matching is case-insensitive and picks the longest matching name, so Googlebot-Image obeys its own block rather than the generic googlebot one. This project lowercases the bot, scans the non-wildcard keys for substrings of the bot name, and keeps the longest. Token specificity, not file order, decides the group, and an unmatched bot falls back to the wildcard.

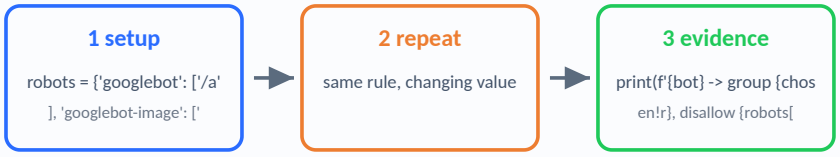
What You'll Build & Learn

Select a bot's group by the longest user-agent token contained in its name, falling back to the wildcard.

- user-agent matching is case-insensitive
- the longest token name wins
- specificity beats file order

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 59: allow everything when no group applies. Project 61 changes the surface problem while preserving the underlying method.



progress check

Reading target: match the most specific user-agent token is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `robots = {'googlebot': ['/a'], 'googlebot-image': ['/b'], '*': ['/c']}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{bot} -> group {chosen!r}, disallow {robots[chosen]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = {'googlebot': ['/a'], 'googlebot-image': ['/b'], '*': ['/c']}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if ua != '*' and ua in bot:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{bot} -> group {chosen!r}, disallow {robots[chosen]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the

behaviour.

CORE LINE `if ua != '*' and ua in bot:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language.    from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{bot} -> group {chosen!r}, disallow {robots[chosen]}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `robots = {'googlebot': ['/a'], 'googlebot-image': ['/b'], '*': ['/c']}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of match the most specific user-agent token and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Lowercasing both sides and choosing the longest group name that is a substring of the bot string implements Google's most-specific-token rule, with `*` as the final fallback.

```
robots = {'googlebot': ['/a'], 'googlebot-image': ['/b'], '*': ['/c']}
def pick(bot):
    bot = bot.lower()
    best = None
    for ua in robots:
        if ua != '*' and ua in bot:
            if best is None or len(ua) > len(best):
                best = ua
    return best or '*'
for bot in ['Googlebot', 'Googlebot-Image', 'Bingbot']:
    chosen = pick(bot)
    print(f'{bot} -> group {chosen!r}, disallow {robots[chosen]}')
```

```
output
Googlebot -> group 'googlebot', disallow ['/a']
Googlebot-Image -> group 'googlebot-image', disallow ['/b']
Bingbot -> group '*', disallow ['/c']
```

How it works:

1. robots maps googlebot, googlebot-image, and wildcard keys to disallow lists.
2. pick lowercases the bot and scans non-wildcard keys for ones contained in the bot name.
3. It keeps the longest such match, defaulting to the wildcard when none is found.
4. Googlebot-Image picks its own longer token, while Bingbot matches nothing and lands on the wildcard.

Try it:

1. Add a googlebot-news key and confirm a news bot picks it over plain googlebot
2. Reorder the dictionary and verify the chosen group does not change
3. Reject a partial-word match like goog so only real token names count

4. Add a `googlebot-news` group and route a matching bot to it.

⚠ Common Mistakes

- Matching case-sensitively misses `Googlebot` against a lowercased `googlebot` group.
- Picking the first substring match instead of the longest sends `Googlebot-Image` to the wrong group.
- Letting `*` win as a substring of everything; it must be excluded from the specificity check.

Skills gained token specificity | case-insensitive match | substring scan

→ Where You'll Use This: Longest-token selection matters because Google runs many sub-bots like Googlebot-Image and Googlebot-News, each meant to honour its own most-specific block.

Mental Model

It is like name tags at a conference: Googlebot-Image wears the most specific badge it qualifies for, ignoring the broader googlebot table it could also sit at.

Project 61 Match a Mid-Path Wildcard and Query String

The Idea Behind It

A pattern like /products/*?sort= blocks any product URL carrying a sort parameter, using an asterisk in the middle of the path. This project compiles the wildcard pattern to a regex and tests several URLs. The mid-pattern star absorbs whatever path segment sits between /products/ and the query marker, which is exactly how robots.txt targets faceted-navigation URLs.

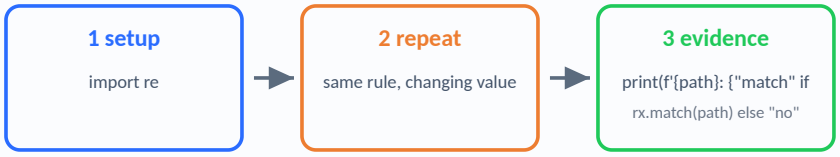
What You'll Build & Learn

Match URLs with a mid-path wildcard and a query fragment to target parameterised product pages.

- wildcards can sit mid-pattern
- a star spans path and query
- targets faceted navigation

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 60: match the most specific user-agent token. Project 62 changes the surface problem while preserving the underlying method.



progress check

Reading target: match a mid-path wildcard and query string is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"match" if rx.match(path) else "no"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {"match" if rx.match(path) else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

🛠️ Reader to Writer Bridge

1. Read: explain match a mid-path wildcard and query string in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 60.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 62 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"match" if rx.match(path) else "no"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of match a mid-path wildcard and query string and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The `*` expands to `.*`, so `/products/` followed by anything and then `?sort=` matches faceted URLs while leaving the plain `/products/shoes` page crawlable.

```
import re
def to_rx(pat):
    rx = ['^']
    for ch in pat:
        rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))
    return re.compile(''.join(rx))
pattern = '/products/*?sort='
rx = to_rx(pattern)
paths = ['/products/shoes?sort=price', '/products/a/b?sort=name',
'/products/shoes', '/products/?sort=x']
for path in paths:
    print(f'{path}: {"match" if rx.match(path) else "no"}')
```

```
output
/products/shoes?sort=price: match
/products/a/b?sort=name: match
/products/shoes: no
/products/?sort=x: match
```

How it works:

1. to_rx compiles a pattern, mapping star to .* and dollar to $.
2. The pattern /products/*?sort= compiles to a regex requiring that literal prefix, any text, then ?sort=.
3. /products/shoes?sort=price and /products/a/b?sort=name match because .* spans the middle.
4. /products/shoes lacks the query fragment, so it does not match.

Try it:

1. Add a pattern catching ?color= as well and test a multi-parameter URL
2. Anchor the query so only sort exactly at the start of the query string matches
3. Confirm a page with sort in the path but not the query is correctly excluded
4. Add `?sort=` to `/products/shoes` and watch it start matching.

⚠ Common Mistakes

- Forgetting to escape the literal `?` lets it act as a regex 'optional' quantifier and over-match.
- Expecting `/products/shoes` to match; without `?sort=` it correctly does not.
- Assuming `*` stops at a `/`; it greedily crosses slashes, matching `/a/b` too.

Skills gained mid-path wildcard | query matching | faceted nav

→ Where You'll Use This: Mid-path wildcard patterns are the standard robots tool for pruning crawl waste from faceted navigation and sort parameters on large catalogue sites.

Mental Model

The mid-path star is a wildcard in the middle of a phone number: the prefix and the suffix are fixed, but any digits can fill the gap between them.

Project 62 Collapse Repeated Wildcards Before Matching

The Idea Behind It

Some robots.txt files write a double asterisk by mistake, but consecutive wildcards mean exactly the same as a single one. This project normalises runs of asterisks to one with a regex substitution before compiling the pattern, so /a/**/*.js collapses to /a//*.js. Normalising keeps the generated regex tidy and the matching behaviour predictable instead of letting redundant stars confuse it.

What You'll Build & Learn

Collapse consecutive wildcards into one before compiling so redundant asterisks behave predictably.

- double stars equal a single star
- normalise before compiling
- redundant wildcards are harmless

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 61: match a mid-path wildcard and query string. Project 63 changes the surface problem while preserving the underlying method.

progress check

Reading target: collapse repeated wildcards before matching is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{path}: {"match" if rx.match(path) else "no"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: {"match" if rx.match(path) else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Intent	Collapse Repeated Wildcards Before Matching: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, normalize, pat, sub, to_rx. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: rx.append('.' *if ch ==* '' else ('$' if ch == '$' else re.escape(ch))) | Evidence: print(f'{path}: {"match" if rx.match(path) else "no"}')

🛠️ Reader to Writer Bridge

1. Read: explain collapse repeated wildcards before matching in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 61.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 63 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: {"match" if rx.match(path) else "no"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of collapse repeated wildcards before matching and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A regex pre-pass squeezes `*+` down to one `*`, so `/a/**/*.js` becomes `/a/*/*.js`, which still requires a directory segment between the two wildcards.

```
import re
def normalize(pat):
    return re.sub(r'\*+', '*', pat)
def to_rx(pat):
    pat = normalize(pat)
    rx = ['^']
    for ch in pat:
        rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))
    return re.compile(''.join(rx)), pat
raw = '/a/**/*.js'
rx, norm = to_rx(raw)
print(f'normalized {raw!r} -> {norm!r}')
for path in ['/a/b/c/x.js', '/a/x.js', '/b/x.js']:
    print(f'{path}: {"match" if rx.match(path) else "no"}')
```

```
output
normalized '/a/**/*.js' -> '/a/*/*.js'
/a/b/c/x.js: match
/a/x.js: no
/b/x.js: no
```

How it works:

1. normalize uses re.sub to replace any run of asterisks with a single asterisk.
2. to_rx normalises first, then compiles the cleaned pattern to an anchored regex.
3. /a/**/*.js normalises to /a/*/*.js and the code prints that transformation.
4. /a/b/c/x.js matches the two-star form, while /a/x.js lacks a middle segment and does not.

Try it:

1. Feed a triple-asterisk pattern and confirm it collapses to a single star
2. Print the regex both before and after normalisation to compare them
3. Decide whether to also trim a leading wildcard and test the effect
4. Feed `/a/***/x` and confirm it collapses to `/a/*/x`.

⚠ Common Mistakes

- Skipping normalization makes the generated regex have `.*.*`, which is correct but harder to read and reason about.
- Expecting `/a/x.js` to match; the pattern needs a segment between the wildcards, so it does not.
- Collapsing wildcards inside `re.escape`d text would corrupt the pattern; normalize before escaping.

Skills gained wildcard normalisation | re.sub | pattern cleanup

→ Where You'll Use This: Wildcard normalisation hardens a robots parser against the malformed patterns hand-written files contain, keeping verdicts stable regardless of redundant asterisks.

Mental Model

Two asterisks in a row are like saying anything anything: it adds no meaning, so normalising trims the stutter down to one clean wildcard.

Project 63 Block Query Strings but Keep One Path

The Idea Behind It

A Disallow: /*? rule hides every URL carrying a query string, while a specific Allow: /search keeps the search page crawlable. This project compiles both patterns, then resolves each URL by effective length with an Allow tie-break. The pairing is how sites prune crawl waste from parameter URLs while still letting a deliberately useful query-bearing page through.

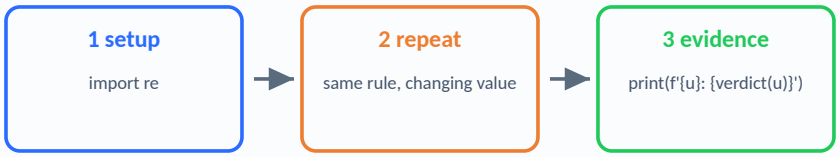
What You'll Build & Learn

Block all query-string URLs with a wildcard Disallow while an Allow keeps one path crawlable.

- a /*? rule blocks all query URLs
- a specific Allow rescues one path
- prunes parameter crawl waste

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 62: collapse repeated wildcards before matching. Project 64 changes the surface problem while preserving the underlying method.



progress check

Reading target: block query strings but keep one path is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{u}: {verdict(u)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

3. Transfer: change one small part of block query strings but keep one path and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The wildcard `/*?` matches any path containing a `?`, blocking parameterised URLs, but the longer effective-length `/search` Allow rescues the search page even when it carries a query.

```
import re
def to_rx(pat):
    rx = ['^']
    for ch in pat:
        rx.append('.*' if ch == '*' else ('$' if ch == '$' else re.escape(ch)))
    return re.compile(''.join(rx))
rules = [('disallow', '/*?'), ('allow', '/search')]
def verdict(path):
    best_len, action = -1, 'allow'
    for a, pat in rules:
        if to_rx(pat).match(path):
            eff = len(pat.replace('*', ''))
            if eff > best_len or (eff == best_len and a == 'allow'):
                best_len, action = eff, a
    return action
urls = ['/page', '/page?ref=ad', '/search?q=x', '/list?sort=1']
for u in urls:
    print(f'{u}: {verdict(u)}')
```

```
output
/page: allow
/page?ref=ad: disallow
/search?q=x: allow
/list?sort=1: disallow
```

How it works:

1. rules pairs a Disallow /*? with an Allow /search.
2. verdict compiles each pattern, and for matches computes effective length with stars removed.
3. The longer effective length wins, with Allow favoured on a tie.
4. /page?ref=ad is disallowed by the query rule, but /search?q=x is allowed because /search matches longer.

Try it:

1. Add a second Allow for /filter and confirm it survives the query block
2. Tighten the Disallow to only block ?sort and retest the parameter URLs
3. Print the effective length of each matching rule for clarity

4. Add `/list` to an Allow and watch `/list?sort=1` open up.

⚠ Common Mistakes

- Forgetting effective-length precedence lets the short `/*?` block override the longer `/search` Allow.
- Escaping the `?` wrong makes the wildcard rule match the empty query and over-block.
- Treating `/page` (no query) as blocked; the `/*?` rule needs a `?` to match.

Skills gained query-string blocking | Allow exception | effective length

→ Where You'll Use This: The block-all-queries-with-one-exception pattern is a frequent crawl-budget tactic, hiding endless parameter permutations while protecting a key dynamic page.

Mental Model

Disallow: /*? is a blanket ban on anything wearing a query string, and the Allow: /search is the one VIP wristband that gets a parameterised page past the rope.

Project 64 Compare Percent-Decoded Paths in Rules

The Idea Behind It

A crawler compares robots rules against the percent-decoded path, so %20 and a literal space name the same target. This project decodes percent-escapes with a regex substitution that maps each hex pair to its character, then runs the prefix test on the decoded path. Decoding before matching prevents an encoded URL from sneaking past a Disallow that uses the plain character.

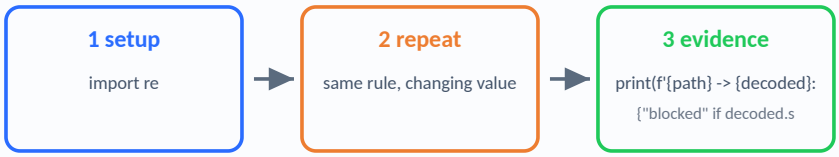
What You'll Build & Learn

Percent-decode requested paths before matching so encoded URLs cannot slip past a Disallow rule.

- rules match the decoded path
- %20 equals a literal space
- decode before comparing

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 63: block query strings but keep one path. Project 65 changes the surface problem while preserving the underlying method.



progress check

Reading target: compare percent-decoded paths in rules is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 65 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path} -> {decoded}: {"blocked" if decoded.startswith(disallow) else "crawl"}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare percent-decoded paths in rules and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A small regex replaces each `%XX` escape with its character, so both the encoded and literal forms normalize to `/private folder` and match the same Disallow rule.

```
import re
def pct_decode(s):
    return re.sub(r'%([0-9A-Fa-f]{2})', lambda m: chr(int(m.group(1), 16)), s)
disallow = '/private folder'
requested = ['/private%20folder/x', '/private folder/y', '/public']
for path in requested:
    decoded = pct_decode(path)
    print(f'{path} -> {decoded}: {"blocked" if decoded.startswith(disallow)
else "crawl"}')
```

```
output
/private%20folder/x -> /private folder/x: blocked
/private folder/y -> /private folder/y: blocked
/public -> /public: crawl
```

How it works:

1. pct_decode uses re.sub to replace each %XX escape with chr of the parsed hex value.
2. disallow is /private folder with a literal space.
3. Each requested path is decoded, so /private%20folder becomes /private folder.
4. Both the encoded and literal-space paths block after decoding, while /public crawls.

Try it:

1. Add a path using %2F for a slash and decide how decoding should treat it
2. Decode the disallow value too so encoded rules are handled symmetrically
3. Handle a malformed escape like %2 gracefully instead of raising an error
4. Add `/private%2Ffolder` and note `%2F` should stay encoded.

⚠ Common Mistakes

- Matching the raw encoded path lets `/private%20folder` slip past a rule written with a space.
- Decoding `%2F` to `/` is unsafe; real parsers keep `%2F` encoded because it is a path-segment delimiter.
- A malformed `%2` with no following hex digit would be left untouched, which the regex handles by not matching.

Skills gained percent decoding | re.sub callback | normalised matching

→ Where You'll Use This: Percent-decoding before matching closes a real evasion gap, ensuring an audit treats encoded and plain URL forms identically as crawlers actually do.

⚡ Mental Model

Percent-encoding is a disguise; decoding first is the bouncer wiping off the costume so an escaped path cannot stroll past a rule written in plain characters.

Project 65 Catch Rules Above the First User-Agent

💡 The Idea Behind It

Allow and Disallow lines that appear before any User-agent line belong to no group and are ignored by crawlers. This project tracks whether a user-agent has been seen yet and, for each rule line that arrives before one, records an issue naming the line number and text. Catching these orphaned rules explains why a directive that should apply quietly does nothing.

What You'll Build & Learn

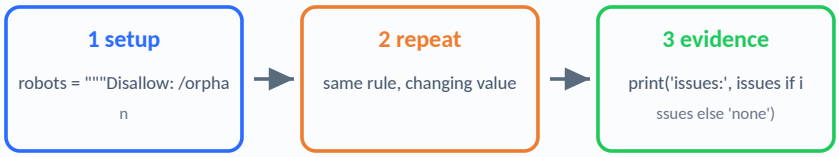
Flag Allow or Disallow lines that appear before the first User-agent and therefore belong to no group.

- rules need a User-agent above them
- orphaned lines are ignored
- report by line number

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 64: compare percent-decoded paths in rules. Project 66 changes the surface problem while preserving the underlying method.

progress check



Reading target: catch rules above the first user-agent is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `robots = """Disallow: /orphan` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('issues:', issues if issues else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Catch Rules Above the First User-Agent: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, Disallow, orphan, User, agent. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: robots = """Disallow: /orphan | Core: if not line: | Evidence: print('issues:', issues if issues else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain catch rules above the first user-agent in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 64.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 66 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('issues:', issues if issues else 'none')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `robots = """Disallow: /orphan` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of catch rules above the first user-agent and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Tracking whether a `User-agent` line has been seen lets the parser flag any Allow/Disallow that precedes the first group as orphaned and inert.

```
robots = """Disallow: /orphan
User-agent: *
Disallow: /admin
Allow: /admin/help
"""
issues = []
agent = None
for n, line in enumerate(robots.splitlines(), 1):
    line = line.strip()
    if not line:
        continue
    f = line.partition(':')[0].strip().lower()
    if f == 'user-agent':
        agent = True
    elif f in ('allow', 'disallow') and not agent:
        issues.append(f'line {n}: {line!r} has no User-agent above it')
print('issues:', issues if issues else 'none')
```

```
output
issues: ["line 1: 'Disallow: /orphan' has no User-agent above it"]
```

How it works:

1. The robots string opens with a Disallow before any User-agent line.
2. agent starts None and enumerate provides each line's number.
3. A user-agent line sets agent to True; a rule line while agent is still None records an issue.
4. Line 1's orphaned Disallow: /orphan is reported, while the later rules under the wildcard are fine.

Try it:

1. Add a second orphaned Allow and confirm both are reported with their line numbers
2. Treat a Sitemap above the first group as valid since it is group-independent
3. Suggest moving each orphan under a User-agent line in the warning text
4. Move the orphan rule below the `User-agent` line and confirm the issue clears.

⚠ Common Mistakes

- Resetting the `agent` flag on blank lines wrongly orphans valid rules after a block break.
- Reporting line numbers off by one by not using `enumerate(..., 1)`.
- Treating a `Sitemap` line before the first group as orphaned; sitemaps are global and fine there.

Skills gained orphan detection | enumerate | line-number reporting

→ Where You'll Use This: Detecting orphaned rules is a useful linter check, explaining the confusing case where a correctly spelled directive has no effect because it sits above any group header.

Mental Model

An orphaned rule is a sentence before the chapter heading: it sits on the page but belongs to no section, so the reader skips right over it.

Project 66 Resolve Per-Bot Crawl-Delay Values

The Idea Behind It

Different bots can be given different Crawl-delay values, and a missing one falls back to the wildcard group's delay. This project parses crawl-delay per agent into a dictionary, then resolves the effective delay for each bot using get with the wildcard as the fallback. Computing the per-bot delay drives a polite scheduler that throttles aggressive crawlers harder than well-behaved ones.

What You'll Build & Learn

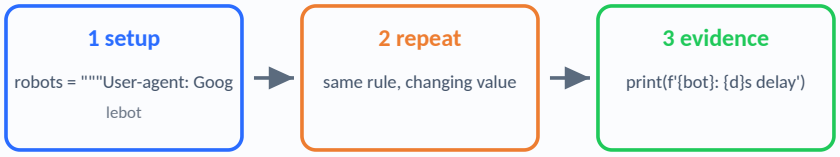
Resolve each bot's effective Crawl-delay, falling back to the wildcard group's value when unset.

- bots can have distinct crawl-delays
- missing delay falls to the wildcard
- resolve per-bot for scheduling

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 65: catch rules above the first user-agent. Project 67 changes the surface problem while preserving the underlying method.

progress check



Reading target: resolve per-bot crawl-delay values is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `robots = """User-agent: Googlebot` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{bot}: {d}s delay')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`robots = """User-agent: Googlebot`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{bot}: {d}s delay')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Resolve Per-Bot Crawl-Delay Values: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: robots, User, agent, Googlebot, Crawl. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: robots = """User-agent: Googlebot | Core: if not line: | Evidence: print(f'{bot}: {d}s delay')

🛠️ Reader to Writer Bridge

1. Read: explain resolve per-bot crawl-delay values in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 65.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 67 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{bot}: {d}s delay')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `robots = """User-agent: Googlebot` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of resolve per-bot crawl-delay values and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Storing each group's Crawl-delay keyed by bot lets a lookup with a `*` fallback give every bot its effective wait, including the unlisted Yandex inheriting the wildcard's 5 seconds.

```
robots = """User-agent: Googlebot
Crawl-delay: 0

User-agent: BadBot
Crawl-delay: 30

User-agent: *
Crawl-delay: 5
"""
delays, agent = {}, None
for line in robots.splitlines():
    line = line.strip()
    if not line:
        continue
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent':
        agent = v
    elif f == 'crawl-delay' and agent:
        delays[agent] = int(v)
for bot in ['Googlebot', 'BadBot', 'Yandex']:
    d = delays.get(bot, delays.get('*'))
    print(f'{bot}: {d}s delay')
```

```
output
Googlebot: 0s delay
BadBot: 30s delay
Yandex: 5s delay
```

How it works:

1. The robots string sets crawl-delays of 0 for Googlebot, 30 for BadBot, and 5 for the wildcard.
2. The parser tracks the current agent and stores each crawl-delay in the delays dictionary.
3. For each queried bot, delays.get(bot, delays.get('*')) returns its own delay or the fallback.
4. Yandex has no entry, so it inherits the wildcard's 5-second delay.

Try it:

1. Add Bingbot with its own delay and confirm it overrides the wildcard
2. Convert each resolved delay into a fetches-per-minute budget like an earlier project

3. Handle a robots file with no wildcard delay and report None gracefully
4. Remove the `*` Crawl-delay and decide what an unlisted bot should get.

⚠ Common Mistakes

- Falling back to a hardcoded default instead of the `*` group's delay ignores the file's own catch-all.
- Storing the delay as a string makes later arithmetic fail.
- Letting a Crawl-delay outside any group attach to the wrong bot.

Skills gained per-bot delay | dict fallback | scheduler input

→ Where You'll Use This: Per-bot crawl-delay resolution feeds a polite scheduler, letting a crawler obey a generous delay for friendly bots and a harsh one for resource-hungry scrapers.

Mental Model

It is a speed-limit sign per vehicle type: named bots read their own posted limit, and anything unlisted obeys the default sign at the entrance.

Project 67 Combine Meta and Header Robots Directives

The Idea Behind It

A page can carry indexing directives in both its meta robots tag and the X-Robots-Tag header, and the most restrictive wins. This project parses each source into a directive set, unions them, and checks for noindex in the combined set. A header noindex therefore overrides a meta tag that says index, showing how the two robots channels combine into one effective decision.

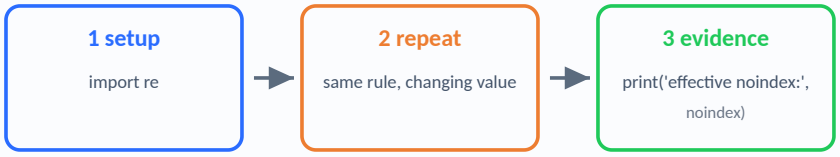
What You'll Build & Learn

Combine meta robots and X-Robots-Tag directives so the most restrictive instruction decides indexability.

- meta and header directives combine
- the most restrictive wins
- union the two directive sets

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 66: resolve per-bot crawl-delay values. Project 68 changes the surface problem while preserving the underlying method.



progress check

Reading target: combine meta and header robots directives is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print('effective noindex:', noindex)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`return {d.strip().lower() for d in text.split(',') if d.strip()}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('effective noindex:', noindex)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return {d.strip().lower() for d in text.split(',') if d.strip()}`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Combine Meta and Header Robots Directives: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, html, meta, name, robots. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: return {d.strip().lower() for d in text.split(',') if d.strip()} | Evidence: print('effective noindex:', noindex)

🛠️ Reader to Writer Bridge

1. Read: explain combine meta and header robots directives in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 66.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 68 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('effective noindex:', noindex)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of combine meta and header robots directives and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Unioning the meta and header directive sets and testing for `noindex` enforces the rule that any source asking for noindex wins, even against an explicit `index`.

```
import re
html = '<meta name="robots" content="index, follow">'
headers = {'X-Robots-Tag': 'noindex'}
def parse(text):
    return {d.strip().lower() for d in text.split(',') if d.strip()}
meta = set()
m = re.search(r'content=["\']([^"\']+)["\']', html)
if m:
    meta = parse(m.group(1))
hdr = parse(headers.get('X-Robots-Tag', ''))
combined = meta | hdr
noindex = 'noindex' in combined
print('meta:', sorted(meta))
print('header:', sorted(hdr))
print('effective noindex:', noindex)
```

```
output
meta: ['follow', 'index']
header: ['noindex']
effective noindex: True
```

How it works:

1. The meta tag says index, follow while the X-Robots-Tag header says noindex.
2. parse splits a comma string into a lowercased set; meta is read via a content regex.
3. combined is the union of the meta and header sets.
4. Because noindex is present in the header, effective noindex prints True despite the meta tag's index.

Try it:

1. Add nofollow to the header and report the combined link-following status
2. Reverse the conflict so the meta says noindex and the header says index
3. Print which source supplied the winning noindex directive
4. Add `nofollow` to the header and report the effective follow state.

⚠ Common Mistakes

- Letting the meta `index` cancel the header `noindex`; restrictive directives are not undone.
- Comparing the two sources instead of unioning them misses directives that appear in only one.
- Not lowercasing one source so `NoIndex` and `noindex` fail to match.

Skills gained directive merging set union restrictive wins

→ **Where You'll Use This:** Combining both robots channels is essential for diagnosing pages that stay out of the index because a header silently overrides an apparently index-friendly meta tag.

⚡ Mental Model

Two memos arrive about the same page; the strictest instruction governs, so a header that says keep it out of the index trumps a page that asks to be listed.

Project 68 Scope an X-Robots-Tag to a Named Bot

💡 The Idea Behind It

An X-Robots-Tag value can start with a bot name, like googlebot: noindex, scoping that directive to one crawler. This project inspects each header value, and when its prefix ends in bot it applies the directive only if that name matches my_bot; unprefixed values apply to every bot. The result is the set of directives that actually bind for the chosen crawler.

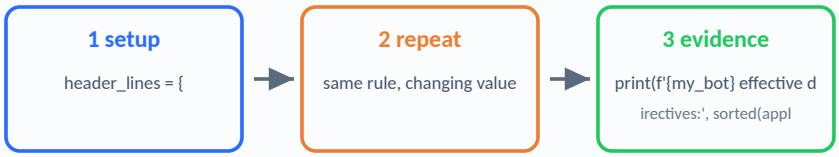
What You'll Build & Learn

Apply only the X-Robots-Tag directives scoped to a named bot plus the unprefixed ones meant for all.

- a header can name a target bot
- unprefixed directives apply to all
- prefixed ones bind one crawler

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 67: combine meta and header robots directives. Project 69 changes the surface problem while preserving the underlying method.



progress check

Reading target: scope an x-robots-tag to a named bot is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `header_lines = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{my_bot} effective directives:', sorted(applied))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`header_lines = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if sep and head.strip().lower().endswith('bot'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{my_bot} effective directives:', sorted(applied))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if sep and head.strip().lower().endswith('bot'):`

Construction pattern

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Scope an X-Robots-Tag to a Named Bot: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: header_lines, Robots, Tag, googlebot, noindex. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: header_lines = { | Core: if sep and head.strip().lower().endswith('bot'): | Evidence: print(f'{my_bot} effective directives:', sorted(applied))

🛠️ Reader to Writer Bridge

1. Read: explain scope an x-robots-tag to a named bot in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 67.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 69 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{my_bot} effective directives:', sorted(applied))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `header_lines = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of scope an x-robots-tag to a named bot and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting each header value on the first colon detects an optional bot prefix; a matching prefix or no prefix at all contributes its directives to the chosen bot's set.

```
header_lines = {
    'X-Robots-Tag': 'googlebot: noindex',
    'X-Robots-Tag-2': 'nosnippet',
}
my_bot = 'googlebot'
applied = set()
for value in header_lines.values():
    head, sep, rest = value.partition(':')
    if sep and head.strip().lower().endswith('bot'):
        if head.strip().lower() == my_bot:
            applied |= {d.strip() for d in rest.split(',')}
    else:
        applied |= {d.strip() for d in value.split(',')}
print(f'{my_bot} effective directives:', sorted(applied))
```

```
output
googlebot effective directives: ['noindex', 'nosnippet']
```

How it works:

1. header_lines holds a googlebot-scoped noindex and an unprefixed nosnippet.
2. Each value is partitioned on its first colon into head and rest.
3. When head ends in bot, the directive applies only if head equals my_bot; otherwise the whole value applies to all.
4. googlebot receives both noindex and nosnippet, the scoped one matching and the unscoped one applying universally.

Try it:

1. Add a bingbot-scoped directive and confirm googlebot does not pick it up
2. Handle a prefix that names a bot without the literal bot suffix
3. Resolve directives for a different my_bot and compare the applied sets
4. Change the prefix to `bingbot:` and watch `noindex` stop applying to Googlebot.

⚠ Common Mistakes

- Applying a `bingbot:`-prefixed directive to Googlebot by ignoring the prefix entirely.
- Splitting on every colon mangles values; partition on the first colon only.
- Treating an unprefixed value as bot-specific drops directives meant for all crawlers.

Skills gained scoped directives | header prefix parsing | bot targeting

→ Where You'll Use This: Bot-scoped X-Robots-Tag parsing matters when a server tailors indexing rules per crawler, ensuring an audit attributes each directive to the right bot rather than all of them.

Mental Model

A scoped header is mail with a name on the envelope: googlebot opens its addressed note plus every unaddressed all-staff memo, but not a note meant for bingbot.

Project 69 Run a Combined robots.txt Audit

The Idea Behind It

A real audit parses every directive in one pass: rules, sitemaps, and crawl-delay, then classifies a URL list for the active bot. This project strips comments, routes each field to its collection, compiles patterns to regex, and resolves verdicts by effective length with an Allow tie-break. That single pass is the skeleton of a robots.txt linter that reports the file's settings and per-URL outcomes.

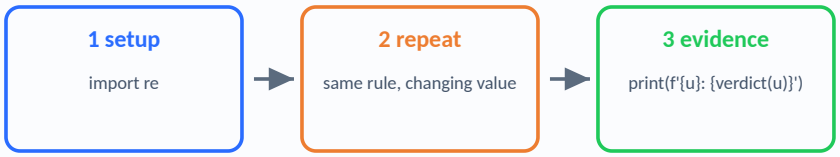
What You'll Build & Learn

Parse rules, sitemaps, and crawl-delay in one pass, then classify a URL list for the active bot.

- one pass parses every directive
- route fields to collections
- classify URLs after parsing

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 68: scope an x-robots-tag to a named bot. Project 70 changes the surface problem while preserving the underlying method.



progress check

Reading target: run a combined robots.txt audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'{u}: {verdict(u)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
2. Apply the rule	`if not line:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{u}: {verdict(u)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if not line:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Run a Combined robots.txt Audit: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, robots, User, agent, Disallow. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if not line: | Evidence: print(f'{u}: {verdict(u)}')

🛠️ Reader to Writer Bridge

1. Read: explain run a combined robots.txt audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 68.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 70 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{u}: {verdict(u)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of run a combined robots.txt audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One scan collects rules, sitemaps, and the crawl-delay while a regex-backed `verdict` applies longest-match precedence, summarising both the file's metadata and its per-URL decisions.

```
import re
robots = """User-agent: *
Disallow: /admin
Disallow: /*.json$
Allow: /admin/public
Crawl-delay: 5
Sitemap: https://example.com/sitemap.xml
"""
rules, sitemaps, delay, agent = [], [], None, None
for line in robots.splitlines():
    line = line.split('#', 1)[0].strip()
    if not line:
        continue
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent': agent = v
    elif f in ('allow', 'disallow') and agent: rules.append((f, v))
    elif f == 'crawl-delay': delay = int(v)
    elif f == 'sitemap': sitemaps.append(v)
def to_rx(p):
    return re.compile('^' + ''.join('.*' if c == '*' else ('$' if c == '$' else
re.escape(c)) for c in p))
def verdict(path):
    best, act = -1, 'allow'
    for a, p in rules:
        if to_rx(p).match(path):
            e = len(p.replace('*', '').replace('$', ''))
            if e > best or (e == best and a == 'allow'): best, act = e, a
    return act
urls = ['/home', '/admin', '/admin/public', '/data.json']
print('crawl-delay:', delay, '| sitemaps:', len(sitemaps))
for u in urls:
    print(f'{u}: {verdict(u)}')
```

```
output
crawl-delay: 5 | sitemaps: 1
/home: allow
/admin: disallow
```

```
/admin/public: allow
/data.json: disallow
```

How it works:

1. Each line has its comment stripped, then routes to rules, delay, or sitemaps by field.
2. to_rx compiles a pattern to an anchored regex handling star and dollar.
3. verdict keeps the longest effective-length match per URL, favouring Allow on ties.
4. It prints the crawl-delay and sitemap count, then classifies /admin as disallow and /admin/public as allow.

Try it:

1. Add the unknown-directive check from an earlier project into the same pass
2. Report the rule count and any orphaned rules alongside the existing summary
3. Accept a bot name argument so the audit selects the right group instead of the last agent
4. Add an `Allow: /data-public.json` and re-classify the JSON URLs.

⚠ Common Mistakes

- Letting a `Crawl-delay` or `Sitemap` line accidentally enter the Allow/Disallow rule list skews the verdicts.
- Stripping comments after splitting on the colon can drop a trailing `#` inside a value; strip first.
- Forgetting effective-length stripping makes the `/*.json$` rule mis-rank against `/admin/public`.

Skills gained single-pass parsing | robots linter | URL classification

→ Where You'll Use This: A one-pass audit is the working core of any robots.txt linter or testing tool an SEO runs to validate a file before or after a deploy.

Mental Model

This is the dashboard build: one sweep reads every gauge in the file at once, then runs your URLs through the wash and prints the verdicts.

Project 70 Report Crawl Coverage From a Policy

The Idea Behind It

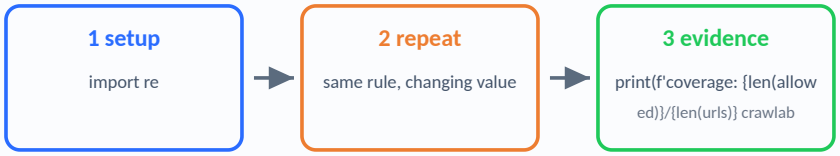
The bottom line of a robots audit is coverage: of all the URLs you care about, how many can the bot actually reach. This project parses the rules, compiles patterns to regex, and resolves each URL to a boolean crawlable verdict, then splits the list into crawlable and blocked and prints a coverage ratio. It rolls parsing and matching into one crawlability score.

What You'll Build & Learn

Compute crawl coverage by classifying a URL list and reporting the crawlable fraction as a ratio.

- coverage measures reachable URLs
- split into crawlable and blocked
- report a crawlability ratio

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 69: run a combined robots.txt audit. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: report crawl coverage from a policy is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
- Evidence: `print(f'coverage: {len(allowed)}/{len(urls)} crawlable')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.

Move	Code to inspect	Why it matters
2. Apply the rule	`if f == 'user-agent': agent = v`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print(f'coverage: {len(allowed)}/{len(urls)} crawlable')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: robots.txt and Crawl Directives becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if f == 'user-agent': agent = v`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Report Crawl Coverage From a Policy: connect the surface task to the chapter skill, parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay.
Names	Watch these names first: re, robots, User, agent, Disallow. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: if f == 'user-agent': agent = v | Evidence: print(f'coverage: {len(allowed)}/{len(urls)} crawlable')

Reader to Writer Bridge

1. Read: explain report crawl coverage from a policy in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 69.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'coverage: {len(allowed)}/{len(urls)} crawlable')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of report crawl coverage from a policy and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Parsing the rules once and running each URL through a longest-match `verdict` partitions the list into crawlable and blocked sets, and the ratio is the site's crawl coverage under this policy.

```
import re
robots = """User-agent: *
Disallow: /search
Disallow: /*.json$
Allow: /search/help
Sitemap: https://example.com/sitemap.xml
"""
rules, agent = [], None
for line in robots.splitlines():
    f, _, v = line.partition(':')
    f, v = f.strip().lower(), v.strip()
    if f == 'user-agent': agent = v
    elif f in ('allow', 'disallow') and agent: rules.append((f, v))
def to_rx(p):
    return re.compile('^' + ''.join('.*' if c == '*' else ('$' if c == '$' else
re.escape(c)) for c in p))
def verdict(path):
    best, act = -1, 'allow'
    for a, p in rules:
        if to_rx(p).match(path):
            e = len(p.replace('*', '').replace('$', ''))
```

```
            if e > best or (e == best and a == 'allow'): best, act = e, a
    return act == 'allow'
urls = ['/home', '/search', '/search/help', '/feed.json', '/about']
allowed = sorted(u for u in urls if verdict(u))
blocked = sorted(u for u in urls if not verdict(u))
print('crawlable:', allowed)
print('blocked:', blocked)
print(f'coverage: {len(allowed)}/{len(urls)} crawlable')
```

```
output
crawlable: ['/about', '/home', '/search/help']
blocked: ['/feed.json', '/search']
coverage: 3/5 crawlable
```

How it works:

1. Rules are parsed for the active agent, ignoring sitemaps for the verdict.
2. verdict compiles each pattern and returns whether the longest effective-length match is an allow.
3. The URL list is partitioned into sorted allowed and blocked lists by that verdict.
4. The code prints both lists and a coverage line reading 3 of 5 crawlable.

Try it:

1. Print the coverage as a percentage in addition to the raw ratio
2. Add more URLs including a .json file and confirm the end-anchored rule blocks it
3. Group blocked URLs by which rule blocked them for a richer report
4. Add `/search/secret` and confirm the `/search` Disallow blocks it.

⚠ Common Mistakes

- Calling `verdict` twice per URL (once for each list) is wasteful; compute it once and bucket the result.
- Forgetting that `/search/help` survives because its Allow out-ranks the `/search` Disallow.
- Sorting only one of the two lists makes the output partly nondeterministic.

Skills gained crawl coverage | URL partitioning | coverage ratio

→ Where You'll Use This: A coverage score is the headline metric of a crawlability report, telling an SEO at a glance how much of a target URL set a robots policy actually permits.

Mental Model

Coverage is the attendance count after the door policy runs: of everyone you invited, it tells you what share actually made it inside.

✅ Chapter Progress Checkpoint

What this chapter added: after 40 mini-projects, robots.txt and Crawl Directives should feel like a reusable Python move: parse and validate robots rules, user-agent matching, allow/disallow precedence and crawl-delay. *chapter checkpoint*

1 Read
Open any project from Projects 31-70 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 3 (XML Sitemaps and URL Discovery) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

6 questions · 4 categories · graded

1 Recall · 3 Meaning · 1 Structure · 1 Transfer

2.1.Q1 Recall · MEDIUM
Turn back to Project 42 (Treat an Empty Disallow as Allow-All). Without running it, what exactly does it print?

2.1.Q2 Meaning · MEDIUM
Turn back to Project 41 (Detect a Site-Wide Disallow Block). Without running it, what exactly does it print?

2.1.Q3 Structure · EASY
A robots.txt names a **`Googlebot`** block AND a `*` block. Which rules does Googlebot obey?

- A. Both blocks combined
- B. Only the `*` block
- C. Only its own `Googlebot` block
- D. Whichever block comes first

2.1.Q4 Transfer MEDIUM For path **`/public/page`**, the active group has **`Disallow: /`** and **`Allow: /public`**. What is the verdict and why?

- A Blocked — Disallow always wins
- B Crawl — `/public` (7 chars) is a longer match than `/` (1 char)
- C Blocked — the first rule wins
- D Crawl — Allow always wins

2.1.Q5 Meaning EASY What does a trailing **`0`** ?

- A Marks the end of the file
- B Means "match any single character"
- C Anchors the pattern to the end of the path, so it matches only paths that END there
- D Escapes the preceding character

2.1.Q6 Meaning EASY A path matches no Allow or Disallow rule in the bot's group. Is it crawlable?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 2 – robots.txt and Crawl Directives

2.1.Q1. `empty Disallow -> entire site allowed`

2.1.Q2. `disallow rules: ['/']` then `blocks entire site: True`

2.1.Q3. C a bot with its own named group obeys only that group and ignores the * block entirely.

2.1.Q4. B longest-match precedence: the 7-character Allow out-matches the 1-character Disallow.

2.1.Q5. C $ requires the path to end at that point, so `/a.pdf` matches but `/a.pdf?v=2` does not.

2.1.Q6. Yes — robots.txt is permissive by default, so any path the file never mentions is crawlable.

Chapter 3 · XML Sitemaps and URL Discovery

Build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

Chapter Skill Map

What this chapter adds: In XML Sitemaps and URL Discovery, the focus is build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors. You practise it across 40 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples.

chapter arc

What it builds on: Chapter 3 assumes the reading habits from Chapter 2: robots.txt and Crawl Directives. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 4, HTTP Status Codes and Redirects, reuses this chapter's discipline with a new kind of problem.

1 **Projects 71-83**	2 **Projects 84-96**	3 **Projects 97-110**
Recognise the pattern and read the code slowly. name it first	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. own the move

The Idea Behind It

A sitemap is a machine-readable list of the URLs you want found, written as XML.

you tell the crawler where to look, instead of hoping it finds the links

In Chapter 1 the crawler discovered pages by walking the link graph — follow an edge, fetch a node, repeat. That works, but it is at the mercy of your internal linking: an orphan page with no inbound link is invisible. A sitemap is the second discovery channel. It is a file you publish that simply *lists the URLs you want crawled*, so the bot has a seed set that does not depend on link-following at all.

The format is plain XML. The top-level element is a `<urlset>`, and inside it sits one `<url>` entry per page. Each `<url>` must contain exactly one `<loc>` — the absolute URL — and may optionally carry `<lastmod>`, `<changefreq>` and `<priority>`. That is the entire grammar. Parsing one is the first move of any sitemap audit: read the urlset, pull each `<loc>`.

We show sitemaps here as namespace-free fixtures — bare `<urlset>` and `<url>` tags — so the parsing logic stays readable. A real sitemap declares the sitemaps.org namespace on the root element (an `xmlns` attribute holding an http URI). It changes how you address the tags but not the structure you are learning.

real file: <urlset xmlns="...sitemaps.org schema..."> — we omit it on purpose

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/</loc></url>'
       '<url><loc>https://example.com/blog</loc></url>'
       '<url><loc>https://example.com/about</loc></url>'
       '</urlset>')
```

```
root = ET.fromstring(xml)
for u in root.findall('url'):
    print(u.findtext('loc'))
```

```
output
https://example.com/
https://example.com/blog
https://example.com/about
```

That loop is the whole skeleton of a sitemap tool. Everything else in this chapter — counting URLs, validating dates, flagging out-of-range priorities, splitting oversized files — is a variation on *parse the urlset, then check each entry*. parse once, audit each <url>

One sitemap cannot grow forever. A single file is capped at 50,000 URLs and 50 MB uncompressed. Past either limit you split the URLs across several sitemaps and publish one `<sitemapindex>` that points to them — a sitemap *of sitemaps*, each child referenced by its own `<loc>`. Big sites are always a shallow tree: one index at the top, many urlsets below.

SITEMAP

An XML file you publish listing the URLs you want a search engine to crawl, giving the bot a discovery seed independent of internal links.

URLSET

The root `<urlset>` element of a normal sitemap; it contains one `<url>` entry per page.

LOC

The required child of each `<url>`: the page's absolute, fully-qualified URL (e.g. `https://example.com/blog`). A `<url>` with no `<loc>` is invalid.

LASTMOD

Optional date a page last changed, in W3C/ISO form like `2026-01-01` (or a full timestamp with a `T`). It hints to crawlers what is fresh.

CHANGEFREQ & PRIORITY

<changefreq> is one of seven keywords (always, hourly, daily, weekly, monthly, yearly, never); <priority> is a decimal 0.0–1.0 (default 0.5). Both are hints, not commands.

SITEMAPINDEX

A root <sitemapindex> element whose <sitemap> children each <loc> a child sitemap file — used to fan out past the 50,000-URL / 50 MB limit.

The grammar: urlset, url, loc

A sitemap is a tree with a fixed shape. The root is <urlset>. Each child is a <url>. Inside every <url> is exactly one <loc> (required) plus optional metadata. So the *number of URLs a sitemap declares* is simply the number of <url> elements — the simplest health metric there is, and the quantity a search console reports back to you:

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/</loc></url>'
       '<url><loc>https://example.com/blog</loc></url>'
       '<url><loc>https://example.com/shop</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
print('sitemap contains', len(root.findall('url')), 'URLs')
```

```
output
sitemap contains 3 URLs
```

Because <loc> is the one required field, the first validation any linter runs is *does every <url> actually have one?* A <url> carrying only a <lastmod> and no <loc> is a broken entry the crawler cannot use.

no loc, no URL, no point

The optional metadata: lastmod, changefreq, priority

Beyond <loc>, three optional tags add signal. <lastmod> is a date; Google expects ISO/W3C form like 2026-01-01, so slashes or a reversed day-month order are rejected. <changefreq> must be one of seven exact keywords. <priority> is a decimal from 0.0 to 1.0 and defaults to 0.5 when omitted — so a sitemap where every page claims 1.0 sends no signal at all. Each tag has its own validity rule, and an audit checks all three:

```
import xml.etree.ElementTree as ET
from datetime import datetime
ALLOWED = {'always','hourly','daily','weekly','monthly','yearly','never'}
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc>'
```

```
        '<lastmod>2026/02/15</lastmod>'
        '<changefreq>often</changefreq>'
        '<priority>1.5</priority></url>'
        '</urlset>')
root = ET.fromstring(xml)
u = root.find('url')
try:
    datetime.strptime(u.findtext('lastmod'), '%Y-%m-%d'); d = 'ok'
except ValueError:
    d = 'BAD DATE'
p = float(u.findtext('priority'))
print('lastmod:', d)
print('changefreq:', 'ok' if u.findtext('changefreq') in ALLOWED else 'INVALID')
print('priority:', 'ok' if 0.0 <= p <= 1.0 else 'OUT OF RANGE')
```

```
output
lastmod: BAD DATE
changefreq: INVALID
priority: OUT OF RANGE
```

All three fields in that entry are wrong — and notice `datetime.strptime` does more than a regex could: it would also reject `2026-02-30`, a date that *looks* valid but is not a real calendar day.

strptime knows February has 28 or 29 days

Locations must be absolute, same-host HTTPS

A `<loc>` is not a path — it must be a fully-qualified absolute URL on the host that serves the sitemap. Relative paths (`/about`), scheme-less strings (`example.com/x`), non-HTTPS schemes (`ftp://`) and cross-domain URLs are all rejected or ignored by crawlers. The cheapest sound check is "does it start with `https://`?":

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>/relative/path</loc></url>'
       '<url><loc>ftp://example.com/file.zip</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    print(loc, '->', 'ok' if loc.startswith('https://') else 'NOT ABSOLUTE HTTPS')
```

```
output
https://example.com/a -> ok
/relative/path -> NOT ABSOLUTE HTTPS
ftp://example.com/file.zip -> NOT ABSOLUTE HTTPS
```

One more well-formedness trap lives in the URL itself: a raw & in a query string breaks XML parsing and must be escaped to &. So `https://example.com/search?q=shoes&sort=price` has to be written `https://example.com/search?q=shoes&sort=price` inside the file.

The two hard limits and the sitemap index

A single sitemap may hold at most 50,000 URLs and weigh at most 50 MB uncompressed. Hit either and you must split the list into multiple files. The check on each side is just a measurement — count the entries, or measure the encoded byte length:

```
urls = [f'https://example.com/p/{i}' for i in range(50002)]
LIMIT = 50000
n = len(urls)
print(n, 'URLs (limit', LIMIT, ') ->', 'SPLIT NEEDED' if n > LIMIT else 'ok')
print('overflow:', n - LIMIT)
```

```
output
50002 URLs (limit 50000 ) -> SPLIT NEEDED
overflow: 2
```

When you split, you publish one <sitemapindex> — a sitemap whose children are *other sitemaps*. Each <sitemap> child carries its own <loc> (and optional <lastmod>). Reading the index is how a crawler fans out from one file to dozens; note that the index hides the real URL total, so to know your full declared coverage you sum each child's count:

```
import xml.etree.ElementTree as ET
xml = ('<sitemapindex>'
       '<sitemap><loc>https://example.com/sitemap-posts.xml</loc>'
       '<lastmod>2026-01-10</lastmod></sitemap>'
       '<sitemap><loc>https://example.com/sitemap-pages.xml</loc>'
       '<lastmod>2026-02-01</lastmod></sitemap>'
       '</sitemapindex>')
root = ET.fromstring(xml)
for sm in root.findall('sitemap'):
    print(sm.findtext('loc'), '->', sm.findtext('lastmod'))
print('child sitemaps:', len(root.findall('sitemap')))
```

```
output
https://example.com/sitemap-posts.xml -> 2026-01-10
https://example.com/sitemap-pages.xml -> 2026-02-01
child sitemaps: 2
```

Sitemaps drive URL discovery — and reveal gaps

The payoff is discovery. The set of <loc> values *is* the seed set the crawler can fetch without following a single link, which is exactly how you surface orphan pages. But the sitemap is most useful when you compare it to the

crawl. Set subtraction exposes two different problems: URLs you declared that were never reached, and URLs the crawler found that you forgot to declare.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/orphan</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
sitemap = {u.findtext('loc') for u in root.findall('url')}
crawled = {'https://example.com/a', 'https://example.com/b',
'https://example.com/extra'}
print('in sitemap, not crawled:', sorted(sitemap - crawled))
print('crawled, not in sitemap:', sorted(crawled - sitemap))
```

```
output
in sitemap, not crawled: ['https://example.com/orphan']
crawled, not in sitemap: ['https://example.com/extra']
```

A URL in the sitemap but never crawled may be orphaned or blocked; a crawled URL missing from the sitemap probably ought to be added. The sitemap is not a magic ranking lever — it is a *discovery and inventory* tool.

sitemap ∪ crawl tells you what you have; the difference tells you what to fix

Example 1

You parse a urlset and find an entry: <url><loc>https://example.com/sale</loc><lastmod>2026/03/01</lastmod><priority>0.9</priority><changefreq>weekly</changefreq></url>. Which fields, if any, are invalid?

SOLUTION

1. `<loc>` is an absolute `https://` URL on the host — valid.
2. `<lastmod>` is `2026/03/01` with slashes; the ISO form needs hyphens (`2026-03-01`), so this is invalid date format.
3. `<priority>` is 0.9, inside 0.0–1.0 — valid; `<changefreq>` is `weekly`, one of the seven keywords — valid.

Only `<lastmod>` is invalid: the date uses slashes instead of the required ISO hyphen form. The loc, priority and changefreq are all fine.

one bad tag does not invalidate the others, but a linter still flags it

Example 2

A site has 50,000 product URLs plus 12,000 blog URLs. Can they go in one sitemap? If not, how do you structure the files?

SOLUTION

1. Total URLs = 50,000 + 12,000 = 62,000, which exceeds the 50,000-URL cap for a single sitemap.
2. So you split: e.g. `sitemap-products.xml` (50,000) and `sitemap-blog.xml` (12,000), each under the limit.
3. You then publish one `<sitemapindex>` whose two `<sitemap>` children `<loc>` those files, so the crawler reads the index and fans out to both.

No — 62,000 > 50,000, so you split into child sitemaps and reference them from a single sitemap index. Summing the children (50,000 + 12,000) gives the true declared coverage of 62,000.

index at the top, urlsets below

Mental-Math Shortcut

List it, don't lose it. A sitemap is just "the URLs I want found, written down." Every audit reduces to: parse the `<urlset>`, and for each `<url>` ask is the `<loc>` an absolute same-host HTTPS URL, is the `<lastmod>` a real ISO date, is `<priority>` in 0.0–1.0, is `<changefreq>` one of the seven words — and does the whole file stay under 50,000 URLs and 50 MB. Past those caps, fan out with a `<sitemapindex>`.

⚠ Common Mistakes

- Putting relative paths or non-HTTPS / cross-domain URLs in <loc>. Locations must be absolute, fully-qualified URLs on the same host that serves the sitemap, or crawlers ignore them.
- Writing <lastmod> with slashes or reversed day-month order (2026/03/01, 15-03-2026). Google expects ISO/W3C form 2026-03-01; strptime also catches impossible dates like 2026-02-30.
- Letting a single sitemap exceed 50,000 URLs or 50 MB. Past either cap you must split the URLs and publish a <sitemapindex> pointing to the child files.
- Treating <priority> and <changefreq> as ranking levers. They are crawl hints only; setting every page to priority 1.0 conveys nothing, and a raw & in a URL must still be escaped to & or the XML breaks.

This chapter contains 40 hands-on mini-projects (Projects 71–110). Type each one out, run it, and experiment.

Project 71 Extract Every loc From a Urlset

The Idea Behind It

A sitemap is a urlset wrapper holding many url elements, and every url carries exactly one loc with the page address. This project loads a urlset string with ElementTree, walks each url node, and pulls the text inside its

loc child into a list. It proves that reading a sitemap is really just tree traversal: find the repeated element, read its child, collect the values.

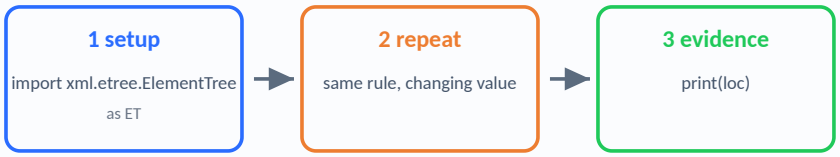
What You'll Build & Learn

Parse a urlset string and print every URL declared inside its loc tags.

- ElementTree parses XML into a node tree
- findall gathers all repeated url elements
- findtext reads a child element's inner text

🧭 Skill Roadmap

Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 72 changes the surface problem while preserving the underlying method. *progress check*



Reading target: extract every loc from a urlset is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(loc)` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`locs = [u.findtext('loc') for u in root.findall('url')]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(loc)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `locs = [u.findtext('loc') for u in root.findall('url')]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Extract Every loc From a Urlset: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: locs = [u.findtext('loc') for u in root.findall('url')] | Evidence: print(loc)

🛠️ Reader to Writer Bridge

1. Read: explain extract every loc from a urlset in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 72 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(loc)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of extract every loc from a urlset and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`ET.fromstring` parses the XML string into an element tree, and `findall('url')` plus `findtext('loc')` reads each entry's location; real sitemaps add an `xmlns` attribute but this parsing logic is identical.

```
import xml.etree.ElementTree as ET
xml = '<urlset><url><loc>https://example.com/</loc></url><url>
<loc>https://example.com/blog</loc></url><url>
<loc>https://example.com/about</loc></url></urlset>'
root = ET.fromstring(xml)
locs = [u.findtext('loc') for u in root.findall('url')]
for loc in locs:
    print(loc)
```

```
output
https://example.com/
https://example.com/blog
https://example.com/about
```

How it works:

1. ET.fromstring turns the urlset string into a root element holding three url children.
2. root.findall('url') returns the list of url nodes to iterate.
3. The list comprehension calls u.findtext('loc') on each, extracting the URL string.
4. The for loop prints each loc on its own line.

Try it:

1. Add a fourth url element and confirm the new loc prints.
2. Collect the locs into a set instead of a list to drop accidental duplicates.
3. Print the total count of URLs after the loop finishes.
4. Add a fourth `<url>` and confirm the loop prints it too.

⚠ Common Mistakes

- Real sitemaps declare a default namespace, which would make `findall('url')` return nothing unless you prefix the tag; this fixture omits it on purpose.
- Using `root.findall('loc')` looks one level too shallow because `<loc>` is nested inside `<url>`.
- `find` returns only the first match, so use `findall` to get every URL.

Skills gained ElementTree parsing | findall | findtext | list comprehension

→ Where You'll Use This: Extracting the loc list is the opening move of any sitemap audit, feeding crawl comparisons, broken-link checks, and coverage reports downstream.

Mental Model

The urlset is a shipping manifest and each loc is one parcel's address: you read the manifest line by line to learn where everything goes.

Project 72 Count the URLs in a Sitemap

The Idea Behind It

Search consoles surface how many URLs a sitemap declares, and that figure is simply the number of url elements. This code parses a urlset, calls findall to gather every url node into a list, and reports len of that list inside an f-string. It is the smallest possible health metric and the foundation for the later check that no file exceeds fifty thousand entries.

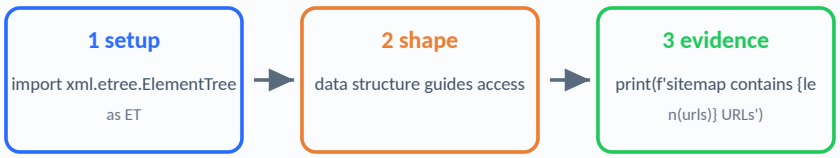
What You'll Build & Learn

Count the url elements in a sitemap and print the total in a readable sentence.

- findall returns a list you can measure
- len gives the declared URL count
- Counting is the first sitemap health check

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 71: extract every loc from a urlset. Project 73 changes the surface problem while preserving the underlying method.



progress check

Reading target: count the urls in a sitemap is the surface task; the transferable Python move is to mark setup, rule, and output before running. setup -> rule -> result

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The data structure is doing part of the thinking. Ask what the collection stores, how items are found, and what order or uniqueness it promises.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'sitemap contains {len(urls)} URLs')` exposes the result; match it against the output before changing the program. output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, shape applies the chapter idea, and evidence proves your trace against the output. visual trace

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`xml = '<urlset><url><loc>https://example.com/</loc></url><url><loc>https://example.com/blog</loc></url><url><loc>https://example.com/shop</loc></url></urlset>'`	This line depends on the chosen data shape. Ask how items are stored, found, or ordered. slow line
3. Check the evidence	`print(f'sitemap contains {len(urls)} URLs')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
xml = '<urlset><url><loc>https://example.com/</loc></url><url>
<loc>https://example.com/blog</loc></url><url><loc>https://example.com/shop</...
```

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Name the collection shape, then ask how an item is added, selected, transformed, or counted.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Count the URLs in a Sitemap: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: xml = '<urlset><url><loc>https://example.com/</loc></url><url><loc>http... | Evidence: print(f'sitemap contains {len(urls)} URLs')

Reader to Writer Bridge

1. Read: explain count the urls in a sitemap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 71.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 73 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'sitemap contains {len(urls)} URLs')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count the urls in a sitemap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`findall('url')` returns a list of every `<url>` element, so its length is the declared URL count for the sitemap.

```
import xml.etree.ElementTree as ET
xml = '<urlset><url><loc>https://example.com/</loc></url><url>
<loc>https://example.com/blog</loc></url><url>
<loc>https://example.com/shop</loc></url></urlset>'
root = ET.fromstring(xml)
urls = root.findall('url')
print(f'sitemap contains {len(urls)} URLs')
```

```
output
sitemap contains 3 URLs
```

How it works:

1. ET.fromstring parses the urlset into a root element.
2. root.findall('url') collects the three url nodes into a list named urls.
3. len(urls) yields the count of declared URLs.
4. The f-string prints sitemap contains 3 URLs.

Try it:

1. Warn when the count exceeds a threshold you choose, like 2.
2. Print the count of unique locs alongside the raw url total.
3. Wrap the count in a function that accepts any urlset string.
4. Add a `<url>` with no `<loc>` and confirm it still counts as a URL entry.

⚠ Common Mistakes

- Counting `<loc>` tags instead of `<url>` entries miscounts when a url block holds extra child tags.
- `len(root)` counts direct children which happens to match here but breaks if non-url tags appear.
- A real namespaced sitemap needs the prefixed tag name or the count comes back zero.

Skills gained `findall` `len` `f-string`

→ **Where You'll Use This:** URL counts feed directly into Search Console comparisons, where a mismatch between declared and indexed pages flags coverage problems worth investigating.

Mental Model

Counting url elements is like tallying chairs in a room before a meeting: a quick headcount tells you whether the space fits everyone.

Project 73 Flag URLs Missing a lastmod

The Idea Behind It

The lastmod tag is optional, yet it tells crawlers when a page changed, so auditors list the URLs that omit it. This project parses each url, reads both loc and lastmod with findtext, and substitutes a MISSING lastmod marker when findtext returns a falsy value. The conditional cleanly separates dated pages from undated ones so editors can backfill the gaps.

What You'll Build & Learn

Report each URL's lastmod value, flagging the entries that lack one.

- findtext returns None when a child is absent
- A truthiness test selects a fallback label
- lastmod signals page freshness to crawlers

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 72: count the urls in a sitemap. Project 74 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag urls missing a lastmod is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

- Evidence: `print(f'{loc}: {status}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`status = lastmod if lastmod else 'MISSING lastmod'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: {status}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `status = lastmod if lastmod else 'MISSING lastmod'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag URLs Missing a lastmod: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: status = lastmod if lastmod else 'MISSING lastmod' | Evidence: print(f'{loc}: {status}')

🛠️ Reader to Writer Bridge

1. Read: explain flag urls missing a lastmod in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 72.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 74 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {status}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag urls missing a lastmod and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`findtext('lastmod')` returns `None` when the tag is absent, so a falsy check cleanly separates dated URLs from those needing a lastmod.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/</loc><lastmod>2026-01-01</lastmod>
</url>'
       '<url><loc>https://example.com/blog</loc></url>'
```

```
        '<url><loc>https://example.com/shop</loc><lastmod>2026-02-15</lastmod>
</url>'
        '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    lastmod = u.findtext('lastmod')
    status = lastmod if lastmod else 'MISSING lastmod'
    print(f'{loc}: {status}')
```

```
output
https://example.com/: 2026-01-01
https://example.com/blog: MISSING lastmod
https://example.com/shop: 2026-02-15
```

How it works:

1. The urlset holds three url nodes; the middle one has no lastmod child.
2. For each url, loc and lastmod are read via findtext.
3. status becomes the lastmod value if present, otherwise the string MISSING lastmod.
4. The f-string prints each loc followed by its status.

Try it:

1. Count how many URLs are missing a lastmod and print the total.
2. Collect only the missing locs into a separate list for export.
3. Replace the marker text with a sortable empty string and re-sort.
4. Add an empty `<lastmod></lastmod>` and see it flagged as missing.

⚠ Common Mistakes

- `findtext` returns `None` (not an empty string) for a missing tag, so `lastmod == ''` would never match.
- An empty `<lastmod></lastmod>` returns `''`, also falsy, which may or may not be what you want to flag.
- Treating a missing lastmod as an error rather than a warning; it is valid to omit it.

Skills gained findtext | conditional expression | truthiness

→ Where You'll Use This: Backfilling missing lastmod dates helps crawlers schedule recrawls efficiently, so this gap report drives a concrete content-hygiene task list.

Mental Model

Think of lastmod like a sell-by date: a missing one does not spoil the item, but stockers cannot tell what needs rotating to the front.

Project 74 Validate lastmod as an ISO Date

The Idea Behind It

Google expects lastmod in W3C/ISO form like 2026-01-01, and this project enforces that by trying to parse each value with a fixed strptime pattern. When the format has slashes or a reversed day-month order, strptime raises ValueError, which the try/except catches and labels BAD FORMAT. The technique turns a vague formatting rule into a hard pass/fail per URL.

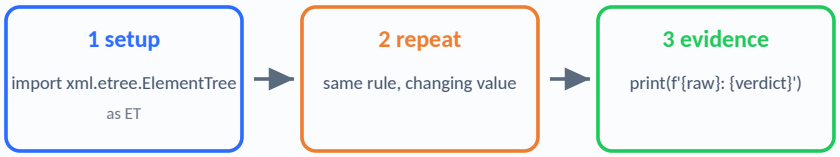
What You'll Build & Learn

Validate every lastmod against the strict YYYY-MM-DD pattern and mark bad formats.

- strptime parses a string against a format
- A wrong format raises ValueError
- try/except converts errors into verdicts

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 73: flag urls missing a lastmod. Project 75 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate lastmod as an iso date is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{raw}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

🛠️ Reader to Writer Bridge

1. Read: explain validate lastmod as an iso date in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 73.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 75 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{raw}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate lastmod as an iso date and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`datetime.strptime` with the `%Y-%m-%d` pattern raises `ValueError` on any string that does not match exactly, which is the validity test; note `strptime` parses a fixed string and never reads the current date.

```
import xml.etree.ElementTree as ET
from datetime import datetime
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><lastmod>2026-01-01</lastmod>
</url>'
       '<url><loc>https://example.com/b</loc><lastmod>2026/02/15</lastmod>
</url>'
```

```
        '<url><loc>https://example.com/c</loc><lastmod>15-03-2026</lastmod>
</url>'
        '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    raw = u.findtext('lastmod')
    try:
        datetime.strptime(raw, '%Y-%m-%d')
        verdict = 'valid'
    except ValueError:
        verdict = 'BAD FORMAT'
    print(f'{raw}: {verdict}')
```

```
output
2026-01-01: valid
2026/02/15: BAD FORMAT
15-03-2026: BAD FORMAT
```

How it works:

1. Three url nodes carry an ISO date, a slash date, and a reversed date.
2. For each, raw holds the lastmod text.
3. datetime.strptime(raw, '%Y-%m-%d') succeeds only for the ISO form.
4. The except branch sets verdict to BAD FORMAT, and each result prints.

Try it:

1. Accept a full timestamp form by trying a second strptime pattern on failure.
2. Tally how many dates pass versus fail and print a summary line.
3. Add a date with a two-digit year and observe the verdict.
4. Add `2026-1-1` and confirm `%Y-%m-%d` rejects the unpadded month.

⚠ Common Mistakes

- Using `datetime.now` to compare would be nondeterministic; `strptime` only parses the given string.
- A loose pattern like `%Y-%m-%d` still accepts a date plus a trailing time unless you strip it first.
- Catching a bare `except` would also swallow a `TypeError` when `raw` is `None`.

Skills gained strptime | try/except | date validation

→ Where You'll Use This: Date-format validation prevents silent rejection of lastmod values by search engines, a subtle failure that otherwise hides until indexing signals weaken.

Mental Model

strptime is a passport officer with one stamp shape: present a date in any other layout and it gets turned away at the desk.

Project 75 Check priority Is Within 0.0 to 1.0

The Idea Behind It

The priority tag must be a decimal between 0.0 and 1.0, and values outside that band are quietly ignored by crawlers. This code reads each priority, converts it with float, and applies a chained comparison to decide ok or OUT OF RANGE. Casting to float lets the numeric bounds check work directly on what XML stores only as text.

What You'll Build & Learn

Confirm each URL's priority falls within the legal 0.0 to 1.0 range.

- float casts text into a comparable number
- Chained comparison checks a numeric band
- Out-of-range priorities are ignored by crawlers

Skill Roadmap

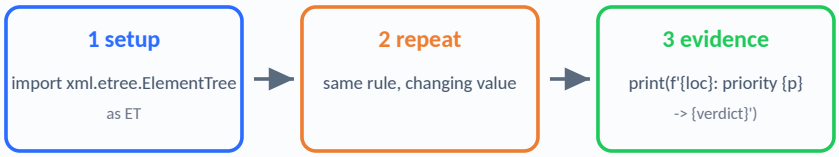
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 74: validate lastmod as an iso date. Project 76 changes the surface problem while preserving the underlying method.

progress check

Reading target: check priority is within 0.0 to 1.0 is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: priority {p} -> {verdict}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`verdict = 'ok' if 0.0 <= p <= 1.0 else 'OUT OF RANGE'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{loc}: priority {p} -> {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'ok' if 0.0 <= p <= 1.0 else 'OUT OF RANGE'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check priority Is Within 0.0 to 1.0: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'ok' if 0.0 <= p <= 1.0 else 'OUT OF RANGE' | Evidence: print(f'{loc}: priority {p} -> {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain check priority is within 0.0 to 1.0 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 74.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 76 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: priority {p} -> {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check priority is within 0.0 to 1.0 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Converting the text to `float` lets a single chained comparison `0.0 <= p <= 1.0` test the allowed band in one expression.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><priority>0.8</priority></url>'
       '<url><loc>https://example.com/b</loc><priority>1.5</priority></url>'
       '<url><loc>https://example.com/c</loc><priority>0.0</priority></url>'
       '</urlset>')
root = ET.fromstring(xml)
```

```
for u in root.findall('url'):
    loc = u.findtext('loc')
    p = float(u.findtext('priority'))
    verdict = 'ok' if 0.0 <= p <= 1.0 else 'OUT OF RANGE'
    print(f'{loc}: priority {p} -> {verdict}')
```

```
output
https://example.com/a: priority 0.8 -> ok
https://example.com/b: priority 1.5 -> OUT OF RANGE
https://example.com/c: priority 0.0 -> ok
```

How it works:

1. Three url nodes declare priorities 0.8, 1.5, and 0.0.
2. p = float(u.findtext('priority')) converts the text to a number.
3. The expression 0.0 <= p <= 1.0 decides ok versus OUT OF RANGE.
4. Each loc, its priority, and the verdict print together.

Try it:

1. Handle a missing priority by defaulting to 0.5 before the check.
2. Catch a non-numeric priority with try/except and label it MALFORMED.
3. Count how many URLs fall outside the legal band.
4. Add a `<priority>abc</priority>` and wrap the `float` in a try/except.

⚠ Common Mistakes

- `float('')` or `float(None)` raises, so a missing `<priority>` would crash without a guard.
- Comparing the raw string with `<=` would do lexicographic, not numeric, comparison.
- Priority is relative within your own site, not a ranking promise; out-of-range just gets ignored.

Skills gained float casting | chained comparison | range check

→ Where You'll Use This: Range-checking priority keeps a sitemap free of values crawlers discard, so the priority signals you do send actually reach the indexer intact.

Mental Model

Priority is a volume knob that only turns from 0 to 10: crank it past the stop and the amplifier simply ignores the impossible setting.

Project 76 Validate changefreq Against the Enum

The Idea Behind It

The changefreq tag accepts only seven keywords from always to never, so anything else is invalid. This project stores the legal words in a set, reads each url's changefreq, and tests membership with the in operator to find typos like often. Using a set makes each lookup constant time and expresses the closed enumeration directly in code.

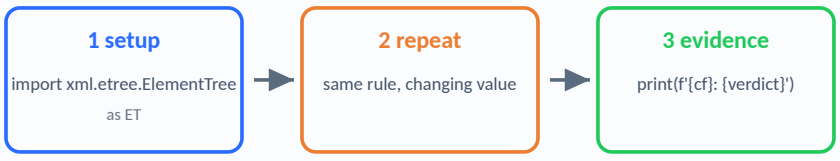
What You'll Build & Learn

Validate every changefreq value against the seven-keyword allowed set.

- A set encodes a closed enumeration
- The in operator tests set membership
- changefreq has exactly seven legal values

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 75: check priority is within 0.0 to 1.0. Project 77 changes the surface problem while preserving the underlying method.



progress check

Reading target: validate changefreq against the enum is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{cf}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'ok' if cf in allowed else 'INVALID' | Evidence: print(f'{cf}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain validate changefreq against the enum in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 75.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 77 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{cf}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate changefreq against the enum and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A `set` of the seven legal keywords turns validation into a constant-time `in` membership test, rejecting any value that is not a recognised frequency.

```
import xml.etree.ElementTree as ET
allowed = {'always', 'hourly', 'daily', 'weekly', 'monthly', 'yearly', 'never'}
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><changefreq>daily</changefreq>
</url>'
       '<url><loc>https://example.com/b</loc><changefreq>often</changefreq>
</url>'
       '<url><loc>https://example.com/c</loc><changefreq>weekly</changefreq>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    cf = u.findtext('changefreq')
    verdict = 'ok' if cf in allowed else 'INVALID'
    print(f'{cf}: {verdict}')
```

```
output
```

```
daily: ok
often: INVALID
weekly: ok
```

How it works:

1. allowed holds the seven valid keywords as a set.
2. Three url nodes declare daily, often, and weekly.
3. cf in allowed returns True only for real keywords.
4. Each value prints with ok or INVALID based on membership.

Try it:

1. Make the comparison case-insensitive by lowercasing cf first.
2. Collect the invalid values into a list and print them once.
3. Add a url with an empty changefreq and inspect the verdict.
4. Add `.lower()` so `WEEKLY` validates.

⚠ Common Mistakes

- Case matters: `Daily` would fail unless you lowercase first.
- A missing `<changefreq>` yields `None`, which is correctly not in the set but may deserve a separate message.
- Treating `changefreq` as a hard directive; crawlers treat it as a hint only.

Skills gained set membership | enum validation | findtext

→ Where You'll Use This: Validating changefreq against its enum catches editorial typos before they reach search engines, where unknown keywords are dropped and recrawl hints are lost.

⚡ Mental Model

The allowed set is a multiple-choice answer sheet: only the seven printed options score, and writing in your own answer earns nothing.

Project 77 Detect Duplicate loc Entries

💡 The Idea Behind It

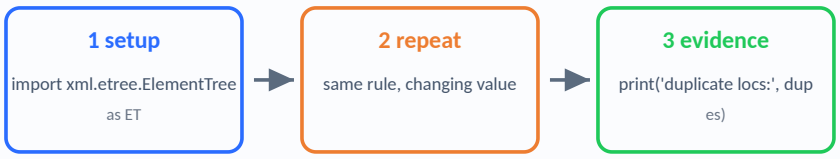
A URL should appear once per sitemap, since duplicate loc values waste crawl budget and muddle reporting. This code feeds every loc into a Counter, then keeps the addresses whose tally exceeds one and sorts them. Counter does the frequency bookkeeping in a single pass, turning duplicate detection into a simple comprehension over its items.

What You'll Build & Learn

Detect and list the loc values that appear more than once in a urlset.

- Counter tallies occurrences in one pass
- Filter items by count greater than one
- Duplicate URLs waste crawl budget

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 76: validate changefreq against the enum. Project 78 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect duplicate loc entries is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('duplicate locs:', dupes)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

1. Read: explain detect duplicate loc entries in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 76.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 78 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('duplicate locs:', dupes)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect duplicate loc entries and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `Counter` tallies how often each loc appears; filtering to counts above one and sorting yields the duplicate URLs in deterministic order.

```
import xml.etree.ElementTree as ET
from collections import Counter
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/c</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
counts = Counter(u.findtext('loc') for u in root.findall('url'))
dupes = sorted(loc for loc, n in counts.items() if n > 1)
print('duplicate locs:', dupes)
```

```
output
duplicate locs: ['https://example.com/a', 'https://example.com/b']
```

How it works:

1. Five url nodes include /a and /b twice each.
2. Counter(...) tallies each loc's frequency from a generator.
3. The comprehension keeps locs where n > 1 and sorted orders them.
4. print shows duplicate locs as a sorted list.

Try it:

1. Print each duplicate alongside the number of times it appears.
2. Build a deduplicated loc list preserving first-seen order.
3. Report the percentage of entries that are duplicates.
4. Lowercase each loc before counting to catch case-variant duplicates.

⚠ Common Mistakes

- Building a `set` first would erase the duplicates before you could count them.
- Not sorting the result makes the printed order vary between runs.
- Case or trailing-slash variants are treated as distinct here, so true near-duplicates can slip through.

Skills gained `Counter` `generator expression` `deduplication`

→ Where You'll Use This: Spotting duplicate locs trims wasted recrawls and cleans up coverage reporting, a routine fix when sitemaps are stitched together from several sources.

⚡ Mental Model

Counter is a turnstile tally: it clicks once per visitor, and at day's end you read off who came back through more than once.

Project 78 Flag the 50,000-URL Limit

💡 The Idea Behind It

A single sitemap may hold at most fifty thousand URLs, and this project demonstrates the cap by generating an oversized list with a comprehension. It measures the list length, compares it to the LIMIT constant, and reports SPLIT NEEDED plus the exact overflow. No XML parsing is involved here; the lesson is purely the count-versus-cap arithmetic that decides when a file must be divided.

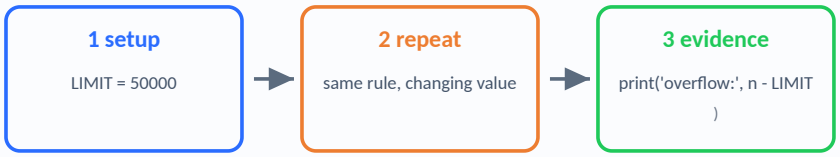
What You'll Build & Learn

Generate an over-limit URL list and report that it must be split, with the overflow.

- A range comprehension builds many URLs fast
- len compared to a cap gates the verdict
- Subtraction reports how far over the limit

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 77: detect duplicate loc entries. Project 79 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag the 50,000-url limit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `LIMIT = 50000` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('overflow:', n - LIMIT)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`LIMIT = 50000`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`verdict = 'SPLIT NEEDED' if n > LIMIT else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('overflow:', n - LIMIT)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'SPLIT NEEDED' if n > LIMIT else 'ok'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

3. Transfer: change one small part of flag the 50,000-url limit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Comparing the generated list length to the 50,000 cap detects when a urlset exceeds the protocol limit and must be partitioned across several sitemaps under an index.

```
LIMIT = 50000
urls = [f'https://example.com/p/{i}' for i in range(50002)]
n = len(urls)
verdict = 'SPLIT NEEDED' if n > LIMIT else 'ok'
print(f'{n} URLs (limit {LIMIT}) -> {verdict}')
print('overflow:', n - LIMIT)
```

```
output
50002 URLs (limit 50000) -> SPLIT NEEDED
overflow: 2
```

How it works:

1. A comprehension builds 50002 fake URLs with range.
2. n = len(urls) measures the list size.
3. n > LIMIT decides SPLIT NEEDED versus ok.
4. The code prints the count, the verdict, and n minus LIMIT as overflow.

Try it:

1. Compute how many capped files the overflow requires using ceiling division.
2. Lower LIMIT to a tiny value and confirm the split triggers.
3. Print the index of the first URL that exceeds the cap.
4. Lower `LIMIT` to 50000 and a list of 50000 to confirm it just passes.

⚠ Common Mistakes

- The limit is 50,000 URLs OR 50 MB uncompressed, whichever comes first; this checks only the count.
- Off-by-one: `range(50002)` produces exactly 50002 items, so `> LIMIT` is the right comparator, not `>=`.
- Counting `<loc>` plus child `<image>` locs against the URL limit double-counts; only `<url>` entries count.

Skills gained `range` `list comprehension` `limit check`

→ **Where You'll Use This:** The fifty-thousand cap forces large sites to shard their sitemaps and publish an index, so this overflow check decides exactly how many files you need.

⚡ Mental Model

Fifty thousand is an elevator's posted capacity: one rider over the placard and someone has to wait for the next car.

Project 79 Parse a Sitemap Index of Children

💡 The Idea Behind It

Large sites use a sitemapindex that points to many child sitemaps, each with its own loc and lastmod. This project parses such an index, iterates its sitemap children, and prints each child's location alongside its modification date, then counts them. Reading the index is how a crawler fans out from one entry point to every shard of a sprawling site.

What You'll Build & Learn

Parse a sitemapindex and print each child sitemap's loc and lastmod, plus the count.

- A sitemapindex lists child sitemaps
- Each sitemap child has loc and lastmod
- findall iterates the sitemap nodes

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 78: flag the 50,000-url limit. Project 80 changes the surface problem while preserving the underlying method.

progress check

Reading target: parse a sitemap index of children is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

- Evidence: `print('child sitemaps:', len(root.findall('sitemap')))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`for sm in root.findall('sitemap'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('child sitemaps:', len(root.findall('sitemap')))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for sm in root.findall('sitemap'):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Parse a Sitemap Index of Children: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, sitemapindex. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: for sm in root.findall('sitemap'): | Evidence: print('child sitemaps:', len(root.findall('sitemap')))

🛠️ Reader to Writer Bridge

1. Read: explain parse a sitemap index of children in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 78.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 80 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('child sitemaps:', len(root.findall('sitemap')))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse a sitemap index of children and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A sitemap index uses `<sitemap>` children (not `<url>`), each carrying a `<loc>` pointing at a child sitemap file, so the parsing mirrors a urlset with different tag names.

```
import xml.etree.ElementTree as ET
xml = ('<sitemapindex>'
       '<sitemap><loc>https://example.com/sitemap-posts.xml</loc><lastmod>2026-
01-10</lastmod></sitemap>'
```

```
        '<sitemap><loc>https://example.com/sitemap-pages.xml</loc><lastmod>2026-
02-01</lastmod></sitemap>'
        '</sitemapindex>')
root = ET.fromstring(xml)
for sm in root.findall('sitemap'):
    print(sm.findtext('loc'), '->', sm.findtext('lastmod'))
print('child sitemaps:', len(root.findall('sitemap')))
```

```
output
https://example.com/sitemap-posts.xml -> 2026-01-10
https://example.com/sitemap-pages.xml -> 2026-02-01
child sitemaps: 2
```

How it works:

1. ET.fromstring parses the sitemapindex into a root element.
2. root.findall('sitemap') yields two sitemap children.
3. For each, findtext reads loc and lastmod, printed with an arrow between.
4. A final print reports child sitemaps: 2.

Try it:

1. Validate each child loc starts with https before printing it.
2. Sort the children by lastmod to surface the freshest shard.
3. Flag any child sitemap whose lastmod child is absent.
4. Add a third child sitemap and watch the count rise.

⚠ Common Mistakes

- Looking for `<url>` in an index returns nothing; the entries are `<sitemap>`.
- A `<loc>` in an index must point to another sitemap file, never to a page.
- Mixing `<url>` and `<sitemap>` entries in one file is invalid; a file is either an index or a urlset.

Skills gained `sitemapindex` `findall` `findtext`

→ Where You'll Use This: Reading the index is how crawlers and audit tools discover every shard of a big site, so this fan-out step underpins full-coverage analysis.

Mental Model

A sitemapindex is a table of contents: it does not hold the chapters, just the page numbers that tell you where each one begins.

Project 80 Build a Urlset From a URL List

The Idea Behind It

Auditing is only half the job; the other half is generating valid XML. This project takes a plain Python list of URLs, opens with a urlset tag, appends one url and loc block per address inside a loop, then closes the tag and joins everything into one string. Building the parts in a list and joining at the end is the efficient way to assemble markup.

What You'll Build & Learn

Wrap a list of URLs into a well-formed urlset XML string.

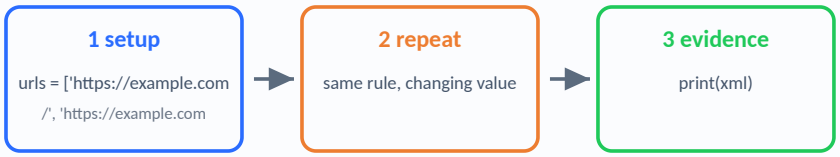
- Build markup as a list of string parts
- An f-string templates each url block
- join concatenates the pieces efficiently

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 79: parse a sitemap index of children. Project 81 changes the surface problem while preserving the underlying method.

progress check

Reading target: build a urlset from a url list is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `urls = ['https://example.com/', 'https://example.com/blog', 'https://example.com/shop']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(xml)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = ['https://example.com/', 'https://example.com/blog', 'https://example.com/shop']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`for u in urls:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(xml)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for u in urls:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Urlset From a URL List: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: urls, https, example, com, blog. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: urls = ['https://example.com/', 'https://example.com/blog', 'https://ex... | Core: for u in urls: | Evidence: print(xml)

🛠️ Reader to Writer Bridge

1. Read: explain build a urlset from a url list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 79.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 81 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(xml)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `urls = ['https://example.com/', 'https://example.com/blog', 'https://example.com/shop']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a urlset from a url list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Accumulating fragments in a list and joining once builds the urlset efficiently; a real sitemap would add the `xmlns` attribute on `<urlset>` but the structure is otherwise identical.

```
urls = ['https://example.com/', 'https://example.com/blog',
'https://example.com/shop']
parts = ['<urlset>']
for u in urls:
    parts.append(f'<url><loc>{u}</loc></url>')
parts.append('</urlset>')
```

```
xml = ''.join(parts)
print(xml)
```

```
output
<urlset><url><loc>https://example.com/</loc></url><url>
<loc>https://example.com/blog</loc></url><url><loc>https://example.com/shop</loc>
</url></urlset>
```

How it works:

1. parts starts as a list holding the opening urlset tag.
2. The loop appends a url and loc block for each address via an f-string.
3. parts.append closes the urlset tag.
4. ''.join(parts) fuses the list into one XML string that prints.

Try it:

1. Add a lastmod child to each url block from a parallel list.
2. Escape ampersands in each URL before embedding it.
3. Pretty-print the output with newlines between url blocks.
4. Add a `<lastmod>` child inside each `<url>` block.

⚠ Common Mistakes

- String-concatenating in a loop with `+=` is quadratic; building a list and joining is linear.
- URLs containing `&` must be escaped to `&` first or the XML is malformed.
- Omitting the `xmlns` makes this fixture parse here but invalid as a live sitemap.

Skills gained string building | join | XML generation

→ Where You'll Use This: Generating a urlset is the core of any sitemap publisher, the step that turns a crawl or CMS export into the file you submit to search engines.

Mental Model

Building parts then joining is like prepping ingredients in bowls before stirring once: assembling piecemeal beats restitching the whole string each loop.

Project 81 Build a Sitemap Index File

The Idea Behind It

When you split URLs across many sitemaps, you publish one index listing them all. This project mirrors the urlset builder but emits a sitemapindex: it opens the index tag, appends a sitemap and loc block per child URL,

closes the tag, and joins the parts. It is the final assembly step that ties a fleet of child files together for crawlers.

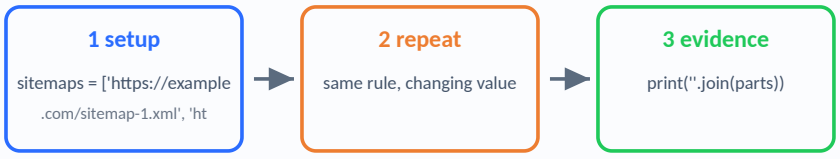
What You'll Build & Learn

Generate a sitemapindex XML string from a list of child sitemap URLs.

- An index wraps sitemap not url elements
- Loop and append builds each child block
- join produces the final index string

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 80: build a urlset from a url list. Project 82 changes the surface problem while preserving the underlying method.



progress check

Reading target: build a sitemap index file is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `sitemaps = ['https://example.com/sitemap-1.xml', 'https://example.com/sitemap-2.xml']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(''.join(parts))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`sitemaps = ['https://example.com/sitemap-1.xml', 'https://example.com/sitemap-2.xml']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`for s in sitemaps:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(''.join(parts))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for s in sitemaps:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Sitemap Index File: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: sitemaps, https, example, com, sitemap. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: sitemaps = ['https://example.com/sitemap-1.xml', 'https://example.com/s... | Core: for s in sitemaps: | Evidence: print(''.join(parts))

🛠️ Reader to Writer Bridge

1. Read: explain build a sitemap index file in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 80.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 82 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(''.join(parts))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `sitemaps = ['https://example.com/sitemap-1.xml', 'https://example.com/sitemap-2.xml']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a sitemap index file and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The index mirrors a urlset but uses `<sitemap>`/`<loc>` pairs pointing at child files; this is what you submit to search engines once a site outgrows one sitemap.

```
sitemaps = ['https://example.com/sitemap-1.xml', 'https://example.com/sitemap-2.xml']
parts = ['<sitemapindex>']
for s in sitemaps:
    parts.append(f'<sitemap><loc>{s}</loc></sitemap>')
parts.append('</sitemapindex>')
print(''.join(parts))
```

```
output
<sitemapindex><sitemap><loc>https://example.com/sitemap-1.xml</loc></sitemap>
<sitemap><loc>https://example.com/sitemap-2.xml</loc></sitemap></sitemapindex>
```

How it works:

1. parts begins with the opening sitemapindex tag.
2. The loop appends a sitemap and loc block for each child URL.
3. parts.append closes the sitemapindex tag.
4. ''.join(parts) prints the complete index XML.

Try it:

1. Add a lastmod child to each sitemap block from a parallel list.
2. Validate every child URL is absolute https before appending it.
3. Reuse a helper that takes the tag names so one function builds both file types.
4. Add `<lastmod>` to each `<sitemap>` entry.

⚠ Common Mistakes

- Each child loc must be a full absolute URL, not a relative path.
- An index may not nest another index; it only lists leaf sitemaps.
- Forgetting the closing `</sitemapindex>` produces XML that fails to parse.

Skills gained sitemapindex | string building | join

→ Where You'll Use This: Generating the index is the capstone of sharding a large sitemap, producing the single file you actually submit so crawlers can reach every child.

⚡ Mental Model

The index file is a building directory in the lobby: it lists which floor each department occupies so visitors know where to head next.

Project 82 Require Absolute HTTPS Locations

💡 The Idea Behind It

Sitemap URLs must be fully qualified and absolute, never relative paths. This project parses a urlset and tests whether each loc begins with the https scheme, labelling anything that does not as NOT ABSOLUTE HTTPS. The startswith check rejects bare paths like /relative and schemeless hosts like example.com, both of which crawlers cannot resolve from inside a sitemap.

What You'll Build & Learn

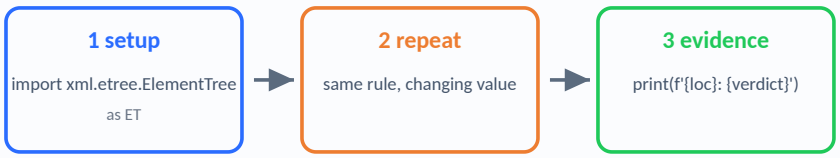
Verify each loc is an absolute https URL and flag relative or schemeless ones.

- Sitemap locs must be absolute, not relative
- startswith tests a required prefix

- Schemeless hosts are invalid entries

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 81: build a sitemap index file. Project 83 changes the surface problem while preserving the underlying method.



progress check

Reading target: require absolute https locations is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`verdict = 'ok' if loc.startswith('https://') else 'NOT ABSOLUTE HTTPS'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f'{loc}: {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'ok' if loc.startswith('https://') else 'NOT ABSOLUTE HTTPS'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Require Absolute HTTPS Locations: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'ok' if loc.startswith('https://') else 'NOT ABSOLUTE HTTPS' | Evidence: print(f'{loc}: {verdict}')

Reader to Writer Bridge

1. Read: explain require absolute https locations in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 81.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 83 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of require absolute https locations and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A simple `startswith('https://')` prefix test enforces that every loc is an absolute, secure URL, the form the sitemap protocol requires.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>/relative/path</loc></url>'
       '<url><loc>example.com/no-scheme</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    verdict = 'ok' if loc.startswith('https://') else 'NOT ABSOLUTE HTTPS'
    print(f'{loc}: {verdict}')
```

```
output
https://example.com/a: ok
/relative/path: NOT ABSOLUTE HTTPS
example.com/no-scheme: NOT ABSOLUTE HTTPS
```

How it works:

1. The urlset holds an absolute URL, a relative path, and a schemeless host.
2. For each url, loc is read with findtext.
3. loc.startswith('https://') decides ok versus NOT ABSOLUTE HTTPS.
4. Each loc prints with its verdict.

Try it:

1. Also accept http during a migration and note which scheme each uses.
2. Use urllib.parse to confirm both a scheme and a netloc are present.

3. Collect only the invalid locs for a remediation list.
4. Accept either https or an uppercase scheme by lowercasing the prefix check.

⚠ Common Mistakes

- A protocol-relative `//example.com/x` is not absolute and rightly fails this test.
- Allowing any scheme by checking only for `://` would pass ftp and mailto links.
- Whitespace around the loc would defeat `startswith`; strip first if your source is messy.

Skills gained `startswith` `absolute URLs` `validation`

→ **Where You'll Use This:** Rejecting relative or schemeless locs prevents crawlers from discarding entries they cannot resolve, a frequent defect when sitemaps are templated by hand.

⚡ Mental Model

An absolute URL is a full mailing address with city and country; a relative path is just an apartment number that means nothing without the building.

Project 83 Detect a url Entry With No loc

💡 The Idea Behind It

Every url element must contain exactly one loc; a block without it is invalid and unparseable for crawlers. This project enumerates the url nodes, reads loc with findtext, and tests for None to spot the empty entry. Using enumerate gives a positional index so the report can pinpoint exactly which url block is malformed.

What You'll Build & Learn

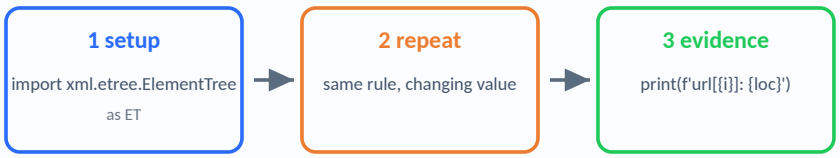
Find any url entry that lacks a loc child and report its position.

- findtext returns None for a missing loc
- enumerate supplies a positional index
- Every url needs exactly one loc

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 82: require absolute https locations. Project 84 changes the surface problem while preserving the underlying method.

progress check



Reading target: detect a url entry with no loc is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'url[{i}]: {loc}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`if loc is None:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'url[{i}]: {loc}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if loc is None:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a url Entry With No loc: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: if loc is None: | Evidence: print(f'url[{i}]: {loc}')

🛠️ Reader to Writer Bridge

1. Read: explain detect a url entry with no loc in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 82.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 84 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'url[{i}]: {loc}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect a url entry with no loc and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`findtext` returns `None` when `<loc>` is absent, so an `is None` test isolates url blocks that violate the one-loc-per-url rule.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><lastmod>2026-01-01</lastmod></url>'
       '<url><loc>https://example.com/c</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for i, u in enumerate(root.findall('url')):
    loc = u.findtext('loc')
    if loc is None:
        print(f'url[{i}]: MISSING loc (invalid entry)')
    else:
        print(f'url[{i}]: {loc}')
```

```
output
url[0]: https://example.com/a
url[1]: MISSING loc (invalid entry)
url[2]: https://example.com/c
```

How it works:

1. Three url nodes appear; the middle one has lastmod but no loc.
2. enumerate pairs each url with its index i.
3. loc is None for the second entry, triggering the MISSING loc branch.
4. Valid entries print their index and URL instead.

Try it:

1. Count the invalid entries and print a total at the end.
2. Also flag url blocks that contain two loc children.
3. Skip the invalid entries while collecting the valid locs into a list.
4. Also flag entries that contain more than one `<loc>` via `len(u.findall('loc'))`.

⚠ Common Mistakes

- Checking `if not loc` would also flag a present-but-empty `<loc></loc>`, which may be a different error.
- `enumerate` indexes are positional, not the URL itself, so report the loc when you can.

- A `<url>` with two `<loc>` tags is also invalid but this check only catches zero.

Skills gained `enumerate` `None check` `findtext`

→ **Where You'll Use This:** Catching loc-less url blocks keeps a sitemap parseable, since search engines may reject the whole file when even one entry breaks the required structure.

Mental Model

A url without a loc is an envelope with no address line: the post office cannot route it no matter what else is written inside.

Project 84 Escape Ampersands in a URL

The Idea Behind It

A raw ampersand in a URL breaks XML parsing because the parser reads it as the start of an entity. This project uses xml.sax.saxutils.escape to convert each ampersand in a query string into the entity & before the URL is embedded. Escaping reserved characters is what keeps a generated sitemap well-formed even when URLs carry multiple parameters.

What You'll Build & Learn

Escape ampersands in query-string URLs so the resulting XML stays well-formed.

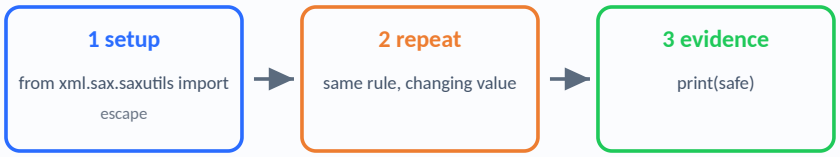
- Raw ampersands break XML parsing
- saxutils.escape encodes reserved characters
- & is the safe encoding of &

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 83: detect a url entry with no loc. Project 85 changes the surface problem while preserving the underlying method.

progress check

Reading target: escape ampersands in a url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `from xml.sax.saxutils import escape` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(safe)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from xml.sax.saxutils import escape`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

Code Reading Stack

Layer	What to read
Intent	Escape Ampersands in a URL: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, sax, saxutils, escape, urls. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from xml.sax.saxutils import escape | Core: for u in urls: | Evidence: print(safe)

🛠️ Reader to Writer Bridge

1. Read: explain escape ampersands in a url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 83.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 85 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(safe)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from xml.sax.saxutils import escape` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of escape ampersands in a url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`xml.sax.saxutils.escape` converts the XML-special characters `&`, `<` and `>` into entities, so a query string with `&` can be safely placed inside a `<loc>`.

```
from xml.sax.saxutils import escape
urls = [
    'https://example.com/search?q=shoes&sort=price',
    'https://example.com/page?a=1&b=2&c=3',
]
for u in urls:
    safe = escape(u)
    print(safe)
```

```
output
https://example.com/search?q=shoes&amp;sort=price
https://example.com/page?a=1&amp;b=2&amp;c=3
```

How it works:

1. Two URLs carry query strings joined by raw ampersands.
2. escape(u) replaces each & with the entity &.
3. The loop prints each escaped URL.
4. Output shows sort=price and the chained parameters now safely encoded.

Try it:

1. Add a URL containing a literal less-than sign and confirm it is escaped too.
2. Round-trip by unescaping the result and checking it matches the input.
3. Embed each escaped URL inside a full loc element.
4. Add a URL containing `<` or `>` and watch them become `<`/`>`.

⚠ Common Mistakes

- Replacing `&` by hand can double-escape an already-encoded `&` into `&`.
- `escape` does not touch quotes by default; pass a mapping if attribute values need it.
- Forgetting to escape before building the XML yields a `ParseError` at read time.

Skills gained saxutils escape | XML entities | query strings

→ Where You'll Use This: Escaping reserved characters is mandatory when emitting sitemaps for sites with parameterised URLs, since one unescaped ampersand can invalidate the entire file.

Mental Model

An unescaped ampersand is a live wire in the XML circuit: escape turns it into insulated & so the parser does not short out.

Project 85 Flag URLs Longer Than 2048 Chars

The Idea Behind It

Sitemap locs have a practical ceiling of 2048 characters, and search engines may reject anything longer. This project builds an oversized URL by repeating a character 2050 times, embeds it in a urlset, then measures each loc's length and flags any over the limit. The string-multiplication trick fabricates a runaway URL so the length guard has something to catch.

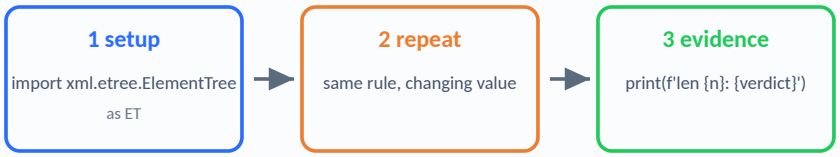
What You'll Build & Learn

Measure each loc's character length and flag URLs longer than 2048.

- String multiplication fabricates a long URL
- len measures a loc's character count
- URLs over 2048 chars may be rejected

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 84: escape ampersands in a url. Project 86 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag urls longer than 2048 chars is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'len {n}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Intent	Flag URLs Longer Than 2048 Chars: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, long_path. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'TOO LONG' if n > 2048 else 'ok' | Evidence: print(f'len {n}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain flag urls longer than 2048 chars in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 84.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 86 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'len {n}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag urls longer than 2048 chars and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`len(loc)` measures the character count of each URL, and comparing against 2048 flags entries that exceed the conventional URL-length limit.

```
import xml.etree.ElementTree as ET
long_path = 'x' * 2050
xml = ('<urlset>'
       f'<url><loc>https://example.com/{long_path}</loc></url>'
       '<url><loc>https://example.com/short</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
```

```
for u in root.findall('url'):
    loc = u.findtext('loc')
    n = len(loc)
    verdict = 'TOO LONG' if n > 2048 else 'ok'
    print(f'len {n}: {verdict}')
```

```
output
len 2070: TOO LONG
len 25: ok
```

How it works:

1. long_path repeats x 2050 times to build an over-length segment.
2. That path is embedded in a urlset beside a short URL.
3. n = len(loc) measures each loc, and n > 2048 sets TOO LONG.
4. The lengths 2070 and 25 print with their verdicts.

Try it:

1. Print the full loc only when it is under the limit to keep output short.
2. Lower the ceiling to test the boundary at exactly 2048 characters.
3. Report the longest loc in the set and its length.
4. Lower the threshold to 2000 and watch the short URL still pass.

⚠ Common Mistakes

- The limit is on characters, but very long multibyte URLs may also blow the byte budget.
- Building the fixture path with `'x' * 2050` makes the total length 2070 once the prefix is added, not 2050.
- A few long URLs are usually a CMS bug (endless faceted params) rather than real content.

Skills gained len | string multiplication | length limit

→ Where You'll Use This: Length guards catch runaway URLs produced by deep faceted navigation or stacked parameters, which crawlers may silently drop from the index.

⚡ Mental Model

The 2048 ceiling is a doorframe height: most URLs walk through fine, but the occasional giant has to duck or gets turned away.

Project 86 Sort URLs by lastmod, Newest First

💡 The Idea Behind It

Editors want to see what changed most recently, so this project sorts URLs by their lastmod in descending order. It builds a list of loc and lastmod tuples from the urlset, then sorts using a key lambda on the date field with reverse set to True. Because ISO dates sort lexicographically the same way they sort chronologically, plain string comparison suffices.

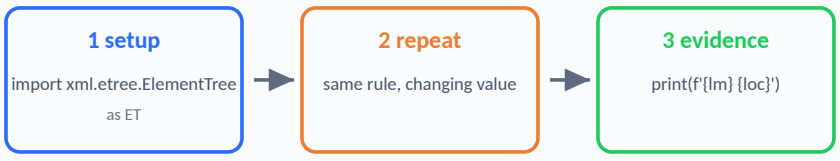
What You'll Build & Learn

Sort the sitemap's URLs by lastmod, newest first, and print them.

- Build tuples of loc and lastmod
- A key lambda sorts on the date field
- ISO dates sort correctly as strings

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 85: flag urls longer than 2048 chars. Project 87 changes the surface problem while preserving the underlying method.



progress check

Reading target: sort urls by lastmod, newest first is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{lm} {loc}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`rows = [(u.findtext('loc'), u.findtext('lastmod')) for u in root.findall('url')]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{lm} {loc}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `rows = [(u.findtext('loc'), u.findtext('lastmod')) for u in root.findall('url')]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Sort URLs by lastmod, Newest First: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.

Layer	What to read
Evidence	Entry: import xml.etree.ElementTree as ET | Core: rows = [(u.findtext('loc'), u.findtext('lastmod')) for u in root.findal... | Evidence: print(f'{lm} {loc}')

🛠️ Reader to Writer Bridge

1. Read: explain sort urls by lastmod, newest first in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 85.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 87 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{lm} {loc}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of sort urls by lastmod, newest first and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Because ISO `YYYY-MM-DD` dates sort identically as strings and as dates, a plain `reverse=True` string sort on the lastmod field orders pages newest-first without parsing.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><lastmod>2026-01-05</lastmod>
</url>'
       '<url><loc>https://example.com/b</loc><lastmod>2026-03-20</lastmod>
</url>'
       '<url><loc>https://example.com/c</loc><lastmod>2026-02-10</lastmod>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
rows = [(u.findtext('loc'), u.findtext('lastmod')) for u in
root.findall('url')]
for loc, lm in sorted(rows, key=lambda r: r[1], reverse=True):
    print(f'{lm}  {loc}')
```

```
output
2026-03-20  https://example.com/b
2026-02-10  https://example.com/c
2026-01-05  https://example.com/a
```

How it works:

1. A comprehension builds rows of loc and lastmod tuples.
2. sorted with key=lambda r: r[1] orders by the date.
3. reverse=True puts the newest date first.
4. Each row prints its lastmod then its loc, newest at the top.

Try it:

1. Sort ascending to find the oldest pages first.
2. Handle URLs with no lastmod by sorting them to the bottom.
3. Limit the output to the five most recent URLs.
4. Add a URL with no lastmod and default it to an empty string before sorting.

⚠ Common Mistakes

- String sorting only works because the dates are zero-padded ISO; `2026-3-20` would sort wrong.
- A `None` lastmod would crash the comparison; filter or default missing dates first.
- Forgetting `reverse=True` lists the oldest pages first instead.

Skills gained sorted | key lambda | tuples

→ Where You'll Use This: Sorting by recency surfaces the freshest pages for editorial review and helps verify that recently updated content is actually reflected in the sitemap.

⚡ Mental Model

Sorting by lastmod is stacking the newspaper pile so today's edition sits on top and last month's settles to the bottom.

Project 87 Flag Stale lastmod Against an As-Of Date

💡 The Idea Behind It

Pages untouched for months may signal neglected content, so this project flags any whose lastmod predates a staleness window. It parses a fixed AS_OF date, then for each url computes the day gap to its lastmod by subtracting datetimes and reading the timedelta's days attribute. Comparing that age against STALE_DAYS turns a fuzzy notion of freshness into a measured threshold.

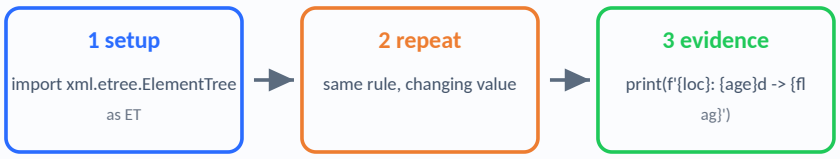
What You'll Build & Learn

Flag URLs whose lastmod is older than a staleness window relative to a fixed date.

- Subtracting datetimes yields a timedelta
- The days attribute gives the age gap
- A threshold turns age into a flag

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 86: sort urls by lastmod, newest first. Project 88 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag stale lastmod against an as-of date is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {age}d -> {flag}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build

Move	Code to inspect	Why it matters
		and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`flag = 'STALE' if age > STALE_DAYS else 'fresh'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: {age}d -> {flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = 'STALE' if age > STALE_DAYS else 'fresh'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Stale lastmod Against an As-Of Date: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, datetime. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: flag = 'STALE' if age > STALE_DAYS else 'fresh' | Evidence: print(f'{loc}: {age}d -> {flag}')

Reader to Writer Bridge

1. Read: explain flag stale lastmod against an as-of date in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 86.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 88 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {age}d -> {flag}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag stale lastmod against an as-of date and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Parsing both the lastmod and a fixed `AS_OF` constant with `strptime` lets a `timedelta.days` subtraction measure each page's age deterministically, with no call to the real clock.

```
import xml.etree.ElementTree as ET
from datetime import datetime
AS_OF = '2026-06-01'
STALE_DAYS = 90
cutoff = datetime.strptime(AS_OF, '%Y-%m-%d')
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><lastmod>2026-05-20</lastmod>
</url>'
       '<url><loc>https://example.com/b</loc><lastmod>2026-01-01</lastmod>
</url>'
       '<url><loc>https://example.com/c</loc><lastmod>2025-09-01</lastmod>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    lm = datetime.strptime(u.findtext('lastmod'), '%Y-%m-%d')
    age = (cutoff - lm).days
    flag = 'STALE' if age > STALE_DAYS else 'fresh'
    print(f'{loc}: {age}d -> {flag}')
```

```
output
https://example.com/a: 12d -> fresh
https://example.com/b: 151d -> STALE
https://example.com/c: 273d -> STALE
```

How it works:

1. cutoff is the AS_OF date parsed with strptime.
2. Each url's lastmod is parsed to a datetime named lm.
3. (cutoff - lm).days computes the age in days.
4. age greater than STALE_DAYS prints STALE, otherwise fresh.

Try it:

1. Make STALE_DAYS configurable and rerun with a 30-day window.
2. Sort the stale pages oldest first for a refresh queue.
3. Use today's date instead of a fixed AS_OF constant.
4. Raise `STALE_DAYS` to 200 and watch URL b flip to fresh.

⚠ Common Mistakes

- Using `datetime.now` here would make the output change daily; a fixed `AS_OF` keeps it reproducible.
- A future lastmod gives a negative age that is never stale, which may itself be a data error worth flagging.
- Comparing the date strings directly would tell you order but not the age in days.

Skills gained datetime arithmetic | timedelta | threshold check

→ Where You'll Use This: Staleness reports prioritise refresh work by surfacing pages that have drifted out of date, a common input to content-pruning and update campaigns.

⚡ Mental Model

STALE_DAYS is a milk expiry rule: anything past the window goes in the review bin, no matter how fine the carton looks from outside.

Project 88 Find Sitemap URLs Not in the Crawl

💡 The Idea Behind It

A URL listed in the sitemap but never reached by the crawler is suspicious, since it may be orphaned or blocked. This project builds a set from the sitemap's locs and another representing crawled pages, then subtracts the crawled set to expose the orphans. Set difference does in one operation what would otherwise be a nested membership loop.

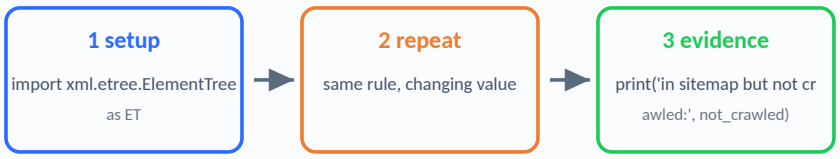
What You'll Build & Learn

Find URLs declared in the sitemap that the crawler never visited.

- A set comprehension collects the sitemap locs
- Set subtraction finds the difference
- Sitemap-only URLs may be orphaned

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 87: flag stale lastmod against an as-of date. Project 89 changes the surface problem while preserving the underlying method.



progress check

Reading target: find sitemap urls not in the crawl is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('in sitemap but not crawled:', not_crawled)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build

		and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`sitemap = {u.findtext('loc') for u in root.findall('url')}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('in sitemap but not crawled:', not_crawled)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `sitemap = {u.findtext('loc') for u in root.findall('url')}`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Sitemap URLs Not in the Crawl: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: sitemap = {u.findtext('loc') for u in root.findall('url')} | Evidence: print('in sitemap but not crawled:', not_crawled)

Reader to Writer Bridge

1. Read: explain find sitemap urls not in the crawl in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 87.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 89 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('in sitemap but not crawled:', not_crawled)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find sitemap urls not in the crawl and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Subtracting the crawled set from the sitemap set yields URLs the sitemap promised but the crawler never fetched, a classic orphan or broken-link signal.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/orphan</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
sitemap = {u.findtext('loc') for u in root.findall('url')}
crawled = {'https://example.com/a', 'https://example.com/b',
'https://example.com/extra'}
not_crawled = sorted(sitemap - crawled)
print('in sitemap but not crawled:', not_crawled)
```

```
output
in sitemap but not crawled: ['https://example.com/orphan']
```

How it works:

1. A set comprehension gathers the three sitemap locs.
2. crawled is a literal set of pages the crawler reached.
3. sitemap - crawled keeps locs absent from the crawl.
4. sorted prints the single orphan, /orphan.

Try it:

1. Print the count of sitemap-only URLs alongside the list.
2. Read the crawled set from a file instead of a literal.
3. Show the intersection as the URLs found in both.
4. Print the crawled-but-not-in-sitemap set as well with the operands swapped.

⚠ Common Mistakes

- Reversing the operands answers the opposite question; order matters in set difference.
- URL normalization differences (trailing slash, case) cause false mismatches between the two sets.
- Not sorting the difference gives nondeterministic output order.

Skills gained set difference | set comprehension | crawl comparison

→ Where You'll Use This: Comparing sitemap declarations against an actual crawl exposes orphaned or blocked pages, one of the most actionable findings in a technical-SEO audit.

⚡ Mental Model

Set subtraction is a guest list against the door scanner: names on the list that never beeped in are the no-shows worth chasing.

Project 89 Find Crawled URLs Missing From the Sitemap

💡 The Idea Behind It

The reverse gap matters too: pages the crawler found but the sitemap omits should probably be added. This project builds a set of sitemap locs, then subtracts it from the crawled set so the leftover URLs are exactly those missing from the sitemap. It is the mirror image of the orphan check, reusing set difference in the opposite direction.

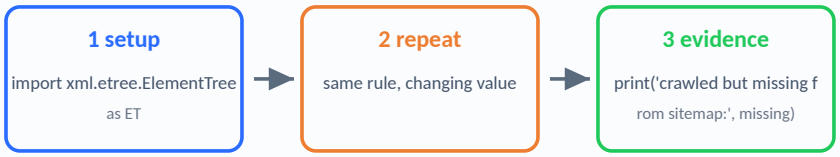
What You'll Build & Learn

List crawled URLs that the sitemap fails to declare.

- Set difference runs in either direction
- crawled minus sitemap finds omissions
- Missing URLs are candidates to add

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 88: find sitemap urls not in the crawl. Project 90 changes the surface problem while preserving the underlying method.



progress check

Reading target: find crawled urls missing from the sitemap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

🛠️ Reader to Writer Bridge

1. Read: explain find crawled urls missing from the sitemap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 88.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 90 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('crawled but missing from sitemap:', missing)`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find crawled urls missing from the sitemap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

`crawled - sitemap` returns URLs discovered by following links that the sitemap never declared, the candidates for inclusion to improve discovery.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
sitemap = {u.findtext('loc') for u in root.findall('url')}
crawled = {'https://example.com/a', 'https://example.com/b',
'https://example.com/c', 'https://example.com/d'}
missing = sorted(crawled - sitemap)
print('crawled but missing from sitemap:', missing)
```

```
output
crawled but missing from sitemap: ['https://example.com/c', 'https://example.com/d']
```

How it works:

1. A set comprehension collects the two sitemap locs.
2. crawled is a literal set of four reached pages.
3. crawled - sitemap keeps the pages the sitemap omits.
4. sorted prints /c and /d as missing from the sitemap.

Try it:

1. Print both gaps from this and the previous project side by side.
2. Exclude paginated or filtered URLs from the missing list.
3. Report the share of crawled URLs the sitemap covers.
4. Combine both gaps into one report with two labelled lines.

⚠ Common Mistakes

- This is the mirror of the previous project; subtracting in the wrong direction answers the other question.
- Some crawled URLs (tag pages, filters) are intentionally excluded from the sitemap, so not every gap is a bug.
- Forgetting to sort yields unstable output between runs.

Skills gained set difference | set comprehension | coverage gap

→ Where You'll Use This: Finding crawled pages absent from the sitemap completes the two-way reconciliation, helping ensure valuable pages are declared rather than left to chance discovery.

Mental Model

This is the inventory count run the other way: items on the shelf that the catalogue never listed are the ones you forgot to publish.

Project 90 Histogram the Priority Distribution

The Idea Behind It

A sitemap where every URL claims priority 1.0 sends no useful signal at all. This project bins the priority values with a Counter, then prints a text histogram by multiplying a hash character by each count. Sorting the keys in reverse order draws the bars from highest priority down, revealing at a glance whether the values are meaningfully spread.

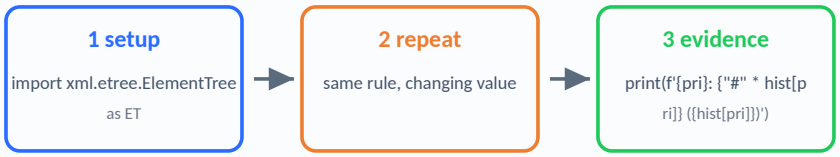
What You'll Build & Learn

Build a text histogram of the priority values to check their spread.

- Counter buckets values by frequency
- String multiplication draws a bar
- Uniform priority sends no signal

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 89: find crawled urls missing from the sitemap. Project 91 changes the surface problem while preserving the underlying method.



progress check

Reading target: histogram the priority distribution is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{pri}: {"#" * hist[pri]} ({hist[pri]})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Evidence	Entry: import xml.etree.ElementTree as ET | Core: hist = Counter(u.findtext('priority') for u in root.findall('url')) | Evidence: print(f'{pri}: {"#" * hist[pri]} ({hist[pri]})')

🛠️ Reader to Writer Bridge

1. Read: explain histogram the priority distribution in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 89.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 91 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{pri}: {"#" * hist[pri]} ({hist[pri]})')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of histogram the priority distribution and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `Counter` over the priority strings groups the URLs, and printing one `#` per URL in descending priority order draws a quick text histogram of the distribution.

```
import xml.etree.ElementTree as ET
from collections import Counter
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><priority>1.0</priority></url>'
       '<url><loc>https://example.com/b</loc><priority>0.8</priority></url>'
       '<url><loc>https://example.com/c</loc><priority>0.8</priority></url>'
       '<url><loc>https://example.com/d</loc><priority>0.5</priority></url>'
       '</urlset>')
root = ET.fromstring(xml)
hist = Counter(u.findtext('priority') for u in root.findall('url'))
for pri in sorted(hist, reverse=True):
    print(f'{pri}: {"#" * hist[pri]} ({hist[pri]})')
```

```
output
1.0: # (1)
0.8: ## (2)
0.5: # (1)
```

How it works:

1. Counter tallies the priority text of each url into hist.
2. sorted(hist, reverse=True) orders the buckets high to low.
3. '#' * hist[pri] draws a bar of that length.
4. Each priority prints its bar and its count in parentheses.

Try it:

1. Sort the bars by count instead of by priority value.
2. Normalise bar lengths so the tallest is a fixed width.
3. Flag the sitemap when one priority dominates the distribution.
4. Convert keys to `float` before sorting to handle `0.80` correctly.

⚠ Common Mistakes

- Counting the raw strings means `0.8` and `0.80` would land in different buckets.

- Sorting the string keys works here because they are equal width; mixed widths need float keys.
- A sitemap with every priority at 1.0 produces a single bar, which is the smell this surfaces.

Skills gained Counter | histogram | string multiplication

→ Where You'll Use This: A priority histogram quickly reveals whether a site differentiates its pages or wastes the field by setting everything identically, guiding a priority cleanup.

Mental Model

The histogram is a sound equaliser: if every band peaks at the same level, the mix is flat and tells the listener nothing about emphasis.

Project 91 Histogram the changefreq Values

The Idea Behind It

Knowing how many pages claim daily versus monthly change helps gauge whether your frequencies are realistic. This project tallies the changefreq keywords with a Counter and prints them via most_common, which orders the buckets from most to least frequent. The result is a compact frequency table that exposes overuse of any single keyword.

What You'll Build & Learn

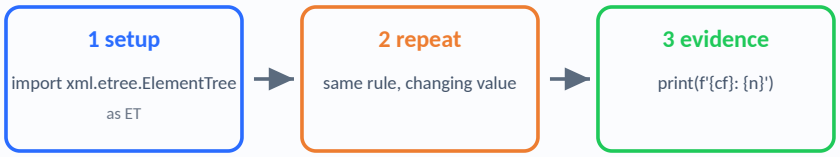
Tally each changefreq keyword and print them ordered by frequency.

- Counter tallies changefreq keywords
- most_common orders by descending count
- Frequency mix reveals unrealistic claims

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 90: histogram the priority distribution. Project 92 changes the surface problem while preserving the underlying method.

progress check



Reading target: histogram the changefreq values is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{cf}: {n}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`hist = Counter(u.findtext('changefreq') for u in root.findall('url'))`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{cf}: {n}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `hist = Counter(u.findtext('changefreq') for u in root.findall('url'))`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Histogram the changefreq Values: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, collections. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: hist = Counter(u.findtext('changefreq') for u in root.findall('url')) | Evidence: print(f'{cf}: {n}')

🛠️ Reader to Writer Bridge

1. Read: explain histogram the changefreq values in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 90.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 92 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{cf}: {n}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of histogram the changefreq values and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`Counter.most_common()` returns the frequencies ordered by count, and for equal counts it preserves first-seen insertion order, keeping the output deterministic.

```
import xml.etree.ElementTree as ET
from collections import Counter
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><changefreq>daily</changefreq>
</url>'
       '<url><loc>https://example.com/b</loc><changefreq>daily</changefreq>
</url>'
       '<url><loc>https://example.com/c</loc><changefreq>weekly</changefreq>
</url>'
       '<url><loc>https://example.com/d</loc><changefreq>monthly</changefreq>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
hist = Counter(u.findtext('changefreq') for u in root.findall('url'))
for cf, n in hist.most_common():
    print(f'{cf}: {n}')
```

```
output
daily: 2
weekly: 1
monthly: 1
```

How it works:

1. Four url nodes declare daily twice plus weekly and monthly.
2. Counter tallies each changefreq text into hist.
3. hist.most_common() returns keyword and count pairs sorted by count.
4. The loop prints daily: 2, weekly: 1, monthly: 1.

Try it:

1. Show only the top two most common keywords.
2. Compute the percentage each keyword represents of the total.
3. Warn when one keyword exceeds a share threshold like 80 percent.
4. Add a second weekly URL and watch the ordering shift.

⚠ Common Mistakes

- Ties in `most_common()` fall back to insertion order, which is stable in modern Python but easy to forget.
- A missing `<changefreq>` counts as a `None` key in the histogram.
- An invalid keyword would appear as its own bar; validate separately before counting.

Skills gained `Counter` `most_common` `frequency table`

→ **Where You'll Use This:** A changefreq distribution exposes whether a site over-claims daily updates, which crawlers learn to distrust, undermining the very recrawl hint the tag is meant to give.

⚡ Mental Model

most_common is a vote tally read aloud loudest first: it tells you at once which option swamped the ballot and which barely registered.

Project 92 Flag Non-HTTPS Locations

💡 The Idea Behind It

Modern sites should list only secure URLs, so any loc whose scheme is not https is flagged. This project parses a urlset and applies a startswith check to each loc, catching an ftp scheme and a protocol-relative double-slash that both fail the test. The same prefix technique from the absolute-URL check is reused here to enforce transport security specifically.

What You'll Build & Learn

Flag any loc that does not use the https scheme as insecure.

- startswith enforces the https prefix
- ftp and protocol-relative URLs fail it
- Sitemaps should list only secure URLs

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 91: histogram the changefreq values. Project 93 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag non-https locations is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

- Evidence: `print(f'{loc}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`verdict = 'secure' if loc.startswith('https://') else 'NOT HTTPS'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'secure' if loc.startswith('https://') else 'NOT HTTPS'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Non-HTTPS Locations: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'secure' if loc.startswith('https://') else 'NOT HTTPS' | Evidence: print(f'{loc}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain flag non-https locations in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 91.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 93 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag non-https locations and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Testing `startswith('https://')` accepts only the secure scheme; an ftp link or a protocol-relative `//` URL both fail because neither begins with the secure prefix.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>ftp://example.com/file.zip</loc></url>'
       '<url><loc>//example.com/protocol-relative</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    verdict = 'secure' if loc.startswith('https://') else 'NOT HTTPS'
    print(f'{loc}: {verdict}')
```

```
output
https://example.com/a: secure
ftp://example.com/file.zip: NOT HTTPS
//example.com/protocol-relative: NOT HTTPS
```

How it works:

1. Three url nodes use https, ftp, and a protocol-relative prefix.
2. loc.startswith('https://') decides secure versus NOT HTTPS.
3. The ftp and double-slash entries both fail the prefix test.
4. Each loc prints with its verdict.

Try it:

1. Extract and print the actual scheme of each failing loc.
2. Allow http only when an ALLOW_INSECURE flag is set.
3. Count how many locs are insecure across the set.
4. Accept a scheme list by testing membership against `('https://',)`.

⚠ Common Mistakes

- A protocol-relative `//host/path` inherits the page scheme but is not itself secure, so it fails here.
- Matching only the substring `https` (without `://`) would wrongly accept `https-evil.com`.
- Mixed-scheme sitemaps confuse crawlers; pick one canonical scheme site-wide.

Skills gained `startswith` `scheme check` `https enforcement`

→ **Where You'll Use This:** Enforcing https-only locs aligns the sitemap with a secure canonical, avoiding mixed-signal entries that point crawlers at insecure or unresolvable schemes.

⚡ Mental Model

Checking for https is a bouncer at a members-only door: anything arriving by the wrong entrance gets turned back at the threshold.

Project 93 Check Trailing-Slash Consistency

💡 The Idea Behind It

Mixing /page and /page/ in one sitemap can split ranking signals between two URLs that serve the same content. This project collects every loc, counts how many end with a slash using a generator inside sum, derives the remainder, and declares consistency only when one of the two counts is zero. The endswith test cleanly partitions the URLs by trailing-slash style.

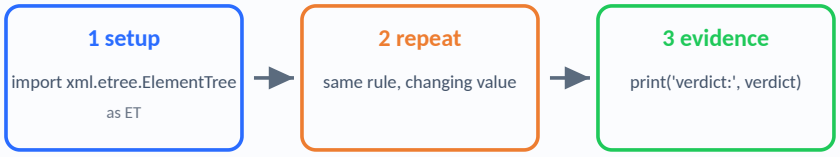
What You'll Build & Learn

Count trailing-slash and non-slash URLs and judge whether the sitemap is consistent.

- endswith tests for a trailing slash
- sum over a generator counts matches
- Mixed slash styles split signals

🧭 Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 92: flag non-https locations. Project 94 changes the surface problem while preserving the underlying method. *progress check*



`Reading target:` check trailing-slash consistency is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The comprehension compresses a loop into a readable noun phrase: `make this` for `each item` if `it qualifies`. Expand it mentally when it feels dense.
- `Writing move:` this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

- Evidence: `print('verdict:', verdict)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`withslash = sum(1 for l in locs if l.endswith('/'))`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('verdict:', verdict)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `withslash = sum(1 for l in locs if l.endswith('/'))`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Trailing-Slash Consistency: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: withslash = sum(1 for l in locs if l.endswith('/')) | Evidence: print('verdict:', verdict)

🛠️ Reader to Writer Bridge

1. Read: explain check trailing-slash consistency in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 92.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 94 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('verdict:', verdict)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check trailing-slash consistency and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Counting how many locs end in `/` versus not reveals whether the site sticks to one convention; a mix means the same content may be reachable under two URLs.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/blog/</loc></url>'
       '<url><loc>https://example.com/about</loc></url>'
       '<url><loc>https://example.com/shop/</loc></url>'
       '<url><loc>https://example.com/contact</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
locs = [u.findtext('loc') for u in root.findall('url')]
withslash = sum(1 for l in locs if l.endswith('/'))
without = len(locs) - withslash
print(f'trailing slash: {withslash}, no slash: {without}')
verdict = 'consistent' if withslash == 0 or without == 0 else 'INCONSISTENT'
print('verdict:', verdict)
```

```
output
trailing slash: 2, no slash: 2
verdict: INCONSISTENT
```

How it works:

1. A comprehension collects all four locs.
2. sum with a generator counts those ending in a slash, giving 2.
3. without is the total minus that count, also 2.
4. The verdict is INCONSISTENT because neither count is zero.

Try it:

1. List the URLs of the minority style so they can be normalised.
2. Treat the root URL specially, since the slash there is required.
3. Report which style is the majority to pick a canonical convention.
4. Exclude the bare-domain root before judging consistency.

⚠ Common Mistakes

- The root URL `https://example.com/` legitimately ends in a slash and should not count as inconsistency.
- Trailing-slash style is a convention, not an error, but inconsistency can dilute ranking signals.
- `endswith('/')` treats a query-string URL ending in `/` the same as a path, which may mislead.

Skills gained endswith | sum generator | consistency check

→ Where You'll Use This: Trailing-slash consistency prevents the sitemap from declaring duplicate variants of the same page, a subtle dilution that fragments link and ranking signals.

⚡ Mental Model

Trailing slashes are like two spellings of one name on a guest list: the host may seat the same person twice and split the credit.

Project 94 Count Image and Video Alternates

💡 The Idea Behind It

Image and video sitemaps nest image and video tags inside each url, and this project counts them per page. It parses the urlset and for every url calls findall on both image and video, taking the length of each result. Counting nested children rather than reading their contents gives a quick coverage tally of rich media per page.

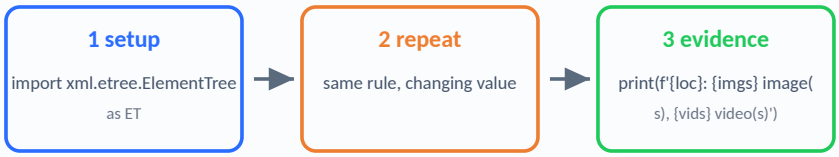
What You'll Build & Learn

Count the image and video child elements nested under each URL.

- image and video tags nest inside url
- findall plus len counts nested children
- Rich-media counts audit coverage

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 93: check trailing-slash consistency. Project 95 changes the surface problem while preserving the underlying method.



progress check

Reading target: count image and video alternates is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {imgs} image(s), {vids} video(s)')` exposes the result; match it against the output before changing the program. *output proves the trace*

🛠️ Reader to Writer Bridge

1. Read: explain count image and video alternates in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 93.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 95 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {imgs} image(s), {vids} video(s)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count image and video alternates and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`findall('image')` and `findall('video')` count the media child elements within each `<url>`; real media sitemaps namespace these tags but the counting logic is the same.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/photo</loc>'
       '<image><loc>https://example.com/a.jpg</loc></image>'
       '<image><loc>https://example.com/b.jpg</loc></image></url>'
       '<url><loc>https://example.com/clip</loc>'
```

```
        '<video><loc>https://example.com/v.mp4</loc></video></url>'
        '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    imgs = len(u.findall('image'))
    vids = len(u.findall('video'))
    print(f'{loc}: {imgs} image(s), {vids} video(s)')
```

```
output
https://example.com/photo: 2 image(s), 0 video(s)
https://example.com/clip: 0 image(s), 1 video(s)
```

How it works:

1. The first url holds two image children, the second one video child.
2. u.findall('image') and u.findall('video') gather the nested tags.
3. len of each result gives the per-page counts.
4. Each loc prints with its image and video totals.

Try it:

1. Also extract and print each nested media loc.
2. Flag pages that declare zero media when media is expected.
3. Total all images and videos across the whole sitemap.
4. Sum the image counts across all URLs for a site-wide total.

⚠ Common Mistakes

- Real image sitemaps use the `image:` namespace prefix, so a live file needs the namespaced tag name.
- An `<image>` block has its own nested `<loc>`, distinct from the page `<loc>`; do not confuse them.
- A page may legitimately have zero media, so absence is not an error.

Skills gained findall | nested elements | media audit

→ Where You'll Use This: Counting media alternates audits whether image and video sitemaps adequately cover a site's rich assets, which influences eligibility for visual search features.

⚡ Mental Model

Each url is a photo album page: counting the image and video tags is flipping it open to see how many prints are slotted in.

Project 95 Count Hreflang Alternates per URL

The Idea Behind It

International sites attach link rel=alternate hreflang tags so search engines serve the right language version. This project parses each url, gathers its link children with findall, and reads the hreflang attribute from each via the get method. Counting and listing the language codes per URL audits how thoroughly localisation alternates are declared.

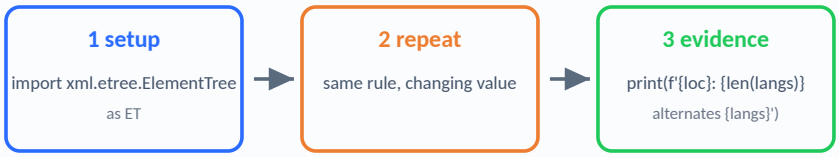
What You'll Build & Learn

Count and list the hreflang alternates declared under each URL.

- link elements carry an hreflang attribute
- get reads an attribute value
- Counting alternates audits localisation

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 94: count image and video alternates. Project 96 changes the surface problem while preserving the underlying method.



progress check

Reading target: count hreflang alternates per url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {len(langs)} alternates {langs}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`for u in root.findall('url'):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{loc}: {len(langs)} alternates {langs}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for u in root.findall('url'):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count Hreflang Alternates per URL: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: for u in root.findall('url'): | Evidence: print(f'{loc}: {len(langs)} alternates {langs}')

🛠️ Reader to Writer Bridge

1. Read: explain count hreflang alternates per url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 94.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 96 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {len(langs)} alternates {langs}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count hreflang alternates per url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`findall('link')` collects the alternate-language link elements and `.get('hreflang')` reads each language code from its attribute; live sitemaps use the `xhtml:` namespace but attribute access is identical.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/en/page</loc>'
       '<link rel="alternate" hreflang="en"
href="https://example.com/en/page"/>'
       '<link rel="alternate" hreflang="de"
href="https://example.com/de/page"/>'
```

```
        '<link rel="alternate" hreflang="fr"
href="https://example.com/fr/page"/></url>'
        '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    langs = [lk.get('hreflang') for lk in u.findall('link')]
    print(f'{loc}: {len(langs)} alternates {langs}')
```

```
output
https://example.com/en/page: 3 alternates ['en', 'de', 'fr']
```

How it works:

1. One url holds three link children for en, de, and fr.
2. u.findall('link') gathers the alternate link elements.
3. lk.get('hreflang') reads each language code into a list.
4. The loc prints with the count and the list of codes.

Try it:

1. Flag URLs missing a self-referential hreflang for their own language.
2. Detect a duplicate language code declared twice on one URL.
3. Also read and print each alternate's href attribute.
4. Detect a missing `x-default` by checking the hreflang values.

⚠ Common Mistakes

- Hreflang links live in the `xhtml` namespace in real sitemaps; the fixture drops it so the bare tag matches.
- A complete hreflang set should also include an `x-default`; counting alternates does not check that.
- Reciprocity matters: each alternate page must link back, which this single-URL view cannot verify.

Skills gained findall | attribute get | hreflang

→ Where You'll Use This: Auditing hreflang alternates per URL helps catch incomplete or asymmetric language clusters, a frequent cause of wrong-locale pages ranking in international search.

Mental Model

hreflang tags are translated road signs at a border: each one points a traveller to the version of the page written in their language.

Project 96 Read a News Sitemap Block

The Idea Behind It

Google News sitemaps nest a news block with a title and publication date inside each url. This project parses the urlset and uses find rather than findall to test whether each url has a news child, branching to print either the headline and date or a plain note. The None check distinguishes news-eligible pages from ordinary ones.

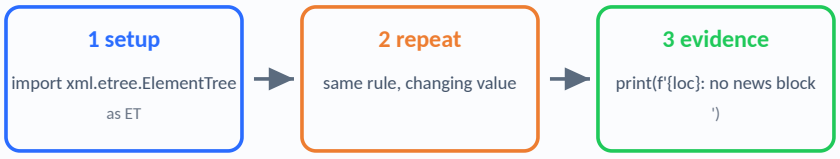
What You'll Build & Learn

Read the news title and date from each URL that carries a news block.

- find returns one child or None
- A None check detects the news block
- news nests a title and pubdate

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 95: count hreflang alternates per url. Project 97 changes the surface problem while preserving the underlying method.



progress check

Reading target: read a news sitemap block is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: no news block')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`if news is not None:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: no news block')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if news is not None:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Reader to Writer Bridge

1. Read: explain read a news sitemap block in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 95.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 97 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: no news block')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of read a news sitemap block and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

From Concept to Code (Python)

`u.find('news')` returns the nested news element or `None`, and reading its child `<title>`/`<pubdate>` pulls the news metadata; live News sitemaps namespace these tags identically in structure.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/news</loc>'
       '<news><title>Big Story</title><pubdate>2026-04-01</pubdate></news>
</url>'
       '<url><loc>https://example.com/plain</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    news = u.find('news')
    if news is not None:
        print(f'{loc}: NEWS "{news.findtext("title")}"
({news.findtext("pubdate")})')
    else:
        print(f'{loc}: no news block')
```

```
output
https://example.com/news: NEWS "Big Story" (2026-04-01)
https://example.com/plain: no news block
```

How it works:

1. One url holds a news block, the other does not.
2. u.find('news') returns the element or None.
3. When present, findtext reads the title and pubdate inside it.
4. Each loc prints either the news details or no news block.

Try it:

1. Flag a news block missing its title or pubdate child.
2. Validate the pubdate parses as a real date.
3. Count how many URLs carry a news block versus none.
4. Validate that `pubdate` parses as an ISO date.

⚠ Common Mistakes

- A real news sitemap uses the `news:` namespace, so the tag names need a prefix on live data.
- News sitemaps should only contain articles from the last two days; older entries are ignored.
- `find` returning `None` must be guarded before calling `.findtext` on it.

Skills gained find | None check | news sitemap

→ Where You'll Use This: Extracting news blocks audits which pages are declared news-eligible, important for publishers chasing Top Stories placement where the news namespace is required.

⚡ Mental Model

find is peeking into one drawer rather than the whole dresser: it either hands you the news folder or comes back empty, and you act accordingly.

Project 97 Measure Sitemap Byte Size

💡 The Idea Behind It

Besides the fifty-thousand-URL cap, an uncompressed sitemap may not exceed fifty megabytes. This project encodes the urlset string to UTF-8 bytes, measures that length, and compares it to a MAX_BYTES constant computed as 50 times 1024 times 1024. Encoding before measuring matters because byte length, not character count, is what the limit governs.

What You'll Build & Learn

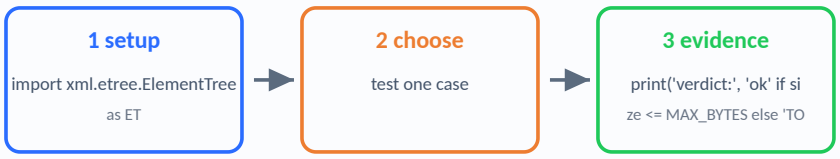
Measure the sitemap's encoded byte size and check it against the 50 MB limit.

- encode turns text into bytes
- len of bytes is the true file size

- Sitemaps are capped at 50 MB

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 96: read a news sitemap block. Project 98 changes the surface problem while preserving the underlying method. *progress check*



Reading target: measure sitemap byte size is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Measure Sitemap Byte Size: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it') | Evidence: print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 98 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure sitemap byte size and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Encoding the XML to UTF-8 bytes and comparing against `50 * 1024 * 1024` enforces the 50 MB uncompressed-size limit, the constraint that bites before the URL count on link-heavy pages.

```
import xml.etree.ElementTree as ET
MAX_BYTES = 50 * 1024 * 1024
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '</urlset>')
size = len(xml.encode('utf-8'))
print(f'sitemap size: {size} bytes (limit {MAX_BYTES})')
print('verdict:', 'ok' if size <= MAX_BYTES else 'TOO LARGE, split it')
```

```
output
sitemap size: 103 bytes (limit 52428800)
verdict: ok
```

How it works:

1. MAX_BYTES is 50 times 1024 times 1024, the byte limit.
2. xml.encode('utf-8') converts the string to bytes.
3. len of those bytes gives 103, the encoded size.
4. The verdict compares size to MAX_BYTES and prints ok.

Try it:

1. Estimate the size after gzip compression for the compressed limit.
2. Lower MAX_BYTES to force the TOO LARGE branch.
3. Print the size in megabytes alongside the raw byte count.
4. Switch the unit to mebibytes in the printout by dividing the size by 1024*1024.

⚠ Common Mistakes

- `len(xml)` counts characters, not bytes; multibyte content needs `.encode('utf-8')` for a true size.
- The 50 MB limit is on the uncompressed file even though you may serve it gzipped.
- Both the URL count and the byte size must pass; either one can force a split.

Skills gained encode | byte length | size limit

→ Where You'll Use This: The byte-size limit, separate from the URL count, forces a split when long URLs or rich metadata bloat a file, so this check guards the second sitemap ceiling.

Mental Model

Byte size is the weight on a luggage scale: even a bag under the item count can tip past the kilo limit and force you to repack.

Project 98 Apply the Default Priority of 0.5

The Idea Behind It

When priority is omitted, crawlers assume a default of 0.5, and this project fills that gap explicitly. It reads each url's priority, casts it to float when present, and substitutes DEFAULT when findtext returns None, also tagging which value was supplied versus inferred. Normalising every URL to a numeric priority lets later analysis treat the whole set uniformly.

What You'll Build & Learn

Assign the default priority of 0.5 to any URL that omits the tag.

- Omitted priority defaults to 0.5
- findtext None triggers the default
- Normalising fills gaps for analysis

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 97: measure sitemap byte size. Project 99 changes the surface problem while preserving the underlying method. *progress check*

Reading target: apply the default priority of 0.5 is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {pri}{note}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

🛠️ Reader to Writer Bridge

1. Read: explain apply the default priority of 0.5 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 97.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 99 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {pri}{note}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of apply the default priority of 0.5 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Treating a missing `<priority>` as the protocol default of 0.5 means an explicit 0.5 and an omitted tag are scored the same, exactly as a crawler would interpret them.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><priority>0.8</priority></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/c</loc><priority>0.5</priority></url>'
       '</urlset>')
root = ET.fromstring(xml)
DEFAULT = 0.5
for u in root.findall('url'):
    loc = u.findtext('loc')
    raw = u.findtext('priority')
    pri = float(raw) if raw is not None else DEFAULT
    note = '' if raw is not None else ' (default)'
    print(f'{loc}: {pri}{note}')
```

```
output
https://example.com/a: 0.8
https://example.com/b: 0.5 (default)
https://example.com/c: 0.5
```

How it works:

1. Three url nodes give 0.8, no priority, and 0.5.
2. raw is the priority text or None.
3. pri is float(raw) when present, otherwise the DEFAULT of 0.5.
4. The middle URL prints 0.5 with a (default) note.

Try it:

1. Count how many URLs relied on the default.
2. Feed the normalised priorities into a histogram from earlier.
3. Make the default configurable rather than hard-coded.
4. Change `DEFAULT` to 0.0 and watch URL b drop.

⚠ Common Mistakes

- `float(raw)` crashes when `raw` is `None`, so the default must be applied before conversion.
- An explicit `0.5` is indistinguishable from a default unless you track the `note` separately.

- Priority is only a relative hint; the default rarely changes crawl outcomes.

Skills gained default value | float casting | None check

→ Where You'll Use This: Filling the implied 0.5 default lets a histogram or comparison treat declared and undeclared URLs on equal footing, avoiding skew from missing tags.

Mental Model

Filling the default is setting a thermostat's resting temperature: rooms nobody adjusted still hold a known value instead of reading blank.

Project 99 Sum URL Counts Across an Index

The Idea Behind It

A sitemap index hides the real URL total, so you must add up each child's count. This project parses a sitemapindex, looks up a precomputed count for every child loc in a dictionary, and sums those numbers to report the site's full declared coverage. The dict lookup keyed on each child URL stands in for fetching and counting the real files.

What You'll Build & Learn

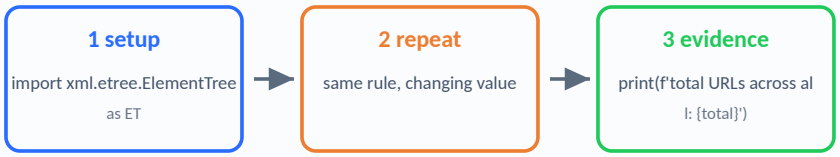
Sum the URL counts of every child sitemap to report total coverage.

- An index hides the true URL total
- A dict maps each child to its count
- sum aggregates across the children

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 98: apply the default priority of 0.5. Project 100 changes the surface problem while preserving the underlying method.

progress check



Reading target: sum url counts across an index is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'total URLs across all: {total}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`total = sum(child_counts[sm.findtext('loc')] for sm in root.findall('sitemap'))`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'total URLs across all: {total}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `total = sum(child_counts[sm.findtext('loc')] for sm in root.findall('sitemap'))`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Sum URL Counts Across an Index: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, sitemapindex. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: total = sum(child_counts[sm.findtext('loc')] for sm in root.findall('si... | Evidence: print(f'total URLs across all: {total}')

🛠️ Reader to Writer Bridge

1. Read: explain sum url counts across an index in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 98.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 100 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'total URLs across all: {total}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of sum url counts across an index and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Looking up each child sitemap's known URL count by its loc and summing them aggregates the index into one site-wide total, which can far exceed any single file's 50,000 cap.

```
import xml.etree.ElementTree as ET
xml = ('<sitemapindex>'
       '<sitemap><loc>https://example.com/sm-1.xml</loc></sitemap>'
       '<sitemap><loc>https://example.com/sm-2.xml</loc></sitemap>'
       '<sitemap><loc>https://example.com/sm-3.xml</loc></sitemap>'
       '</sitemapindex>')
child_counts = {
    'https://example.com/sm-1.xml': 50000,
    'https://example.com/sm-2.xml': 50000,
    'https://example.com/sm-3.xml': 12000,
}
root = ET.fromstring(xml)
total = sum(child_counts[sm.findtext('loc')] for sm in root.findall('sitemap'))
print(f'index references {len(root.findall("sitemap"))} sitemaps')
print(f'total URLs across all: {total}')
```

```
output
index references 3 sitemaps
total URLs across all: 112000
```

How it works:

1. child_counts maps each child loc to its URL count.
2. The index parses into three sitemap nodes.
3. sum looks up each child's count via its loc and adds them.
4. The totals 50000 plus 50000 plus 12000 print as 112000.

Try it:

1. Handle a child loc missing from the dict with a default of zero.
2. Flag any single child whose count exceeds the 50000 cap.
3. Print the average URLs per child sitemap.
4. Use `.get(loc, 0)` so an unlisted child counts as zero rather than crashing.

⚠ Common Mistakes

- A missing key in `child_counts` raises `KeyError`; default with `.get(loc, 0)` if children may be absent.
- An index itself caps at 50,000 child sitemaps, giving a theoretical ceiling of 2.5 billion URLs.

- Trusting declared counts assumes each child actually contains that many URLs.

Skills gained dict lookup | sum | index aggregation

→ Where You'll Use This: Summing per-child counts reconstructs a sharded site's true declared coverage, the number you compare against Search Console's indexed total for big properties.

⚡ Mental Model

The index is a stack of sealed boxes labelled with counts: you add the labels to know the warehouse total without opening a single box.

Project 100 Detect Case-Collision loc Variants

💡 The Idea Behind It

URLs differing only by letter case can resolve to the same page on a case-insensitive server, creating hidden duplicates. This project groups locs by their lowercased form using a dict with setdefault, appending each original into its bucket. Any bucket holding more than one original reveals a case collision, which the final loop prints.

What You'll Build & Learn

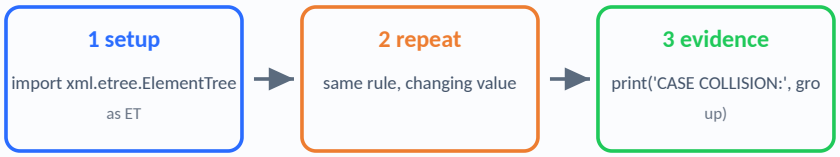
Group locs by lowercased form to surface URLs that collide only on case.

- Lowercasing normalises case differences
- setdefault groups values into buckets
- Buckets with two members are collisions

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 99: sum url counts across an index. Project 101 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect case-collision loc variants is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size

limits and errors.

- Evidence: `print('CASE COLLISION:', group)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`if len(group) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('CASE COLLISION:', group)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(group) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Case-Collision loc Variants: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: if len(group) > 1: | Evidence: print('CASE COLLISION:', group)

🛠️ Reader to Writer Bridge

1. Read: explain detect case-collision loc variants in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 99.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 101 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('CASE COLLISION:', group)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect case-collision loc variants and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Bucketing each loc under its lowercased key groups case variants together; any bucket with more than one member is a potential duplicate on a case-insensitive host.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/A</loc></url>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/B</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
seen = {}
for u in root.findall('url'):
    loc = u.findtext('loc')
    key = loc.lower()
    seen.setdefault(key, []).append(loc)
for key, group in sorted(seen.items()):
    if len(group) > 1:
        print('CASE COLLISION:', group)
```

```
output
CASE COLLISION: ['https://example.com/A', 'https://example.com/a']
```

How it works:

1. Three locs include /A and /a plus a distinct /B.
2. key is each loc lowercased.
3. setdefault(key, []).append(loc) groups originals by lowercase form.
4. Buckets longer than one print as a CASE COLLISION.

Try it:

1. Also collapse trailing slashes before grouping for stricter matching.
2. Print the count of collision groups found.
3. Pick one canonical casing per group to keep.
4. Lowercase only the host, leaving the path untouched, to avoid false positives.

⚠ Common Mistakes

- Lowercasing the whole URL is risky: the path may be genuinely case-sensitive on some servers.
- `setdefault` builds the lists in one pass; a plain dict assignment would overwrite earlier entries.
- Sorting the dict items keeps the report stable across runs.

Skills gained setdefault lowercasing grouping

→ Where You'll Use This: Case-collision detection catches duplicate URLs introduced by inconsistent casing in CMS exports, which can dilute signals or trigger duplicate-content handling.

Mental Model

Lowercasing before grouping is filing names alphabetically while ignoring capital letters: McLaughlin and mclaughlin land in the same folder.

Project 101 Reject Cross-Domain Locations

The Idea Behind It

Every loc in a sitemap must belong to the host that serves it, since cross-domain URLs are ignored. This project extracts the host from each loc by splitting on the scheme separator and then the first slash, comparing it to an ALLOWED_HOST constant. The double split isolates the netloc without a full URL parser, flagging strays from other domains.

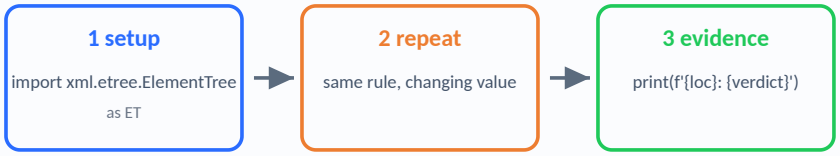
What You'll Build & Learn

Reject any loc whose host differs from the sitemap's allowed domain.

- Splitting on :// and / isolates the host
- Compare the host to an allowed value
- Cross-domain locs are ignored by crawlers

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 100: detect case-collision loc variants. Project 102 changes the surface problem while preserving the underlying method.



progress check

Reading target: reject cross-domain locations is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters

Intent	Reject Cross-Domain Locations: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: verdict = 'ok' if host == ALLOWED_HOST else f'CROSS-DOMAIN ({host})' | Evidence: print(f'{loc}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain reject cross-domain locations in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 100.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 102 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of reject cross-domain locations and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Splitting the loc on `://` then on the first `/` isolates the host, and comparing it to the allowed host flags any URL the sitemap is not authorised to declare.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://shop.example/a</loc></url>'
       '<url><loc>https://other.example/b</loc></url>'
       '<url><loc>https://shop.example/c</loc></url>'
       '</urlset>')
```

```
ALLOWED_HOST = 'shop.example'
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    host = loc.split('://', 1)[1].split('/', 1)[0]
    verdict = 'ok' if host == ALLOWED_HOST else f'CROSS-DOMAIN ({host})'
    print(f'{loc}: {verdict}')
```

```
output
https://shop.example/a: ok
https://other.example/b: CROSS-DOMAIN (other.example)
https://shop.example/c: ok
```

How it works:

1. Three locs span shop.example and one other.example.
2. loc.split('://', 1)[1] drops the scheme.
3. A second split on the first slash yields the host.
4. host equal to ALLOWED_HOST prints ok, otherwise CROSS-DOMAIN.

Try it:

1. Use urllib.parse.urlparse to read the host more robustly.
2. Allow a set of approved subdomains rather than one host.
3. Strip a port number from the host before comparing.
4. Allow a set of hosts instead of a single one.

⚠ Common Mistakes

- Splitting on `/` without first removing the scheme would grab `https:` as the host.
- A `www.` versus bare-domain mismatch counts as cross-domain unless you normalise it.
- Sitemaps in a Search Console domain property may legitimately span subdomains; adjust the rule accordingly.

Skills gained string split | host extraction | domain check

→ Where You'll Use This: Host validation catches stray cross-domain URLs that slip into a shared sitemap template, which search engines discard, silently shrinking declared coverage.

⚡ Mental Model

Checking the host is a postcode filter on a local mailing: any letter addressed to another town gets pulled before the round begins.

Project 102 Split a Urlset Into Capped Chunks

The Idea Behind It

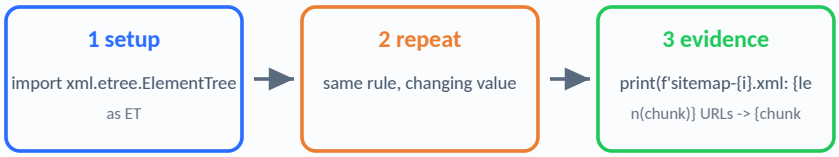
When a urlset grows too big, you slice it into files of at most N URLs each. This project parses the urlset, collects the locs into a list, and uses a range-stepped comprehension to cut that list into chunks of PER_FILE entries. Each chunk corresponds to one output sitemap, and the loop prints how the split would lay out.

What You'll Build & Learn

Chunk a list of URLs into capped slices, one per output sitemap file.

- Slicing with a step builds equal chunks
- range steps by the per-file cap
- Each chunk maps to one output file

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 101: reject cross-domain locations. Project 103 changes the surface problem while preserving the underlying method. *progress check*

Reading target: split a urlset into capped chunks is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'sitemap-{i}.xml: {len(chunk)} URLs -> {chunk}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`locs = [u.findtext('loc') for u in root.findall('url')]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'sitemap-{i}.xml: {len(chunk)} URLs -> {chunk}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `locs = [u.findtext('loc') for u in root.findall('url')]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Split a Urlset Into Capped Chunks: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: locs = [u.findtext('loc') for u in root.findall('url')] | Evidence: print(f'sitemap-{i}.xml: {len(chunk)} URLs -> {chunk}')

🛠️ Reader to Writer Bridge

1. Read: explain split a urlset into capped chunks in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 101.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 103 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'sitemap-{i}.xml: {len(chunk)} URLs -> {chunk}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split a urlset into capped chunks and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Slicing the loc list in steps of `PER_FILE` produces evenly sized chunks (with a smaller final one), the layout you would write into a multi-file sitemap set under an index.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/c</loc></url>'
       '</urlset>')
```

```
root = ET.fromstring(xml)
PER_FILE = 2
locs = [u.findtext('loc') for u in root.findall('url')]
chunks = [locs[i:i + PER_FILE] for i in range(0, len(locs), PER_FILE)]
for i, chunk in enumerate(chunks, 1):
    print(f'sitemap-{i}.xml: {len(chunk)} URLs -> {chunk}')
```

```
output
sitemap-1.xml: 2 URLs -> ['https://example.com/a', 'https://example.com/b']
sitemap-2.xml: 1 URLs -> ['https://example.com/c']
```

How it works:

1. locs collects the three URLs from the urlset.
2. PER_FILE is 2, the chunk size.
3. The comprehension slices locs[i:i+2] for i stepping by 2.
4. Two chunks print as sitemap-1 with two URLs and sitemap-2 with one.

Try it:

1. Set PER_FILE to 50000 to match the real cap.
2. Wrap each chunk into a full urlset string.
3. Print the suggested index entry for each generated file.
4. Raise `PER_FILE` to 3 and confirm a single chunk results.

⚠ Common Mistakes

- Using `PER_FILE` of 0 would make `range` raise; the cap must be positive.
- The last chunk is usually smaller than the cap, which is expected, not an error.
- In production `PER_FILE` is 50000, but a small value makes the splitting visible here.

Skills gained list slicing | range step | chunking

→ Where You'll Use This: Chunking is the mechanism behind splitting an over-cap sitemap into compliant shards, the operational counterpart to the index file that ties them together.

Mental Model

Chunking is portioning a big batch of dough into trays: each tray holds the same maximum and you bake them as separate loaves.

Project 103 Reject Impossible Calendar Dates

The Idea Behind It

A date like 2026-02-30 matches the digit pattern yet is not a real day, and strptime rejects it where a regex would wave it through. This project parses each lastmod with the ISO format and catches the ValueError that impossible months and days raise. It shows why semantic date parsing beats shape-only validation for calendar correctness.

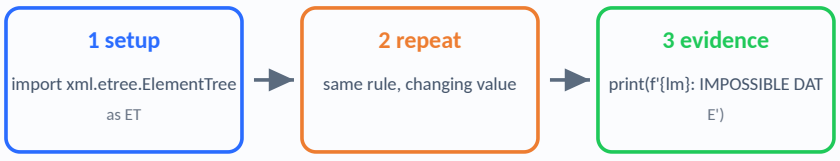
What You'll Build & Learn

Reject lastmod values that fit the digit pattern but name impossible calendar dates.

- Pattern shape does not guarantee a real date
- strptime validates calendar correctness
- ValueError flags impossible days

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 102: split a urlset into capped chunks. Project 104 changes the surface problem while preserving the underlying method.



progress check

Reading target: reject impossible calendar dates is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{lm}: IMPOSSIBLE DATE')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`for u in root.findall('url'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{lm}: IMPOSSIBLE DATE')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for u in root.findall('url'):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Reject Impossible Calendar Dates: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, datetime. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: for u in root.findall('url'): | Evidence: print(f'{lm}: IMPOSSIBLE DATE')

🛠️ Reader to Writer Bridge

1. Read: explain reject impossible calendar dates in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 102.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 104 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{lm}: IMPOSSIBLE DATE')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of reject impossible calendar dates and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`strptime` does real calendar validation, so month 13 and February 30 raise `ValueError` even though they fit the `YYYY-MM-DD` shape; a naive regex would accept both.

```
import xml.etree.ElementTree as ET
from datetime import datetime
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><lastmod>2026-13-01</lastmod>
</url>'
       '<url><loc>https://example.com/b</loc><lastmod>2026-02-30</lastmod>
</url>'
       '<url><loc>https://example.com/c</loc><lastmod>2026-02-28</lastmod>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    lm = u.findtext('lastmod')
    try:
        datetime.strptime(lm, '%Y-%m-%d')
        print(f'{lm}: valid calendar date')
    except ValueError:
        print(f'{lm}: IMPOSSIBLE DATE')
```

```
output
```

```
2026-13-01: IMPOSSIBLE DATE
2026-02-30: IMPOSSIBLE DATE
2026-02-28: valid calendar date
```

How it works:

1. Three lastmod values include month 13, February 30, and February 28.
2. strptime tries to parse each as YYYY-MM-DD.
3. The month-13 and Feb-30 values raise ValueError.
4. Only 2026-02-28 prints as a valid calendar date.

Try it:

1. Add a leap-day test with 2024-02-29 versus 2026-02-29.
2. Report which component, month or day, made a date impossible.
3. Collect only the impossible dates into a list.
4. Add `2026-02-29` and confirm it fails since 2026 is not a leap year.

⚠ Common Mistakes

- A regex that only checks digit groups passes `2026-13-01`; only true date parsing catches it.
- Leap-year rules mean `2024-02-29` is valid but `2026-02-29` is not, which strptime handles for you.
- `strptime` parses a fixed string and does not consult the current date, keeping the test deterministic.

Skills gained strptime | calendar validation | try/except

→ Where You'll Use This: Calendar validation catches dates that pass a naive regex but are genuinely impossible, preventing nonsense lastmod values that crawlers cannot interpret.

⚡ Mental Model

strptime is a calendar with real page tear-offs: ask for February 30 and there simply is no leaf to flip to, so it refuses.

Project 104 Split a lastmod Date From Its Time

💡 The Idea Behind It

A lastmod may be a plain date or a full timestamp carrying a T separator before the time. This project splits each value on T, keeps the part before it as the date, and tests for the separator's presence to note whether a time was attached. The split isolates the date for comparison while flagging which entries include a time component.

What You'll Build & Learn

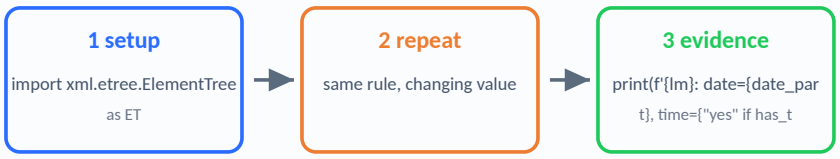
Separate the date portion of each lastmod from any time component.

- T separates the date from the time
- split on T isolates the date part
- Membership tests for a time component

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 103: reject impossible calendar dates. Project 105 changes the surface problem while preserving the underlying method.

progress check



Reading target: split a lastmod date from its time is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{lm}: date={date_part}, time={"yes" if has_time else "no"}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build

🛠️ Reader to Writer Bridge

1. Read: explain split a lastmod date from its time in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 103.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 105 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{lm}: date={date_part}, time={"yes" if has_time else "no"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split a lastmod date from its time and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting on the ISO `T` separator (with a limit of 1) returns the date portion regardless of whether a time follows, letting date-level logic ignore the optional clock component.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><lastmod>2026-05-
01T14:30:00+00:00</lastmod></url>'
       '<url><loc>https://example.com/b</loc><lastmod>2026-05-02</lastmod>
</url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    lm = u.findtext('lastmod')
    date_part = lm.split('T', 1)[0]
    has_time = 'T' in lm
    print(f'{lm}: date={date_part}, time={"yes" if has_time else "no"}')
```

```
output
2026-05-01T14:30:00+00:00: date=2026-05-01, time=yes
2026-05-02: date=2026-05-02, time=no
```

How it works:

1. One lastmod is a full timestamp, the other a plain date.
2. lm.split('T', 1)[0] keeps the date portion.
3. 'T' in lm reports whether a time is present.
4. Each value prints its date part and a yes or no for time.

Try it:

1. Also extract and print the time portion when present.
2. Strip the timezone offset from the time component.
3. Validate the date part with strptime after splitting.
4. Parse the full timestamp with `datetime.fromisoformat` and print it.

⚠ Common Mistakes

- A lowercase `t` would not split; ISO-8601 uses an uppercase `T` separator.
- The time zone offset after the time is dropped here; preserve it if you need exact ordering.
- Comparing full timestamps as strings only works when their formats match exactly.

Skills gained string split | membership test | timestamp parsing

→ Where You'll Use This: Separating date from time normalises mixed lastmod formats so day-level comparisons and staleness checks work uniformly regardless of timestamp precision.

⚡ Mental Model

The T separator is the comma in a date-and-time stamp: split there and you hold the day in one hand, the clock reading in the other.

Project 105 Trim Whitespace Around a loc

💡 The Idea Behind It

Hand-edited sitemaps sometimes pad a loc with spaces or newlines, which quietly break URL comparisons. This project reads each loc, strips surrounding whitespace, and flags any value that changed once trimmed. Comparing the raw text to its stripped form both normalises the URL and identifies which entries were dirty in the first place.

What You'll Build & Learn

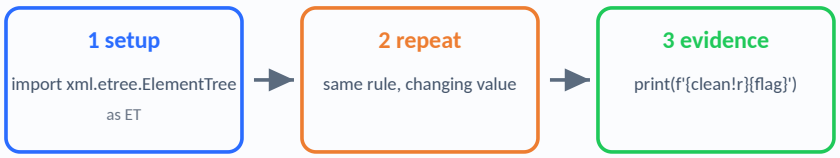
Strip whitespace from each loc and flag the entries that had padding.

- strip removes surrounding whitespace
- Comparing raw to stripped detects padding

- Padded locs break comparisons

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 104: split a lastmod date from its time. Project 106 changes the surface problem while preserving the underlying method.



progress check

Reading target: trim whitespace around a loc is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{clean!r}{flag}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 106 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{clean!r}{flag}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of trim whitespace around a loc and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`str.strip()` removes leading and trailing whitespace including newlines; comparing the stripped value to the original flags entries that carried stray padding.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>   https://example.com/b   </loc></url>'
       '<url><loc>https://example.com/c\n</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    raw = u.findtext('loc')
    clean = raw.strip()
    flag = '' if raw == clean else ' (had whitespace)'
    print(f'{clean!r}{flag}')
```

```
output
'https://example.com/a'
'https://example.com/b' (had whitespace)
'https://example.com/c' (had whitespace)
```

How it works:

1. Three locs include one clean, one space-padded, and one with a newline.
2. raw holds the original text; clean is raw.strip().
3. raw not equal to clean flags the padded entries.
4. Each cleaned loc prints in repr form with a whitespace note.

Try it:

1. Also collapse internal whitespace inside the URL.
2. Count how many locs needed trimming.
3. Feed the cleaned locs into the duplicate detector from earlier.
4. Strip only newlines with `strip(chr(10))` to preserve intentional spaces.

⚠ Common Mistakes

- Unstripped locs cause set comparisons and dedup checks to treat ` url ` and `url` as different.
- `strip()` only trims the ends; internal whitespace inside a URL is a different (encoding) problem.
- Whitespace can be a literal space, tab, or newline; `strip()` handles all of them.

Skills gained strip repr normalisation

→ Where You'll Use This: Whitespace trimming normalises locs before deduplication or crawl comparison, since an invisible trailing newline otherwise makes two identical URLs look distinct.

Mental Model

Stripping a loc is trimming the frayed edges off a label so the barcode scans: the padding was invisible but kept the reader from matching it.

Project 106 Spot Sitemap URLs Blocked by Robots

The Idea Behind It

Listing a URL in the sitemap while robots.txt disallows its path sends crawlers a contradictory message. This project extracts each loc's path by splitting off the scheme and host, then tests whether that path starts with any disallowed prefix using any over a tuple. Matching paths against the disallow rules surfaces the conflict between inviting and blocking the same page.

What You'll Build & Learn

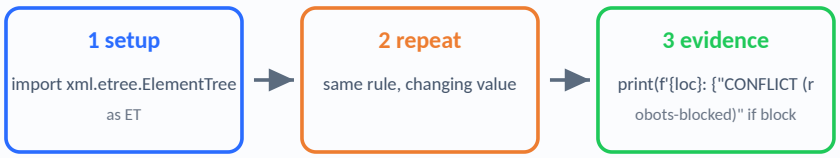
Detect sitemap URLs whose path is blocked by robots.txt disallow rules.

- Splitting isolates the URL path
- any tests against several prefixes
- Listing a blocked path is contradictory

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 105: trim whitespace around a loc. Project 107 changes the surface problem while preserving the underlying method.

progress check



Reading target: spot sitemap urls blocked by robots is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {"CONFLICT (robots-blocked)" if blocked else "ok"}')` exposes the result; match it against the output before changing the program.

🔍 From Concept to Code (Python)

Extracting the path after the host and testing it against the disallow prefixes finds sitemap URLs that robots.txt forbids crawling, a contradiction crawlers will flag.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/blog</loc></url>'
       '<url><loc>https://example.com/admin/users</loc></url>'
       '<url><loc>https://example.com/private/notes</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
DISALLOW = ('/private', '/admin')
for u in root.findall('url'):
    loc = u.findtext('loc')
    host_path = loc.split('://', 1)[1]
    path = '/' + host_path.split('/', 1)[1] if '/' in host_path else '/'
    blocked = any(path.startswith(d) for d in DISALLOW)
    print(f'{loc}: {"CONFLICT (robots-blocked)" if blocked else "ok"}')
```

```
output
https://example.com/blog: ok
https://example.com/admin/users: CONFLICT (robots-blocked)
https://example.com/private/notes: CONFLICT (robots-blocked)
```

How it works:

1. DISALLOW holds the prefixes /private and /admin.
2. Each loc is split to recover its path after the host.
3. any(path.startswith(d) for d in DISALLOW) tests the prefixes.
4. The /admin and /private URLs print CONFLICT, /blog prints ok.

Try it:

1. Load the disallow rules from a parsed robots.txt instead of a tuple.
2. Handle wildcard patterns in the disallow rules.
3. Count how many sitemap URLs conflict with robots.

4. Add a `/blog` disallow rule and watch the first URL flip to a conflict.

⚠ Common Mistakes

- A disallowed URL in the sitemap will not be crawled, so listing it wastes the entry.
- Splitting on the first `/` after the scheme can misfire on a bare-domain URL with no path; the guard handles that.
- Robots matching uses prefix rules, so `/admin` also blocks `/administrator`; tighten with a trailing slash if needed.

Skills gained string split | any | robots conflict

→ Where You'll Use This: Cross-checking sitemap paths against robots.txt disallows catches a common mixed-signal mistake where pages are both submitted for indexing and blocked from crawling.

Mental Model

It is mailing an invitation while locking the front gate: the guest has the address but cannot get in, and everyone wastes the trip.

Project 107 Flag Locations With Query Strings

The Idea Behind It

Tracking parameters like utm_source create duplicate URLs that usually should stay out of a sitemap. This project parses the urlset and checks each loc for a question mark, the marker that begins a query string, labelling matches as carrying parameters. The simple membership test surfaces parameterised URLs without needing to dissect the query itself.

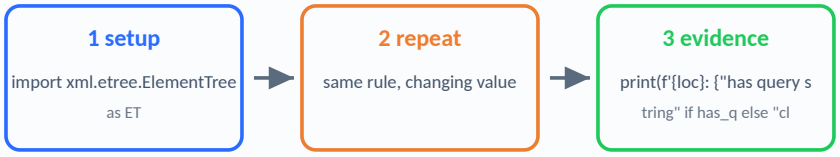
What You'll Build & Learn

Flag the sitemap URLs that contain a query string.

- A question mark begins a query string
- Membership test spots parameters
- Tracking parameters duplicate URLs

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 106: spot sitemap urls blocked by robots. Project 108 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag locations with query strings is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: {"has query string" if has_q else "clean"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`print(f'{loc}: {"has query string" if has_q else "clean"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: {"has query string" if has_q else "clean"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{loc}: {"has query string" if has_q else "clean"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Locations With Query Strings: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: print(f'{loc}: {"has query string" if has_q else "clean"}') | Evidence: print(f'{loc}: {"has query string" if has_q else "clean"}')

🛠️ Reader to Writer Bridge

1. Read: explain flag locations with query strings in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 106.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 108 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: {"has query string" if has_q else "clean"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag locations with query strings and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A simple `'?' in loc` test detects query strings, which often indicate tracking or faceted variants that dilute the canonical URL and are best excluded from a sitemap.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc></url>'
       '<url><loc>https://example.com/a?utm_source=ad</loc></url>'
       '<url><loc>https://example.com/b?id=5</loc></url>'
       '</urlset>')
root = ET.fromstring(xml)
for u in root.findall('url'):
    loc = u.findtext('loc')
    has_q = '?' in loc
    print(f'{loc}: {"has query string" if has_q else "clean"}')
```

```
output
https://example.com/a: clean
https://example.com/a?utm_source=ad: has query string
https://example.com/b?id=5: has query string
```

How it works:

1. Three locs include a clean URL and two with query strings.
2. '?' in loc tests for a query string.
3. The utm_source and id URLs match.
4. Each loc prints has query string or clean.

Try it:

1. Extract and print the parameter names from each flagged URL.
2. Allow a whitelist of harmless parameters before flagging.
3. Strip the query string to show the clean canonical URL.
4. Strip the query string and report the canonical path instead.

⚠ Common Mistakes

- Not every query string is bad; a `?id=` may identify a genuinely distinct page.
- An escaped `&` in the XML still parses back to `&`, so the query is intact when you read it.

- A `#fragment` is not a query string and is invisible to crawlers anyway.

Skills gained membership test | query string | parameter audit

→ Where You'll Use This: Flagging query strings catches tracking-parameter and faceted URLs that bloat a sitemap with duplicates, helping keep only clean canonical addresses in the file.

Mental Model

The question mark is a price tag still stuck to the gift: harmless to the buyer, but you peel it off before wrapping the canonical version.

Project 108 Audit Optional Tags per URL

The Idea Behind It

Beyond loc, the tags lastmod, changefreq, and priority are all optional, and this project profiles which each URL carries. It iterates a tuple of field names, using find to test presence, and builds parallel lists of present and missing tags per URL. The completeness profile shows at a glance which pages are richly annotated and which carry only a bare loc.

What You'll Build & Learn

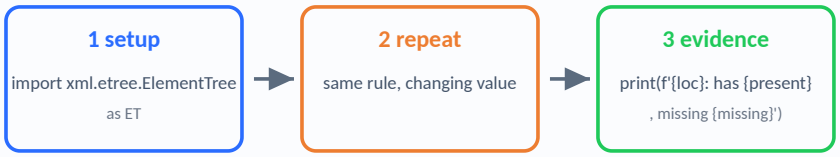
Report which optional tags each URL has and which it lacks.

- find tests whether a child exists
- Iterate a tuple of field names
- Split fields into present and missing

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 107: flag locations with query strings. Project 109 changes the surface problem while preserving the underlying method.

progress check



Reading target: audit optional tags per url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.

- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print(f'{loc}: has {present}, missing {missing}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`present = [f for f in fields if u.find(f) is not None]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{loc}: has {present}, missing {missing}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `present = [f for f in fields if u.find(f) is not None]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Audit Optional Tags per URL: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, urlset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: present = [f for f in fields if u.find(f) is not None] | Evidence: print(f'{loc}: has {present}, missing {missing}')

🛠️ Reader to Writer Bridge

1. Read: explain audit optional tags per url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 107.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 109 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{loc}: has {present}, missing {missing}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of audit optional tags per url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Iterating a fixed field list and testing `u.find(f) is not None` per URL builds present/missing profiles in a stable, declared order independent of the XML's tag ordering.

```
import xml.etree.ElementTree as ET
xml = ('<urlset>'
       '<url><loc>https://example.com/a</loc><priority>0.8</priority>
<changefreq>daily</changefreq><lastmod>2026-01-01</lastmod></url>'
       '<url><loc>https://example.com/b</loc></url>'
       '<url><loc>https://example.com/c</loc><priority>0.5</priority></url>'
       '</urlset>')
root = ET.fromstring(xml)
fields = ('lastmod', 'changefreq', 'priority')
for u in root.findall('url'):
    loc = u.findtext('loc')
    present = [f for f in fields if u.find(f) is not None]
    missing = [f for f in fields if u.find(f) is None]
    print(f'{loc}: has {present}, missing {missing}')
```

```
output
https://example.com/a: has ['lastmod', 'changefreq', 'priority'], missing []
https://example.com/b: has [], missing ['lastmod', 'changefreq', 'priority']
https://example.com/c: has ['priority'], missing ['lastmod', 'changefreq']
```

How it works:

1. fields lists lastmod, changefreq, and priority.
2. For each url, present keeps fields where find is not None.
3. missing keeps the fields where find returns None.
4. Each loc prints its present and missing lists.

Try it:

1. Score each URL by how many optional tags it carries.
2. Report the share of URLs that have every optional tag.
3. Sort URLs from least to most complete.
4. Add a coverage score as `len(present)` out of three.

⚠ Common Mistakes

- Listing `present` in document order would vary; iterating a fixed `fields` tuple keeps it deterministic.
- Only `<loc>` is required, so a fully bare URL is valid even though it scores zero optional tags.
- `u.find(f)` finds the first child; duplicate optional tags are not detected here.

Skills gained find | list comprehension | completeness profile

→ Where You'll Use This: A completeness profile shows how thoroughly a sitemap uses optional metadata, guiding whether to enrich entries with lastmod and other recrawl hints.

Mental Model

The profile is a checklist on each application form: a quick scan shows which boxes the applicant filled and which they left blank.

Project 109 Catch a Malformed Sitemap

The Idea Behind It

A truncated or mismatched-tag sitemap must fail loudly rather than parse into something wrong. This project feeds ElementTree a broken urlset whose closing tags do not match and wraps the parse in a try/except for ET.ParseError. Catching the error and printing its leading reason turns a crash into a controlled, reportable structural failure.

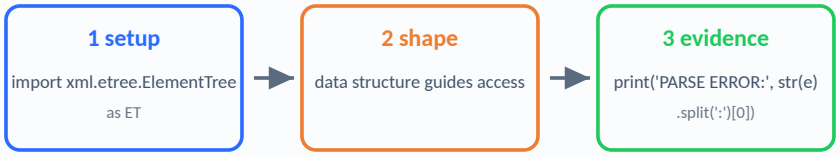
What You'll Build & Learn

Catch a malformed sitemap's parse error and report it instead of crashing.

- Malformed XML raises ParseError
- try/except contains the failure
- Structural errors should fail loudly

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 108: audit optional tags per url. Project 110 changes the surface problem while preserving the underlying method. *progress check*



Reading target: catch a malformed sitemap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The data structure is doing part of the thinking. Ask what the collection stores, how items are found, and what order or uniqueness it promises.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('PARSE ERROR:', str(e).split(':')[0])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, shape applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import xml.etree.ElementTree as ET`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
2. Apply the rule	`broken = '<urlset><url><loc>https://example.com/a</loc></url><url><loc>https://example.com/b</loc></urlset>'`	This line depends on the chosen data shape. Ask how items are stored, found, or ordered. *slow line*
3. Check the evidence	`print('PARSE ERROR:', str(e).split(':')[0])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: XML Sitemaps and URL Discovery becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
broken = '<urlset><url><loc>https://example.com/a</loc></url><url>
<loc>https://example.com/b</loc></urlset>'
```

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Read the try path as the hoped-for route and the catch/except/finally path as the boundary plan.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Catch a Malformed Sitemap: connect the surface task to the chapter skill, build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
Names	Watch these names first: xml, etree, ElementTree, ET, broken. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; exception handling defines failure paths.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import xml.etree.ElementTree as ET | Core: broken = '<urlset><url><loc>https://example.com/a</loc></url><url><loc>... | Evidence: print('PARSE ERROR:', str(e).split(':')[0])

🛠️ Reader to Writer Bridge

1. Read: explain catch a malformed sitemap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 108.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 110 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('PARSE ERROR:', str(e).split(':')[0])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of catch a malformed sitemap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The fixture closes a `<url>` with `</urlset>`, so ElementTree raises `ParseError`; catching it turns a crash into a clear diagnostic, which is how a robust audit handles bad input.

```
import xml.etree.ElementTree as ET
broken = '<urlset><url><loc>https://example.com/a</loc></url><url>
<loc>https://example.com/b</loc></urlset>'
try:
    root = ET.fromstring(broken)
    print('parsed', len(root.findall('url')), 'urls')
except ET.ParseError as e:
    print('PARSE ERROR:', str(e).split(':')[0])
```

```
output
PARSE ERROR: mismatched tag
```

How it works:

1. broken closes a url with the urlset tag, a mismatch.
2. The try block calls ET.fromstring on it.
3. ET.ParseError is raised and caught in the except.
4. The handler prints PARSE ERROR with the mismatched tag reason.

Try it:

1. Print the line and column the parser reports for the error.
2. Continue processing a list of sitemaps after one fails.
3. Distinguish a mismatched tag from an unexpected end of file.
4. Fix the closing tag and confirm it parses two URLs.

⚠ Common Mistakes

- A missing closing tag often surfaces as `mismatched tag` rather than `unexpected end`, depending on where it breaks.
- Catching a broad `Exception` would mask unrelated bugs; catch `ET.ParseError` specifically.
- Splitting the message on `:` drops the line/column detail; keep the full string if you need it.

Skills gained try/except | ParseError | error handling

→ Where You'll Use This: Graceful parse-error handling keeps an audit pipeline running over many sitemaps, reporting the broken ones instead of aborting on the first malformed file.

Mental Model

Wrapping the parse is a smoke detector on the file: instead of the whole kitchen burning silently, it sounds an alarm naming what went wrong.

Project 110 Run a Full Sitemap Validation Report

The Idea Behind It

This capstone ties the chapter together by running every earlier check in one pass over a urlset. It parses the file, then per URL validates the https scheme, parses lastmod as a real date, range-checks priority, and tests changefreq against the allowed set, accumulating an error count. A duplicate tally from comparing list length to set size completes the verdict of a basic sitemap linter.

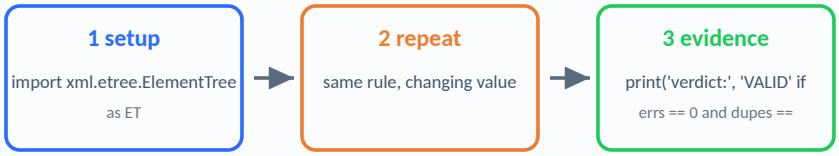
What You'll Build & Learn

Run a combined sitemap linter checking scheme, dates, priority, changefreq, and duplicates.

- Multiple checks combine in one pass
- An error counter aggregates failures
- len versus set size counts duplicates

Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 109: catch a malformed sitemap. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*



Reading target: run a full sitemap validation report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import xml.etree.ElementTree as ET` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.
- Evidence: `print('verdict:', 'VALID' if errs == 0 and dupes == 0 else 'INVALID')` exposes the result; match it against the output before changing the program.

output proves the trace

1. Read: explain run a full sitemap validation report in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 109.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('verdict:', 'VALID' if errs == 0 and dupes == 0 else 'INVALID')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import xml.etree.ElementTree as ET` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full sitemap validation report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One pass runs every per-field check (scheme, calendar date, priority band, frequency enum) and counts duplicates via set arithmetic, producing the kind of pass/fail summary a sitemap linter emits.

```
import xml.etree.ElementTree as ET
from datetime import datetime
xml = ('<urlset>'
```

```
        '<url><loc>https://example.com/</loc><lastmod>2026-01-01</lastmod>
<priority>1.0</priority><changefreq>daily</changefreq></url>'
        '<url><loc>https://example.com/a</loc><lastmod>2026-13-01</lastmod>
<priority>0.8</priority><changefreq>weekly</changefreq></url>'
        '<url><loc>ftp://example.com/b</loc><lastmod>2026-02-01</lastmod>
<priority>1.5</priority><changefreq>often</changefreq></url>'
        '<url><loc>https://example.com/</loc><lastmod>2026-03-01</lastmod>
<priority>0.5</priority><changefreq>monthly</changefreq></url>'
        '</urlset>')
ALLOWED = {'always', 'hourly', 'daily', 'weekly', 'monthly', 'yearly', 'never'}
root = ET.fromstring(xml)
locs = [u.findtext('loc') for u in root.findall('url')]
errs = 0
for u in root.findall('url'):
    if not u.findtext('loc').startswith('https://'):
        errs += 1
    try:
        datetime.strptime(u.findtext('lastmod'), '%Y-%m-%d')
    except ValueError:
        errs += 1
    if not 0.0 <= float(u.findtext('priority')) <= 1.0:
        errs += 1
    if u.findtext('changefreq') not in ALLOWED:
        errs += 1
dupes = len(locs) - len(set(locs))
print(f'urls={len(locs)} duplicates={dupes} field_errors={errs}')
print('verdict:', 'VALID' if errs == 0 and dupes == 0 else 'INVALID')
```

```
output
urls=4 duplicates=1 field_errors=4
verdict: INVALID
```

How it works:

1. ALLOWED holds the seven changefreq keywords.
2. Per url the code checks the https prefix, parses lastmod, range-checks priority, and tests changefreq, incrementing errs on each failure.
3. dupes is len(locs) minus len(set(locs)).
4. It prints url, duplicate, and error counts, then VALID or INVALID.

Try it:

1. Report which specific check each error came from.
2. Add the absolute-URL and length checks to the pass.
3. Return a structured report dict instead of printing.
4. Print a per-URL breakdown of which check each one failed.

⚠ Common Mistakes

- Counting one error per field per URL can tally several errors on a single bad entry, which is intended here.
- A non-numeric priority would raise inside `float`; a production linter would catch that too.
- Duplicates are detected by exact-string match, so case or slash variants slip past this count.

Skills gained validation pipeline · error counter · set deduplication

→ Where You'll Use This: A single-pass linter combining every rule is the backbone of an automated sitemap-QA step in a deployment pipeline, gating bad files before they go live.

Mental Model

The linter is a pre-flight checklist: one walk around the aircraft confirms fuel, flaps, and tires before the sitemap is cleared for takeoff.

✅ Chapter Progress Checkpoint

What this chapter added: after 40 mini-projects, XML Sitemaps and URL Discovery should feel like a reusable Python move: build and validate urlsets and sitemap indexes — loc, lastmod, priority, size limits and errors.

chapter checkpoint

1 Read
Open any project from Projects 71-110 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 4 (HTTP Status Codes and Redirects) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall · 2 Meaning · 2 Structure · 2 Transfer

3.1.Q1 Recall · MEDIUM
Turn back to Project 85 (Flag URLs Longer Than 2048 Chars). Without running it, what exactly does it print?

3.1.Q2 Meaning · MEDIUM
Turn back to Project 88 (Find Sitemap URLs Not in the Crawl). Without running it, what exactly does it print?

3.1.Q3 Structure · MEDIUM
Turn back to Project 97 (Measure Sitemap Byte Size). Without running it, what exactly does it print?

3.1.Q4 Transfer MEDIUM Turn back to Project 84 (Escape Ampersands in a URL). Without running it, what exactly does it print?

3.1.Q5 Recall EASY What is the one required child element of every <url> entry in a urlset?

A <lastmod>

B <priority>

C <loc>

D <changefreq>

3.1.Q6 Meaning MEDIUM A single XML sitemap may contain at most how many URLs, and what is the uncompressed size cap?

A 10,000 URLs / 10 MB

B 50,000 URLs / 50 MB

C 100,000 URLs / 100 MB

D No limit / 5 MB

3.1.Q7 Structure EASY You have 130,000 URLs to submit. Describe the file structure that respects the limits.

3.1.Q8 Transfer MEDIUM Why does a URL appearing in your sitemap but never showing up in the crawl deserve investigation?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 3 – XML Sitemaps and URL Discovery

3.1.Q1. `len 2070: TOO LONG` then `len 25: ok`

3.1.Q2. `in sitemap but not crawled: ['https://example.com/orphan']`

3.1.Q3. `sitemap size: 103 bytes (limit 52428800)` then `verdict: ok`

3.1.Q4. `https://example.com/search?q=shoes&sort=price` then `https://example.com/page?a=1&b=2&c=3`

3.1.Q5. C <loc>, the absolute URL. lastmod, priority and changefreq are all optional; a <url> with no <loc> is invalid.

3.1.Q6. B 50,000 URLs and 50 MB uncompressed. Past either limit you split into multiple files referenced by a <sitemapindex>.

3.1.Q7. Split the URLs across at least three child sitemaps (each ⩽ 50,000 URLs and ⩽ 50 MB), then publish one <sitemapindex> whose <sitemap> children each <loc> a child file. The crawler reads the index and fans out to each urlset.

3.1.Q8. The sitemap declared it as a page you want found, yet the crawler never reached it — a sign it may be orphaned (no internal links) or blocked (e.g. by robots.txt). Set-subtracting the crawled set from the sitemap set surfaces these.

Chapter 4 · HTTP Status Codes and Redirects

Classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

Chapter Skill Map

What this chapter adds: In HTTP Status Codes and Redirects, the focus is classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical. You practise it across 40 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 4 assumes the reading habits from Chapter 3: XML Sitemaps and URL Discovery. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 5, On-Page Signals and the HTML Audit, reuses this chapter's discipline with a new kind of problem.

1 **Projects 111-123**	2 **Projects 124-136**	3 **Projects 137-150**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

Every response is a number first, a page second — and the number tells the crawler what to do next.

2xx keep, 3xx follow, 4xx drop, 5xx retry

When a crawler fetches a URL it gets back a status code before it gets any HTML. That three-digit number is the server's verdict on the request, and the *first digit* sorts it into one of four classes: 2xx success (here is the page), 3xx redirect (the page moved, go here instead), 4xx client error (you asked for something that is not here), and 5xx server error (the page should exist but the server is broken right now). Bucketing the code by its leading digit is the very first thing any audit does.

The bucket is just integer division by 100. A handful of lines turns a raw list of codes into the four classes an audit report leads with:

```
codes = [200, 204, 301, 302, 404, 410, 500, 503]
def klass(c):
    return {2: 'success', 3: 'redirect',
            4: 'client-error', 5: 'server-error'}.get(c // 100, 'other')
for c in codes:
    print(c, '->', klass(c))
```

```
output
200 -> success
204 -> success
301 -> redirect
```

```
302 -> redirect
404 -> client-error
410 -> client-error
500 -> server-error
503 -> server-error
```

Why does an SEO care about a number? Because the code decides a page's fate in the index. A `200` page can be indexed and ranked. A `301` hands its hard-won ranking signals to the new URL it points at. A `404` or `410` tells the engine to drop the page. A `5xx` burns crawl budget and, if it persists, gets the page pulled. So reading status codes is not plumbing — it is the difference between a page that ranks and a page that quietly disappears.

the code is the page's fate in the index

The 3xx class is special because the work is not over: a redirect does not contain a page, it contains a forwarding address in its `Location` header. The crawler has to *follow* that address, and the address may itself redirect, and so on. Following each hop until the code is no longer a 3xx is how you resolve a chain to the live page at the end — and that loop is the engine of this entire chapter.

STATUS CODE

The three-digit integer a server returns for every request. Its first digit fixes its class: 2xx success, 3xx redirect, 4xx client error, 5xx server error. Code `200` means OK; the protocol token is written `HTTP/1.1`.

REDIRECT (3XX)

A response that carries no page, only a `Location` header pointing at another URL. The client must fetch that URL next. A `301` is permanent; a `302` is temporary.

301 MOVED PERMANENTLY

Permanent redirect: the resource has a new home for good. Engines pass ranking signals to the target and eventually swap the old URL for the new one in the index.

302 FOUND

Temporary redirect: the resource is briefly elsewhere but its real home stays. Engines keep the original URL indexed, so a 302 used for a permanent move strands link equity.

REDIRECT CHAIN

A sequence of redirects where each hop points at another that also redirects, e.g. A → B → C → live page. Each hop adds latency and bleeds a little link equity; long chains get abandoned.

CANONICAL

A `link rel="canonical"` hint that tells engines which of several live, near-duplicate URLs to index — without removing any of them. A redirect *removes* the duplicate; a canonical *keeps* it.

The four classes, and the codes inside them

A bare number like `301` means little until you attach its reason phrase, so an audit keeps a lookup table from code to meaning. The codes that matter for SEO cluster in each class: `200 OK` (indexable), `301` / `302` (redirects), `404 Not Found` / `410 Gone` (drop it), and `503 Service Unavailable` (a 5xx that says "try again later"). A code not in the table is simply unknown to your report:

```
meanings = {
    200: 'OK', 301: 'Moved Permanently', 302: 'Found',
    304: 'Not Modified', 404: 'Not Found', 410: 'Gone',
    500: 'Internal Server Error', 503: 'Service Unavailable',
}
for code in [200, 301, 404, 503, 418]:
    print(f'{code}: {meanings.get(code, "Unknown")}')
```

```
output
200: OK
301: Moved Permanently
404: Not Found
503: Service Unavailable
418: Unknown
```

The two error codes are not the same instruction. A `404` means "missing, maybe only for now" — the crawler will recrawl it later. A `410` means "gone for good" — the crawler can retire the URL. Returning the right one tells the engine whether to keep knocking or to walk away:

```
pages = [('https://a/', 404), ('https://b/', 410), ('https://c/', 200)]
for url, code in pages:
    if code == 410:
        action = 'retire permanently'
    elif code == 404:
        action = 'recrawl later'
    else:
```

```
        action = 'keep'
    print(f'{code} {url}: {action}')
```

```
output
404 https://a/: recrawl later
410 https://b/: retire permanently
200 https://c/: keep
```

301 versus 302 — permanent or temporary

This is the costliest distinction in the chapter. A `301` says "this moved for good": engines transfer the old URL's ranking signals to the target and replace it in the index. A `302` says "this is a brief detour": engines keep the *original* URL indexed and pass little or nothing to the target. So when you permanently move a page but emit a 302, the link equity never fully transfers — a silent, classic misconfiguration. The fix is to flag any temporary redirect sitting on a permanent move:

```
redirects = [
    {'url': 'https://old-home/', 'status': 302, 'permanent_move': True},
    {'url': 'https://promo/', 'status': 302, 'permanent_move': False},
    {'url': 'https://legacy/', 'status': 301, 'permanent_move': True},
]
for r in redirects:
    misconfigured = r['permanent_move'] and r['status'] == 302
    note = 'should be 301' if misconfigured else 'ok'
    print(f"{r['url']}: {r['status']} ({note})")
```

```
output
https://old-home/: 302 (should be 301)
https://promo/: 302 (ok)
https://legacy/: 301 (ok)
```

The modern protocol also has `308` (permanent, like 301) and `307` (temporary, like 302) which additionally preserve the request method. For SEO the split is the same: `301`/`308` are permanent, `302`/`307` are temporary, and the mix tells you whether a site moves URLs decisively or leaves them in limbo.

Walking a redirect chain to its final URL

A redirect carries a `Location`, and that target may redirect again. To find where a URL really lands you start at the first URL and keep hopping while the status is a 3xx, appending each `Location` to the path, stopping when the code is no longer a redirect. The model below uses a tiny response map keyed by URL; the loop *is* the resolver every redirect audit is built on:

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 302, 'location': 'https://c/'},
    'https://c/': {'status': 200, 'location': None},
```

```
}
cur = 'https://a/'
chain = [cur]
while responses[cur]['status'] in (301, 302) and responses[cur]['location']:
    cur = responses[cur]['location']
    chain.append(cur)
print(' -> '.join(chain))
print('final:', cur, 'status', responses[cur]['status'])
```

```
output
https://a/ -> https://b/ -> https://c/
final: https://c/ status 200
```

A healthy chain ends in a `200`. The two failure modes are a chain that dead-ends in a `404` (the target was deleted) or one that lands on a `5xx` (the target exists but is failing) — both send users and crawlers to a wall. And each extra hop costs latency and a sliver of link equity, so audits also *count* the hops and flag any chain longer than a small threshold. *shorter is better; one hop ideally, never a dozen*

Loops, and why you need a "seen" set

If A redirects to B, B to C, and C back to A, a naive resolver loops forever fetching the same URLs. Real browsers and crawlers guard against this two ways: a hard hop limit, and recording every URL already visited in a `seen set` so a repeat means a cycle. The instant the current URL is one you have seen, you stop and flag the loop instead of spinning:

```
responses = {
    'https://x/': {'status': 301, 'location': 'https://y/'},
    'https://y/': {'status': 301, 'location': 'https://z/'},
    'https://z/': {'status': 302, 'location': 'https://x/'},
}
cur = 'https://x/'
seen = set()
loop = False
while responses[cur]['status'] in (301, 302):
    if cur in seen:
        loop = True
        break
    seen.add(cur)
    cur = responses[cur]['location']
print('LOOP at ' + cur if loop else 'ends at ' + cur)
```

```
output
LOOP at https://x/
```

The tightest loop of all is a URL whose `Location` equals itself — an immediate crawl trap you can catch before any walk begins, just by comparing the target to the URL. Whatever the shape, a loop never yields a live page, so the engine indexes nothing.

Canonical versus redirect — keep both, or move one

When two URLs hold the same content you can consolidate them two ways. A `301 redirect` *removes* the duplicate: it sends users and signals to one URL and the other stops serving its own page. A `canonical` *keeps both live* but whispers to engines "index this one." The deciding question is whether users still need the duplicate URL. A tracking-parameter variant like `?ref=ad` must keep working for the people who clicked the ad, so it gets a canonical; a retired product URL nobody needs gets a 301:

```
pages = [
    {'url': 'https://shop/item?ref=ad', 'duplicate_of': 'https://shop/item',
'users_need_it': True},
    {'url': 'https://shop/old-item', 'duplicate_of': 'https://shop/item',
'users_need_it': False},
]
for p in pages:
    tool = 'canonical' if p['users_need_it'] else '301 redirect'
    print(f"{p['url']} -> {tool} to {p['duplicate_of']}")
```

```
output
https://shop/item?ref=ad -> canonical to https://shop/item
https://shop/old-item -> 301 redirect to https://shop/item
```

One last trap on the 200 side: a `soft-404`. The server returns `200 OK` but the body says "Sorry, page not found." The code lies, so the engine wastes budget indexing an empty apology. You catch it by reading the status *and* the body — a 200 whose text admits the page is missing is the tell.

Example 1

A crawl returns these codes: [200, 301, 200, 404, 500, 302, 200, 403, 503, 200]. Summarise the crawl by status class.

SOLUTION

1. Take the first digit of each code with integer division by 100, then attach `xx`: `200` -> `2xx`, `301` -> `3xx`, `404` -> `4xx`, `500` -> `5xx`, and so on.
2. Tally each bucket: the four 200s are `2xx`; the 301 and 302 are `3xx`; the 404 and 403 are `4xx`; the 500 and 503 are `5xx`.
3. Report the four counts — this rolled-up histogram is the headline of any crawl report.

Result: `2xx: 4, 3xx: 2, 4xx: 2, 5xx: 2`. Ten codes compress to four numbers an audit can read at a glance. *first digit is the whole story*

Example 2

A URL resolves through this map: https://old/ returns 301 to https://mid/, which returns 301 to https://new/, which returns 200. Is this a healthy redirect, and how many hops?

SOLUTION

1. Start at `https://old/` and follow `Location` while the status is a 301 or 302: `old` (301) → `mid` (301) → `new`.
2. At `https://new/` the status is `200`, not a 3xx, so the walk stops there — that is the final URL.
3. Count the hops taken: old→mid and mid→new is `2 hops`; the final code is 200, so the chain delivers a live page.

Healthy: it ends at `https://new/` with `200` after 2 hops. A chain that ended in 404 or 503 would fail this same check. *PASS only if the last code is 200*

Example 3

Two pages duplicate https://shop/item: the variant https://shop/item?ref=ad (users still click it from an ad) and the retired https://shop/legacy-item (nobody needs it). Which gets a canonical and which gets a 301?

SOLUTION

1. Ask the deciding question for each: does a user still need this exact URL to keep working?
2. The `?ref=ad` variant must keep serving its page for ad clickers, so removing it with a redirect would break their landing — use a `canonical` pointing at `https://shop/item`.
3. The legacy URL serves no one, so consolidate hard: a `301 redirect` to `https://shop/item` moves users and passes signals.

`?ref=ad` gets a canonical (keep it live); `legacy-item` gets a 301 (remove it). Need-it stays with a canonical, dead-weight gets redirected. *keep what users need, redirect what they do not*

⚡ Mental-Math Shortcut

First digit, then follow. Read the leading digit to learn the verdict — 2 keep, 3 follow, 4 drop, 5 retry — and only the 3xx makes you do more work: follow its `Location` until the code stops starting with 3, carrying a `seen` set so a cycle stops you. A redirect is healthy only when that walk ends on a 200, and a permanent move must answer with 301, never 302.

⚠ Common Mistakes

- Using a 302 (temporary) for a move that is actually permanent — engines keep the old URL indexed and the new page never inherits the old one's ranking signals.
- Letting redirect chains grow (A → B → C → D → page). Each hop adds latency and bleeds equity, and crawlers abandon chains past a few hops, so the final page may never be reached.

- Returning 200 on a "page not found" screen (a soft-404) instead of a real 404 or 410, so the engine wastes budget indexing a page that has no content.
- Pointing a canonical at a URL that itself redirects or 404s — the consolidation hint is wasted, since the named "preferred" URL is not even a live 200 page.

This chapter contains 40 hands-on mini-projects (Projects 111–150). Type each one out, run it, and experiment.

Project 111 Classify a Status Code into Its Class

The Idea Behind It

Integer division by 100 collapses any three-digit status into its leading digit, and a small dictionary maps that digit to a family name. The code holds a list of representative codes, defines klass, and prints each code beside its family. This single bucketing step is where almost every crawl analysis begins because the first digit carries the broad verdict.

What You'll Build & Learn

Sort raw HTTP status numbers into success, redirect, client-error, and server-error families using only the first digit.

- First digit decides the status family
- Integer division as a bucketing trick
- Dictionary get with a fallback default

Skill Roadmap

Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 112 changes the surface problem while preserving the underlying method. *progress check*

Reading target: classify a status code into its class is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `codes = [200, 204, 301, 302, 404, 410, 500, 503]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

- Evidence: `print(c, '->', klass(c))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`codes = [200, 204, 301, 302, 404, 410, 500, 503]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`for c in codes:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(c, '->', klass(c))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for c in codes:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Classify a Status Code into Its Class: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: codes, klass, success, redirect, client. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: codes = [200, 204, 301, 302, 404, 410, 500, 503] | Core: for c in codes: | Evidence: print(c, '->', klass(c))

🛠️ Reader to Writer Bridge

1. Read: explain classify a status code into its class in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 112 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(c, '->', klass(c))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `codes = [200, 204, 301, 302, 404, 410, 500, 503]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify a status code into its class and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Integer-dividing the code by 100 yields its leading digit, which a small dict maps straight to the human-readable response class.

```
codes = [200, 204, 301, 302, 404, 410, 500, 503]
def klass(c):
    return {2: 'success', 3: 'redirect', 4: 'client-error', 5: 'server-
error'}.get(c // 100, 'other')
for c in codes:
    print(c, '->', klass(c))
```

```
output
200 -> success
204 -> success
301 -> redirect
302 -> redirect
404 -> client-error
410 -> client-error
500 -> server-error
503 -> server-error
```

How it works:

1. A list named codes holds eight sample statuses spanning the 2xx through 5xx range.
2. klass divides the code by 100 and looks the quotient up in a dictionary mapping 2, 3, 4, 5 to family names.
3. When the quotient is missing the get call returns the string other instead of raising.
4. The for loop prints each code, an arrow, and the family that klass returns.

Try it:

1. Add a 1xx informational branch and feed the function a 100 or 101 code.
2. Return a tuple of the digit and the family name rather than just the name.
3. Count how many codes in the list fall into each family using a Counter.
4. Add 199 and confirm it lands in 'other'.

⚠ Common Mistakes

- Comparing the code as a string (`c[0]`) breaks because the codes are integers, not text.
- Using ranges like `200 <= c < 300` per class works but is far more verbose than `c // 100`.
- Forgetting a default for unknown digits raises KeyError on an odd code like 100 or 600.

Skills gained status classification | integer division | dict.get default

→ Where You'll Use This: Every crawler and log analyser groups responses by family first; this digit-based bucketing underpins dashboards that report how many URLs returned success versus error.

Mental Model

Like sorting incoming mail by the first digit of a postcode before anyone reads the street name.

Project 112 Map a Status Code to Its Meaning

The Idea Behind It

A status number alone is opaque to a human reader, so this project keeps a dictionary mapping each code to its standard reason phrase. The loop walks a list of codes and prints each one with its meaning, using get so an unknown code like 418 falls back to the word Unknown rather than crashing. Audit reports need these phrases, not bare integers.

What You'll Build & Learn

Translate numeric status codes into their human-readable reason phrases for a report, defaulting gracefully on unknown codes.

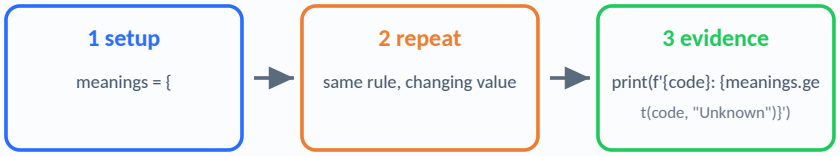
- Reason phrases give codes meaning
- Dictionary lookup with a safe default
- f-string formatting of code and label

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 111: classify a status code into its class. Project 113 changes the surface problem while preserving the underlying method.

progress check

Reading target: map a status code to its meaning is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `meanings = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{code}: {meanings.get(code, "Unknown")}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`meanings = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`for code in [200, 301, 404, 503, 418]:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{code}: {meanings.get(code, "Unknown")}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for code in [200, 301, 404, 503, 418]:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Map a Status Code to Its Meaning: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: meanings, OK, Moved, Permanently, Found. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: meanings = { | Core: for code in [200, 301, 404, 503, 418]: | Evidence: print(f'{code}: {meanings.get(code, "Unknown")}')

🛠️ Reader to Writer Bridge

1. Read: explain map a status code to its meaning in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 111.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 113 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: {meanings.get(code, "Unknown")}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `meanings = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of map a status code to its meaning and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A dict of `code -> reason phrase` is the canonical lookup; `.get` with a default keeps an unmapped code (like 418) from crashing the report.

```
meanings = {
    200: 'OK', 301: 'Moved Permanently', 302: 'Found',
    304: 'Not Modified', 404: 'Not Found', 410: 'Gone',
    500: 'Internal Server Error', 503: 'Service Unavailable',
}
```

```
for code in [200, 301, 404, 503, 418]:
    print(f'{code}: {meanings.get(code, "Unknown")}')
```

```
output
200: OK
301: Moved Permanently
404: Not Found
503: Service Unavailable
418: Unknown
```

How it works:

1. The meanings dictionary maps eight common codes to their official reason phrases like OK and Gone.
2. A for loop iterates over a list that deliberately includes 418, which is absent from the dictionary.
3. Each iteration uses meanings.get(code, 'Unknown') so a missing key yields Unknown rather than a KeyError.
4. An f-string prints the code and its resolved phrase separated by a colon.

Try it:

1. Extend the dictionary with 401, 403, and 429 and their reason phrases.
2. Reverse the dictionary so a phrase like Not Found maps back to its code.
3. Print the family from project 111 alongside the reason phrase for each code.
4. Add 307 ('Temporary Redirect') and 308 ('Permanent Redirect').

⚠ Common Mistakes

- Indexing with `meanings[code]` instead of `.get` raises KeyError on the unmapped 418.
- Hard-coding the phrase for 302 as 'Moved Temporarily' uses the old wording; the modern phrase is 'Found'.
- Treating 304 as an error rather than a cache hit misreads its meaning.

Skills gained reason phrases | dict.get default | f-string output

→ Where You'll Use This: Crawl tools and log viewers show reason phrases beside codes so non-engineers can read a report; this lookup is the labelling layer in any status dashboard.

Mental Model

Like a glossary that turns terse error numbers into the plain sentences a reader understands.

Project 113 Walk a Redirect Chain to the Final URL

The Idea Behind It

Redirects are modelled as a dictionary mapping each URL to its status and location. Starting at the first URL, a while loop follows the location of every 301 or 302 hop, appending each new URL to a chain list until it reaches a non-redirecting response. The result is the full path from entry point to the live destination, which is exactly what a browser silently does.

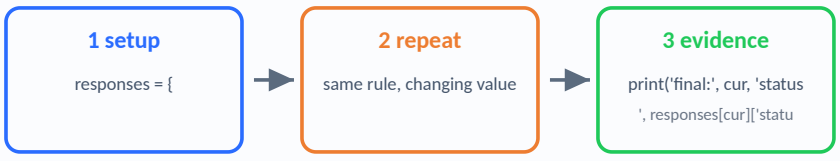
What You'll Build & Learn

Follow a chain of 301 and 302 hops from a starting URL to the final live page and print the whole path.

- A redirect chain is a sequence of hops
- While loops follow location until 200
- Building a path list as you walk

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 112: map a status code to its meaning. Project 114 changes the surface problem while preserving the underlying method.



progress check

Reading target: walk a redirect chain to the final url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('final:', cur, 'status', responses[cur]['status'])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`while responses[cur]['status'] in (301, 302) and responses[cur]['location']:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('final:', cur, 'status', responses[cur]['status'])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: responses = { | Core: while responses[cur]['status'] in (301, 302) and responses[cur]['locati... | Evidence: print('final:', cur, 'status', responses[cur]['status'])

🛠️ Reader to Writer Bridge

1. Read: explain walk a redirect chain to the final url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 112.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 114 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('final:', cur, 'status', responses[cur]['status'])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of walk a redirect chain to the final url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each hop reads the current URL's response, and while it is a redirect with a `location`, the walk moves to that target until a non-redirect status ends the chain.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 302, 'location': 'https://c/'},
    'https://c/': {'status': 200, 'location': None},
}
cur = 'https://a/'
chain = [cur]
while responses[cur]['status'] in (301, 302) and responses[cur]['location']:
    cur = responses[cur]['location']
    chain.append(cur)
print(' -> '.join(chain))
print('final:', cur, 'status', responses[cur]['status'])
```

```
output
https://a/ -> https://b/ -> https://c/
final: https://c/ status 200
```

How it works:

1. The responses dictionary maps three URLs, each to a status code and a location to redirect toward.
2. cur starts at the first URL and chain begins as a list holding that single entry.
3. The while loop continues while the current status is 301 or 302 and a location exists, reassigning cur and appending it.
4. Once cur points at the 200 response the loop stops, and the code prints the joined chain plus the final URL and status.

Try it:

1. Add a fourth hop so the chain runs through five URLs before resolving.
2. Track and print the status code at each hop alongside the URL.
3. Stop the walk early if any hop returns a 404 and report the break.
4. Add a fourth hop and watch the chain grow by one.

⚠ Common Mistakes

- Stopping only on status 200 misses chains that end in a 404 or 500, which are also terminal.
- Appending before checking the next status records a URL that may not exist in the map.
- Treating a 3xx with `location` None as a hop leads to following a missing target.

Skills gained chain following | while loop | list building

→ Where You'll Use This: Resolving redirect chains is core to crawlers and migration checks; you trace where an old URL truly lands before deciding whether the redirect is healthy.

⚡ Mental Model

Like following a trail of forwarding addresses until you reach where someone actually lives now.

Project 114 Catch a Redirect Loop with a Seen Set

💡 The Idea Behind It

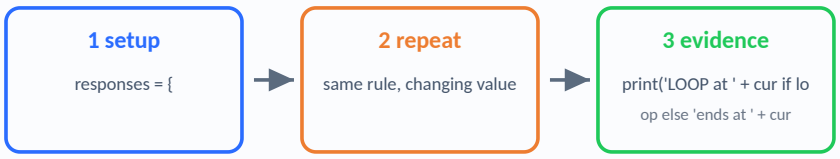
When redirects form a cycle, a naive follower spins forever. This code guards against that by keeping a seen set: before following each hop it checks whether the current URL was already visited, and if so it sets a loop flag and breaks. The sample data deliberately points the third URL back to the first, so the walk detects the cycle and reports the URL where it closed.

What You'll Build & Learn

Detect a redirect cycle by recording visited URLs and stopping the walk the moment one repeats.

- A seen set detects revisited URLs
- Cycle detection breaks an infinite loop
- Boolean flag records that a loop occurred

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 113: walk a redirect chain to the final url. Project 115 changes the surface problem while preserving the underlying method. *progress check*

Reading target: catch a redirect loop with a seen set is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('LOOP at ' + cur if loop else 'ends at ' + cur)` exposes the result; match it against the output before changing the program. *output proves the trace*

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 113.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 115 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('LOOP at ' + cur if loop else 'ends at ' + cur)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of catch a redirect loop with a seen set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Adding each URL to `seen` before stepping to its target means re-encountering a seen URL proves a cycle, which the code reports rather than following endlessly.

```
responses = {
    'https://x/': {'status': 301, 'location': 'https://y/'},
    'https://y/': {'status': 301, 'location': 'https://z/'},
    'https://z/': {'status': 302, 'location': 'https://x/'},
}
cur = 'https://x/'
seen = set()
loop = False
while responses[cur]['status'] in (301, 302):
    if cur in seen:
        loop = True
        break
    seen.add(cur)
    cur = responses[cur]['location']
print('LOOP at ' + cur if loop else 'ends at ' + cur)
```

```
output
LOOP at https://x/
```

How it works:

1. The responses dictionary defines three URLs whose locations form a cycle back to the start.
2. cur begins at the first URL, seen is an empty set, and loop starts False.
3. Inside the while loop, if cur is already in seen the code sets loop True and breaks; otherwise it adds cur and advances.
4. A conditional print announces LOOP at the repeated URL or otherwise where the chain ends.

Try it:

1. Print the full visited sequence stored in seen when a loop is found.
2. Convert the response data so no loop exists and confirm the else path runs.
3. Add a maximum hop count as a second safety net alongside the seen set.
4. Point `https://z/` to a fresh URL with status 200 and confirm a clean finish.

⚠ Common Mistakes

- Checking `seen` after advancing misses the very URL that closes the loop.
- Relying on a hop-count cap alone hides whether it is a true loop or just a long chain.
- Clearing `seen` inside the loop defeats the detection entirely.

Skills gained loop detection | set membership | break statement

→ Where You'll Use This: Crawlers must abort redirect loops to avoid hanging; the seen-set pattern protects any chain walker from infinite redirects that waste crawl budget.

Mental Model

Like dropping breadcrumbs through a maze so you know the instant you re-enter a room you already passed.

Project 115 Count the Hops in a Redirect Chain

The Idea Behind It

Rather than recording the whole path, this walker only counts how many redirect hops separate the start from its destination. A hops counter increments on each 301 or 302 step, and the while loop stops at the first non-redirecting response. The chain of four URLs resolves in three hops, turning a sprawling redirect path into one number an audit can compare against a limit.

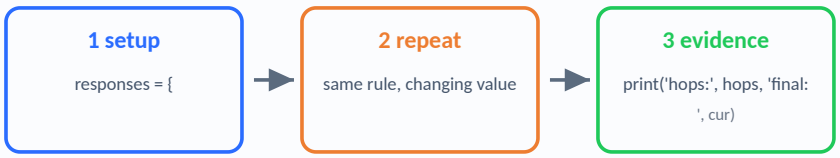
What You'll Build & Learn

Count the number of redirect hops between a starting URL and its final live destination.

- Hop count summarises a chain length
- Incrementing a counter inside a loop

- Latency and link equity cost per hop

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 114: catch a redirect loop with a seen set. Project 116 changes the surface problem while preserving the underlying method. *progress check*

Reading target: count the hops in a redirect chain is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 114.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 116 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('hops:', hops, 'final:', cur)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count the hops in a redirect chain and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Incrementing a counter on every redirect step (not every URL visited) gives the true hop count, which is one less than the number of URLs in the chain.

```
responses = {
    'https://1/': {'status': 301, 'location': 'https://2/'},
    'https://2/': {'status': 301, 'location': 'https://3/'},
    'https://3/': {'status': 302, 'location': 'https://4/'},
    'https://4/': {'status': 200, 'location': None},
}
cur, hops = 'https://1/', 0
while responses[cur]['status'] in (301, 302):
    cur = responses[cur]['location']
    hops += 1
print('hops:', hops, 'final:', cur)
```

```
output
hops: 3 final: https://4/
```

How it works:

1. The responses dictionary defines four URLs forming a three-step redirect chain ending in 200.
2. cur and hops are initialised together, with hops starting at zero.
3. The while loop runs while the current status is 301 or 302, advancing cur and adding one to hops each pass.
4. After the loop the code prints the hop count and the final URL it reached.

Try it:

1. Return both the hop count and the final URL from a function.
2. Raise an error if the hop count exceeds five before resolving.
3. Record the status of each hop in a list as you count.

4. Remove the 302 hop and watch the count drop to 2.

⚠ Common Mistakes

- Counting URLs visited instead of redirects taken overstates the hop count by one.
- Incrementing before moving means the final non-redirect URL is wrongly counted.
- Without a terminal non-redirect entry the `while` would raise KeyError off the end of the map.

Skills gained hop counting | while loop | counter increment

→ Where You'll Use This: SEO audits threshold on hop counts because each extra redirect adds latency and bleeds link equity; this count becomes a per-URL metric in a crawl report.

⚡ Mental Model

Like counting the number of connecting flights before you reach your destination airport.

Project 116 Flag Redirect Chains Longer Than N Hops

💡 The Idea Behind It

Here the chains are pre-resolved into lists of URLs, so the hop count is simply the list length minus one. Iterating the sorted dictionary, each chain is measured and compared against a limit of two; any chain exceeding it is marked FLAG while the rest read ok. This is the reporting step that surfaces the worst redirect offenders from a crawl in one scan.

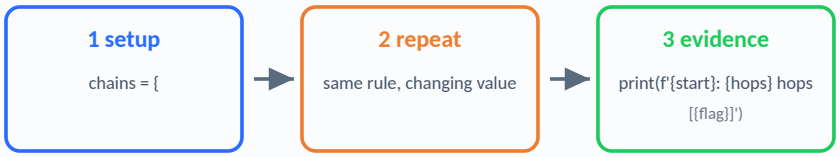
What You'll Build & Learn

Flag every redirect chain whose hop count exceeds a configured limit, marking offenders for review.

- Hop count is list length minus one
- Comparing a metric against a threshold
- Conditional labelling of offenders

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 115: count the hops in a redirect chain. Project 117 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag redirect chains longer than n hops is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `chains = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{start}: {hops} hops [{flag}]')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`chains = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`flag = 'FLAG' if hops > limit else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{start}: {hops} hops [{flag}]')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = 'FLAG' if hops > limit else 'ok'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Redirect Chains Longer Than N Hops: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: chains, https, limit, start, chain. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: chains = { | Core: flag = 'FLAG' if hops > limit else 'ok' | Evidence: print(f'{start}: {hops} hops [{flag}]')

🛠️ Reader to Writer Bridge

1. Read: explain flag redirect chains longer than n hops in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 115.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 117 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{start}: {hops} hops [{flag}]')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `chains = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag redirect chains longer than n hops and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each chain's hop count is its length minus one; comparing that to a fixed limit marks chains that exceed the tolerated number of redirects.

```
chains = {
    'https://a/': ['https://a/', 'https://b/'],
    'https://c/': ['https://c/', 'https://d/', 'https://e/', 'https://f/'],
    'https://g/': ['https://g/'],
}
limit = 2
for start, chain in sorted(chains.items()):
    hops = len(chain) - 1
    flag = 'FLAG' if hops > limit else 'ok'
    print(f'{start}: {hops} hops [{flag}]')
```

```
output
https://a/: 1 hops [ok]
https://c/: 3 hops [FLAG]
https://g/: 0 hops [ok]
```

How it works:

1. The chains dictionary maps each starting URL to a pre-resolved list of the URLs in its chain.
2. limit is set to 2 as the maximum tolerated number of hops.
3. Iterating the sorted items, hops is computed as len(chain) minus one for each chain.
4. A conditional sets flag to FLAG when hops exceeds limit and prints the start, count, and flag.

Try it:

1. Make the limit configurable and rerun with a threshold of one.
2. Collect only the flagged chains into a separate list and print it.
3. Sort the output by hop count descending so the worst chain appears first.
4. Lower `limit` to 1 and watch more chains flagged.

⚠ Common Mistakes

- Using `len(chain)` as the hop count over-reports by one because the start URL is included.
- Comparing with `>=` instead of `>` flags chains that sit exactly at the limit.
- Iterating an unsorted dict makes the printed order vary between runs.

Skills gained `threshold flagging` `len-based hop count` `sorted iteration`

→ **Where You'll Use This:** Crawl reports list chains over a tolerance because search engines give up on long chains; this flagging logic decides which redirects an SEO must shorten first.

⚡ Mental Model

Like a quality inspector who pulls any item off the line that exceeds the allowed number of defects.

Project 117 Spot a 302 Where a 301 Belongs

💡 The Idea Behind It

Permanent moves should return 301, but sites frequently serve a temporary 302 by mistake, so link equity never transfers fully. Each redirect record carries a status and a permanent_move boolean, and the code flags any entry that is a permanent move yet returns 302. The output marks the misconfigured one as should be 301 while correct entries read ok.

What You'll Build & Learn

Identify redirects that use a temporary 302 where the move is permanent and a 301 was required.

- 301 versus 302 carries SEO intent
- Combining two conditions with and
- Flagging misconfigured redirects

🧭 Skill Roadmap

`Skill step:` adds one small variation while the chapter pattern is still new. It builds on Project 116: flag redirect chains longer than n hops. Project 118 changes the surface problem while preserving the underlying method.

progress check

`Reading target:` spot a 302 where a 301 belongs is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- `Setup:` `redirects = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- `Writing move:` this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

- Evidence: `print(f"{r['url']}: {r['status']} ({note})")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirects = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`note = 'should be 301' if misconfigured else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{r['url']}: {r['status']} ({note})")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `note = 'should be 301' if misconfigured else 'ok'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Spot a 302 Where a 301 Belongs: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: redirects, url, https, old, home. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: redirects = [| Core: note = 'should be 301' if misconfigured else 'ok' | Evidence: print(f"{r['url']}: {r['status']} ({note})")

🛠️ Reader to Writer Bridge

1. Read: explain spot a 302 where a 301 belongs in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 116.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 118 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{r['url']}: {r['status']} ({note})")`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `redirects = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spot a 302 where a 301 belongs and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A redirect is mislabelled when the move is permanent yet the status is the temporary 302; the audit pairs intent with the code to catch the mismatch.

```
redirects = [
    {'url': 'https://old-home/', 'status': 302, 'permanent_move': True},
    {'url': 'https://promo/', 'status': 302, 'permanent_move': False},
    {'url': 'https://legacy/', 'status': 301, 'permanent_move': True},
]
for r in redirects:
    misconfigured = r['permanent_move'] and r['status'] == 302
    note = 'should be 301' if misconfigured else 'ok'
    print(f"{r['url']}: {r['status']} ({note})")
```

```
output
https://old-home/: 302 (should be 301)
https://promo/: 302 (ok)
https://legacy/: 301 (ok)
```

How it works:

1. A list of redirect dictionaries each holds a url, a status, and a permanent_move boolean.
2. The loop computes misconfigured as True only when permanent_move is set and the status equals 302.
3. note becomes should be 301 for the misconfigured case, otherwise ok.
4. An f-string prints the URL, its status, and the parenthesised note.

Try it:

1. Also flag a 301 used on a clearly temporary, non-permanent move.
2. Add 307 and 308 to the data and decide which are permanent.
3. Count how many redirects in the list are misconfigured overall.
4. Add a 307 temporary redirect and decide whether it counts.

⚠ Common Mistakes

- Flagging every 302 ignores legitimately temporary redirects like a short-lived promo.
- Checking `status != 301` instead of `== 302` would also flag 307/308 you may intend to keep.
- Assuming a missing `permanent_move` key is False can mask a permanent move with no annotation.

Skills gained redirect auditing | boolean conditions | 302 detection

→ Where You'll Use This: A classic technical-SEO audit hunts for permanent moves wrongly served as 302; fixing them to 301 lets accumulated link equity pass to the new URL.

Mental Model

Like noticing a moving company filed a temporary forwarding order when the family actually moved house for good.

Project 118 Detect a Redirect That Dead-Ends in 404

The Idea Behind It

A redirect only helps if it lands on a live page. This walker follows the 301 and 302 hops to the final URL, then inspects that destination's status. The sample chain ends at a URL returning 404, so the code prints the final URL with its status and declares the redirect BROKEN. A chain whose last hop is missing sends users and crawlers straight into a dead end.

What You'll Build & Learn

Follow a redirect chain to its destination and report it broken when that final URL returns 404.

- A chain can dead-end in a 404
- Inspecting the final status after a walk
- Broken redirects waste a crawler's trip

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 117: spot a 302 where a 301 belongs. Project 119 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a redirect that dead-ends in 404 is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

- Evidence: `print('BROKEN redirect' if final == 404 else 'redirect OK')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`print('BROKEN redirect' if final == 404 else 'redirect OK')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('BROKEN redirect' if final == 404 else 'redirect OK')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Names	Watch these names first: responses, https, status, location, gone. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = { | Core: print('BROKEN redirect' if final == 404 else 'redirect OK') | Evidence: print('BROKEN redirect' if final == 404 else 'redirect OK')

🛠️ Reader to Writer Bridge

1. Read: explain detect a redirect that dead-ends in 404 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 117.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 119 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('BROKEN redirect' if final == 404 else 'redirect OK')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a redirect that dead-ends in 404 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Walking to the end of the chain and then inspecting the terminal status reveals a redirect that, despite hopping correctly, resolves to a missing page.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 301, 'location': 'https://gone/'},
    'https://gone/': {'status': 404, 'location': None},
}
cur = 'https://a/'
while responses[cur]['status'] in (301, 302):
    cur = responses[cur]['location']
final = responses[cur]['status']
print('final URL:', cur, 'status', final)
print('BROKEN redirect' if final == 404 else 'redirect OK')
```

```
output
final URL: https://gone/ status 404
BROKEN redirect
```

How it works:

1. The responses dictionary chains two redirects into a final URL returning 404.
2. cur starts at the first URL and the while loop advances it while the status is 301 or 302.
3. After the loop, final reads the status of the resolved URL.
4. The code prints the final URL and status, then prints BROKEN redirect when final equals 404.

Try it:

1. Treat any 4xx final status as broken, not only 404.
2. Print the full chain leading up to the broken destination.
3. Suggest a fallback target URL when the final hop is a 404.
4. Make the final status 200 and watch the verdict flip to OK.

⚠ Common Mistakes

- Reporting success as soon as a redirect is followed ignores where it ultimately lands.
- Checking only the first hop's status misses a 404 that appears deeper in the chain.

- Treating a 410 the same as a 404 conflates 'gone forever' with 'not found'.

Skills gained dead-end detection | chain following | final status check

→ Where You'll Use This: Redirect audits verify that migrations point at real pages; a chain ending in 404 means an old URL's traffic and equity drain away to nothing and must be repointed.

⚡ Mental Model

Like following forwarding labels on a parcel only to find the final address is a demolished building.

Project 119 Flag a Redirect Landing on a 5xx Error

💡 The Idea Behind It

A redirect that resolves to a server error is worse than a dead link because the target exists but is failing. The walker follows the hops to the final URL, then checks whether its status sits in the 500-to-599 range. The sample chain ends at a 503, so the output flags SERVER ERROR. Catching a 5xx destination exposes infrastructure problems hiding behind an otherwise valid redirect.

What You'll Build & Learn

Detect when a redirect chain resolves to a 5xx response and flag the failing server destination.

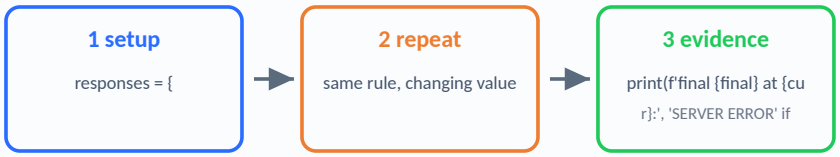
- 5xx means the target is failing
- Range check for the server-error family
- Distinguishing failing from missing targets

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 118: detect a redirect that dead-ends in 404. Project 120 changes the surface problem while preserving the underlying method. *progress check*

Reading target: flag a redirect landing on a 5xx error is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens



- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from

302 from canonical.

- Evidence: `print(f'final {final} at {cur}:', 'SERVER ERROR' if server_error else 'ok')` exposes the result; match it against the output before changing the program.

output proves the trace

1. Predict: before running, write the exact output you expect from `print(f'final {final} at {cur}:', 'SERVER ERROR' if server_error else 'ok')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag a redirect landing on a 5xx error and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

After resolving the chain, the terminal status is tested against the 500-599 range; a hit means the redirect points at a server that is currently failing.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://api/'},
    'https://api/': {'status': 503, 'location': None},
}
cur = 'https://a/'
while responses[cur]['status'] in (301, 302):
    cur = responses[cur]['location']
final = responses[cur]['status']
server_error = 500 <= final < 600
print(f'final {final} at {cur}:', 'SERVER ERROR' if server_error else 'ok')
```

```
output
final 503 at https://api/: SERVER ERROR
```

How it works:

1. The responses dictionary redirects one URL to an API endpoint that returns 503.
2. The while loop follows 301 and 302 hops until cur reaches the failing endpoint.
3. server_error is True when final is at least 500 and below 600.
4. An f-string prints the final status and URL, appending SERVER ERROR or ok.

Try it:

1. Separate a 503 (temporary) from a 500 in the message.
2. Retry the final fetch a configurable number of times before flagging.
3. Combine this with project 118 to report 4xx and 5xx endings together.
4. Change the final status to 502 and confirm it still flags.

⚠ Common Mistakes

- Hard-coding `final == 500` misses 502, 503 and other 5xx codes.
- Stopping the walk on the first 5xx instead of following all redirects first reports the wrong URL.
- Treating a transient 503 as permanently broken may retire a URL that recovers.

Skills gained `5xx detection` `range comparison` `chain following`

→ **Where You'll Use This:** Monitoring catches redirects pointing at flaky backends; flagging a 5xx destination surfaces an outage behind a redirect that a status-only crawl might miss.

⚡ Mental Model

Like following directions to a shop that is open on paper but has its lights off and doors jammed.

Project 120 Decide Between a Redirect and a Canonical

💡 The Idea Behind It

Duplicate pages can be consolidated two ways, and the right choice depends on whether users still need the duplicate URL. This code reads a users_need_it boolean per page: when users need it, a canonical tag keeps both URLs live; when they do not, a 301 redirect moves them off. The output shows the parameterised URL getting a canonical and the old URL getting a redirect.

What You'll Build & Learn

Choose between a canonical tag and a 301 redirect for each duplicate page based on whether users still need it.

- Canonical keeps a URL live, redirect moves it
- Choice hinges on user need
- Boolean-driven tool selection

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 119: flag a redirect landing on a 5xx error. Project 121 changes the surface problem while preserving the underlying method. *progress check*

Reading target: decide between a redirect and a canonical is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

- Evidence: `print(f"{p['url']} -> {tool} to {p['duplicate_of']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`tool = 'canonical' if p['users_need_it'] else '301 redirect'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{p['url']} -> {tool} to {p['duplicate_of']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `tool = 'canonical' if p['users_need_it'] else '301 redirect'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Decide Between a Redirect and a Canonical: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: pages, url, https, shop, item. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = [| Core: tool = 'canonical' if p['users_need_it'] else '301 redirect' | Evidence: print(f"{p['url']} -> {tool} to {p['duplicate_of']}")

🛠️ Reader to Writer Bridge

1. Read: explain decide between a redirect and a canonical in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 119.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 121 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{p['url']} -> {tool} to {p['duplicate_of']}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `pages = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of decide between a redirect and a canonical and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

When the duplicate URL must stay reachable (a tracked link) a canonical is right; when it is obsolete a 301 redirect both consolidates signals and removes the old URL.

```
pages = [
    {'url': 'https://shop/item?ref=ad', 'duplicate_of': 'https://shop/item',
'users_need_it': True},
    {'url': 'https://shop/old-item', 'duplicate_of': 'https://shop/item',
'users_need_it': False},
]
for p in pages:
    tool = 'canonical' if p['users_need_it'] else '301 redirect'
    print(f"{p['url']} -> {tool} to {p['duplicate_of']}")
```

```
output
https://shop/item?ref=ad -> canonical to https://shop/item
https://shop/old-item -> 301 redirect to https://shop/item
```

How it works:

1. A list of page dictionaries each carries a url, its duplicate_of target, and a users_need_it boolean.
2. The loop selects canonical when users_need_it is True and 301 redirect otherwise.
3. An f-string prints the page URL, the chosen tool, and the consolidation target.
4. The result keeps the ad-referral URL via canonical and retires the old item via redirect.

Try it:

1. Add a self-referencing canonical case where the page is its own master.
2. Reject a redirect when the duplicate target is the page itself.
3. Include a reason string explaining each tool choice in the output.
4. Add a page that is not a duplicate and skip both tools.

⚠ Common Mistakes

- Always 301-redirecting breaks URLs that users or campaigns still depend on.
- Always using a canonical leaves dead URLs crawlable instead of retiring them.
- Forgetting that a canonical is a hint while a 301 is enforced overstates the canonical's power.

Skills gained canonical vs redirect | boolean branching | duplicate handling

→ Where You'll Use This: Deciding between canonicals and redirects is a daily SEO judgement; parameter URLs that users hit get canonicals, while genuinely retired URLs get 301s to consolidate signals.

⚡ Mental Model

Like deciding whether to forward someone's mail entirely or just note on file which address is their main one.

Project 121 Detect a Soft-404 Behind a 200

💡 The Idea Behind It

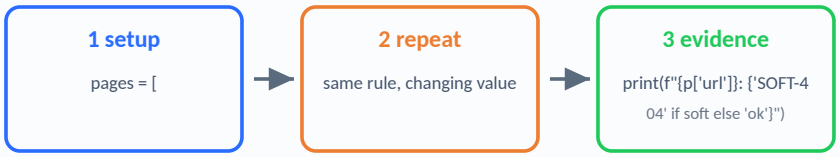
A soft-404 returns status 200 but its body admits the page is missing, so engines waste budget indexing nothing. This code holds a tuple of marker phrases and checks each page: it is a soft-404 when the status is 200 and any marker appears in the lowercased body. The page whose body says page not found is caught, while the genuine 404 with the same words is not, since its status already tells the truth.

What You'll Build & Learn

Catch soft-404 pages that return status 200 yet carry not-found language in their body text.

- Soft-404 mismatches status and body
- any with a generator over markers
- Lowercasing body before matching

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 120: decide between a redirect and a canonical. Project 122 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect a soft-404 behind a 200 is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `pages = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Soft-404 Behind a 200: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: pages, url, https, status, body. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = [| Core: print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}") | Evidence: print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")

🛠️ Reader to Writer Bridge

1. Read: explain detect a soft-404 behind a 200 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 120.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 122 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `pages = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a soft-404 behind a 200 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A soft-404 is the contradiction of a 200 status with body text signalling absence; lower-casing the body and scanning for marker phrases reveals it.

```
pages = [
    {'url': 'https://a/', 'status': 200, 'body': 'Welcome to our store'},
    {'url': 'https://b/', 'status': 200, 'body': 'Sorry, page not found'},
    {'url': 'https://c/', 'status': 404, 'body': 'Not Found'},
]
markers = ('not found', 'no longer exists', 'does not exist')
```

```
for p in pages:
    soft = p['status'] == 200 and any(m in p['body'].lower() for m in markers)
    print(f"{p['url']}: {'SOFT-404' if soft else 'ok'}")
```

```
output
https://a/: ok
https://b/: SOFT-404
https://c/: ok
```

How it works:

1. A list of page dictionaries holds a url, a status, and a body string.
2. markers is a tuple of not-found phrases to search for inside the body.
3. soft is True when the status is 200 and any marker appears in the lowercased body via any.
4. The loop prints SOFT-404 for the offending 200 page and ok for the rest.

Try it:

1. Add more marker phrases such as page removed and content unavailable.
2. Report which specific marker matched for each soft-404.
3. Recommend returning a real 404 or 410 for each flagged page.
4. Add a real product page containing the word 'found' in another context and check for false positives.

⚠ Common Mistakes

- Trusting the status alone never catches a soft-404, since it really is 200.
- Case-sensitive matching misses 'Not Found' when you only search for 'not found'.
- Flagging the genuine 404 as a soft-404 confuses an honest error with a disguised one.

Skills gained soft-404 detection | substring matching | any() over markers

→ Where You'll Use This: Crawlers and SEO tools flag soft-404s because they bloat the index with empty pages; comparing the served status against body language is the standard way to expose them.

Mental Model

Like a store hanging an Open sign on a door while a note inside reads Sorry, we have closed.

Project 122 Count the 4xx Errors in a Crawl

The Idea Behind It

After a crawl, the share of client errors shows how many links point at missing or forbidden pages. This code holds crawl results as tuples of URL and status, then uses a list comprehension to gather every URL whose

status falls in the 400-to-499 range. It prints the count and the sorted offending URLs. Counting 4xx responses is the first health metric an audit reads.

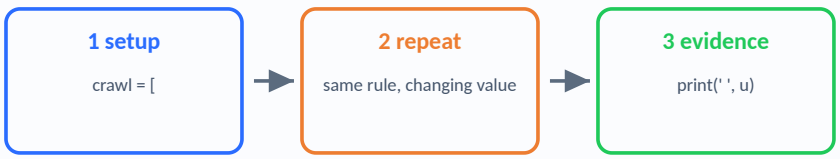
What You'll Build & Learn

Count the 4xx client-error responses in a crawl and list the offending URLs.

- 4xx responses signal broken targets
- List comprehension with a range filter
- Sorting URLs for a readable report

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 121: detect a soft-404 behind a 200. Project 123 changes the surface problem while preserving the underlying method.



progress check

Reading target: count the 4xx errors in a crawl is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `crawl = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(' ', u)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`crawl = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`fourxx = [u for u, s in crawl if 400 <= s < 500]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' ', u)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `fourxx = [u for u, s in crawl if 400 <= s < 500]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count the 4xx Errors in a Crawl: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: crawl, https, fourxx, xx, count. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: crawl = [| Core: fourxx = [u for u, s in crawl if 400 <= s < 500] | Evidence: print(' ', u)

Reader to Writer Bridge

1. Read: explain count the 4xx errors in a crawl in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 121.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 123 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ', u)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `crawl = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count the 4xx errors in a crawl and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the crawl for statuses in the 400-499 range isolates every client error; the length is the count and the URLs name the offenders.

```
crawl = [
    ('https://a/', 200), ('https://b/', 404),
    ('https://c/', 301), ('https://d/', 403),
    ('https://e/', 200), ('https://f/', 410),
]
fourxx = [u for u, s in crawl if 400 <= s < 500]
print('4xx count:', len(fourxx))
for u in sorted(fourxx):
    print(' ', u)
```

```
output
4xx count: 3
  https://b/
  https://d/
  https://f/
```

How it works:

1. crawl is a list of tuples pairing each URL with its returned status code.
2. A comprehension keeps each URL whose status is at least 400 and below 500.
3. The code prints the length of that list as the 4xx count.
4. It then loops over the sorted URLs, printing each indented beneath the count.

Try it:

1. Break the count down by specific code, separating 404 from 403.
2. Express the 4xx count as a percentage of the whole crawl.
3. Also list which source pages link to each 4xx target.
4. Also tally the 5xx errors separately.

⚠ Common Mistakes

- Testing `s == 404` alone misses 403, 410 and other client errors.
- Using `s > 400` excludes 400 itself and includes 5xx codes.
- Counting redirects (3xx) as errors inflates the figure.

Skills gained 4xx counting | list comprehension | range filter

→ Where You'll Use This: The client-error count headlines crawl health reports; a rising 4xx tally tells an SEO that broken links or removed pages are accumulating across the site.

Mental Model

Like tallying how many addresses on a delivery route turned out to be wrong or off-limits.

Project 123 Compute the 5xx Error Rate of a Crawl

The Idea Behind It

Server errors during a crawl can shrink crawl budget and drop pages from the index, so this code expresses 5xx as a rate. It counts statuses in the 500-to-599 range with a generator inside sum, divides by the total, and rounds the percentage to one decimal. The sample gives three of eight as 37.5 percent. A rate makes spikes comparable across crawls of different sizes.

What You'll Build & Learn

Compute the percentage of server-error responses in a crawl so spikes compare across crawl sizes.

- 5xx rate as a comparable metric
- Counting with sum and a generator
- Rounding a percentage to one decimal

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 122: count the 4xx errors in a crawl. Project 124 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute the 5xx error rate of a crawl is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `statuses = [200, 200, 500, 200, 503, 301, 200, 502]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{server_errors}/{total} server errors = {rate}%')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`statuses = [200, 200, 500, 200, 503, 301, 200, 502]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`server_errors = sum(1 for s in statuses if 500 <= s < 600)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{server_errors}/{total} server errors = {rate}%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `server_errors = sum(1 for s in statuses if 500 <= s < 600)`

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute the 5xx Error Rate of a Crawl: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: statuses, total, len, server_errors, sum. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: statuses = [200, 200, 500, 200, 503, 301, 200, 502] | Core: server_errors = sum(1 for s in statuses if 500 <= s < 600) | Evidence: print(f'{server_errors}/{total} server errors = {rate}%')

🛠️ Reader to Writer Bridge

1. Read: explain compute the 5xx error rate of a crawl in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 122.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 124 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{server_errors}/{total} server errors = {rate}%')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `statuses = [200, 200, 500, 200, 503, 301, 200, 502]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute the 5xx error rate of a crawl and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Counting statuses in the 500-599 band and dividing by the total, then scaling to a percentage and rounding, yields a stable error-rate figure.

```
statuses = [200, 200, 500, 200, 503, 301, 200, 502]
total = len(statuses)
server_errors = sum(1 for s in statuses if 500 <= s < 600)
rate = round(100 * server_errors / total, 1)
print(f'{server_errors}/{total} server errors = {rate}%')
```

```
output
3/8 server errors = 37.5%
```

How it works:

1. statuses is a list of eight sample status codes including three server errors.
2. total captures the length of the list.
3. server_errors sums one for each status in the 500-to-599 range using a generator inside sum.
4. rate is the rounded percentage, and an f-string prints the fraction and percent.

Try it:

1. Compute a 4xx rate alongside the 5xx rate in the same report.
2. Trigger an alert string when the rate crosses a configurable threshold.
3. Round to two decimals and compare the output difference.
4. Add more 200s and watch the rate fall.

⚠ Common Mistakes

- Integer division (`server_errors // total`) collapses small rates to 0.
- Forgetting `round` prints a long noisy float that varies in appearance.
- Including 3xx or 4xx in the numerator measures the wrong kind of failure.

Skills gained error rate | sum generator | percentage rounding

→ Where You'll Use This: Monitoring tracks the 5xx rate over time; a spike warns that the server is faltering under crawl load, which can cost crawl budget and de-index pages.

Mental Model

Like reporting failures per hundred attempts rather than a raw count, so two factories of different sizes compare fairly.

Project 124 Verify a Redirect Chain Ends in 200

The Idea Behind It

A healthy redirect ultimately delivers a live page, and this is the pass-or-fail check every audit runs. The walker follows the 301 and 302 hops to the destination, then tests whether that final status equals 200. The sample chain of two permanent redirects ends at a 200, so the code prints PASS with the resolved URL and status. Anything else would print FAIL.

What You'll Build & Learn

Verify that a redirect chain resolves to a 200 response and report a clear pass or fail.

- A healthy chain ends in 200
- Equality test on the final status
- Pass-fail reporting for audits

Skill Roadmap

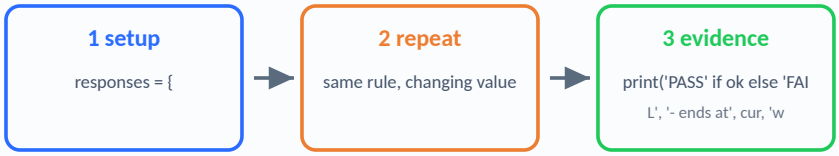
Skill step: moves you from recognition toward independent tracing. It builds on Project 123: compute the 5xx error rate of a crawl. Project 125 changes the surface problem while preserving the underlying method.

progress check

Reading target: verify a redirect chain ends in 200 is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('PASS' if ok else 'FAIL', '– ends at', cur, 'with', responses[cur]['status'])` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur]['status'])`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur]['status'])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur]['status'])`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Verify a Redirect Chain Ends in 200: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: responses, https, old, status, location. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = { | Core: print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur... | Evidence: print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur...

🛠️ Reader to Writer Bridge

1. Read: explain verify a redirect chain ends in 200 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 123.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 125 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur]['status'])`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of verify a redirect chain ends in 200 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Resolving the chain to its terminal URL and asserting the status equals 200 separates redirects that deliver content from those that fail.

```
responses = {
    'https://old/': {'status': 301, 'location': 'https://mid/'},
    'https://mid/': {'status': 301, 'location': 'https://new/'},
    'https://new/': {'status': 200, 'location': None},
}
```

```
cur = 'https://old/'
while responses[cur]['status'] in (301, 302):
    cur = responses[cur]['location']
ok = responses[cur]['status'] == 200
print('PASS' if ok else 'FAIL', '- ends at', cur, 'with', responses[cur]
['status'])
```

```
output
PASS - ends at https://new/ with 200
```

How it works:

1. The responses dictionary chains two 301 redirects into a final URL returning 200.
2. cur starts at the old URL and the while loop advances through the 301 hops.
3. ok is True only when the resolved status equals exactly 200.
4. The code prints PASS or FAIL along with the final URL and its status.

Try it:

1. Accept any 2xx status, not strictly 200, as a pass.
2. Run the check over a dictionary of several chains and tally passes.
3. Report the hop count alongside the pass-fail verdict.
4. Change the final status to 404 and watch it FAIL.

⚠ Common Mistakes

- Asserting 200 on the first hop, not the last, passes a chain that later breaks.
- Accepting any non-3xx status as success would pass a chain ending in 404.
- Missing the terminal map entry raises KeyError when the loop reads it.

Skills gained pass-fail check | chain following | equality test

→ Where You'll Use This: Post-migration verification runs this exact test across the redirect map, confirming each old URL now lands on a real 200 page before declaring the migration successful.

⚡ Mental Model

Like confirming a forwarded letter actually arrived at a real mailbox rather than vanishing en route.

Project 125 Normalise Trailing-Slash Redirects

💡 The Idea Behind It

Many servers enforce one canonical form by redirecting /path to /path/, and this code models that trailing-slash rule. canonicalise returns the URL unchanged if it already ends with a slash, otherwise it appends one.

The loop prints a 200 for URLs that are already canonical and a 301 to the slashed target for those that need rewriting, showing exactly which URLs move and where.

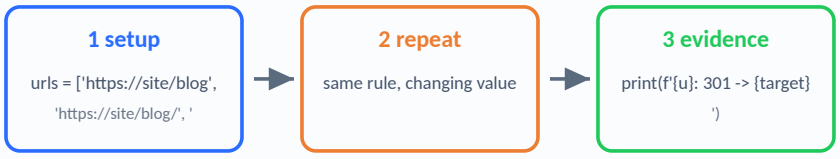
What You'll Build & Learn

Model a trailing-slash canonicalisation rule, issuing a 301 to the slashed form when needed.

- Trailing slash defines one canonical form
- endswith guards the transform
- Already-canonical URLs return 200

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 124: verify a redirect chain ends in 200. Project 126 changes the surface problem while preserving the underlying method.



progress check

Reading target: normalise trailing-slash redirects is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `urls = ['https://site/blog', 'https://site/blog/', 'https://site/about']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{u}: 301 -> {target}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`urls = ['https://site/blog', 'https://site/blog/', 'https://site/about']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`return u if u.endswith('/') else u + '/'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{u}: 301 -> {target}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return u if u.endswith('/') else u + '/'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Normalise Trailing-Slash Redirects: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: urls, https, site, blog, about. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: urls = ['https://site/blog', 'https://site/blog/', 'https://site/about'] | Core: return u if u.endswith('/') else u + '/' | Evidence: print(f'{u}: 301 -> {target}')

🛠️ Reader to Writer Bridge

1. Read: explain normalise trailing-slash redirects in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 124.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 126 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{u}: 301 -> {target}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `urls = ['https://site/blog', 'https://site/blog/', 'https://site/about']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalise trailing-slash redirects and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The policy here is 'always end in a slash'; a URL already ending in `/` returns 200, while one without gets a 301 to its slashed form.

```
urls = ['https://site/blog', 'https://site/blog/', 'https://site/about']
def canonicalise(u):
    return u if u.endswith('/') else u + '/'
for u in urls:
    target = canonicalise(u)
    if target == u:
        print(f'{u}: 200 (already canonical)')
    else:
        print(f'{u}: 301 -> {target}')
```

```
output
https://site/blog: 301 -> https://site/blog/
https://site/blog/: 200 (already canonical)
https://site/about: 301 -> https://site/about/
```

How it works:

1. urls is a list with one already-slashed URL and two without a trailing slash.

2. canonicalise returns the URL as-is when it ends with a slash, else appends one.
3. For each URL the code computes target and compares it to the original.
4. When target equals the URL it prints 200 already canonical, otherwise a 301 to the target.

Try it:

1. Reverse the rule to strip trailing slashes instead of adding them.
2. Leave file-like paths ending in a dot extension unchanged.
3. Skip the homepage so the bare domain is not double-slashed.
4. Switch the policy to strip trailing slashes instead.

⚠ Common Mistakes

- Appending a slash to a URL that already has one creates a double slash.
- Applying the rule to the root URL when the policy differs there can cause a loop.
- Picking the opposite policy (strip the slash) silently reverses every verdict.

Skills gained `trailing slash` `endswith check` `301 modelling`

→ **Where You'll Use This:** Servers normalise slash variants to prevent duplicate URLs; modelling the rule shows an SEO which paths a 301 will rewrite and confirms the canonical form is consistent.

Mental Model

Like a style guide insisting every entry ends with a period, fixing the ones that forgot it.

Project 126 Enforce a www-to-Non-www Redirect

The Idea Behind It

A site should pick one host, with or without www, and 301 the other so ranking signals do not split. to_nonwww replaces the https://www. prefix with https:// exactly once, leaving already-bare hosts untouched. The loop prints a 200 for URLs already on the non-www host and a 301 to the rewritten target for www URLs, encoding a single non-www canonical policy.

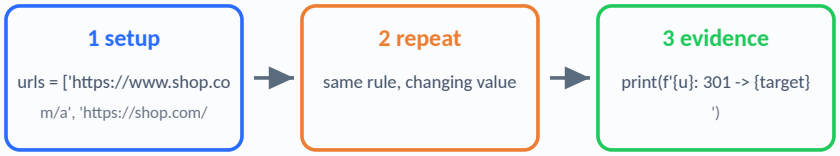
What You'll Build & Learn

Enforce a non-www canonical host, issuing a 301 from any www URL to its bare-host equivalent.

- One host avoids split signals
- replace with a count limit of one
- Non-www as the canonical policy

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 125: normalise trailing-slash redirects. Project 127 changes the surface problem while preserving the underlying method.



progress check

Reading target: enforce a www-to-non-www redirect is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `urls = ['https://www.shop.com/a', 'https://shop.com/b', 'https://www.shop.com/']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

3. Transfer: change one small part of enforce a www-to-non-www redirect and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Stripping a leading `www.` from the host (only the first occurrence) maps every `www` URL to its canonical non-www twin; URLs already canonical return 200.

```
urls = ['https://www.shop.com/a', 'https://shop.com/b',
'https://www.shop.com/']
def to_nonwww(u):
    return u.replace('https://www.', 'https://', 1)
for u in urls:
    target = to_nonwww(u)
    if target == u:
        print(f'{u}: 200')
    else:
        print(f'{u}: 301 -> {target}')
```

```
output
https://www.shop.com/a: 301 -> https://shop.com/a
https://shop.com/b: 200
https://www.shop.com/: 301 -> https://shop.com/
```

How it works:

1. urls mixes two www-prefixed URLs with one already on the bare host.
2. to_nonwww replaces the https://www. prefix with https:// using a count of one.
3. Each URL's target is compared to the original to detect a change.
4. Matching URLs print 200, while www URLs print a 301 to the non-www target.

Try it:

1. Invert the policy to force www and redirect bare hosts to it.
2. Handle http URLs by also upgrading them to https.
3. Only rewrite the host when it begins exactly with www, not any subdomain.
4. Flip the policy to redirect non-www to www.

⚠ Common Mistakes

- Replacing `www.` anywhere in the URL could mangle a path segment that contains 'www.'.
- Omitting the count argument to `replace` risks editing more than the host.
- Choosing non-www here but linking internally to www elsewhere reopens the split.

Skills gained www canonicalisation | string replace | host policy

→ Where You'll Use This: Choosing www or non-www and redirecting the other is foundational SEO hygiene; this models the rule that keeps link equity and rankings on a single host.

⚡ Mental Model

Like a company deciding all email goes to one official address and bouncing anything sent to the old alias.

Project 127 Redirect Mixed-Case URLs to Lowercase

💡 The Idea Behind It

URL paths are case-sensitive, so /Page and /page split signals between two URLs. lower_path splits the scheme from the rest, partitions the host from the path, and lowercases only the path while leaving the host intact. The loop prints a 200 for already-lowercase URLs and a 301 to the lowercased target otherwise, enforcing a single canonical casing without touching the domain.

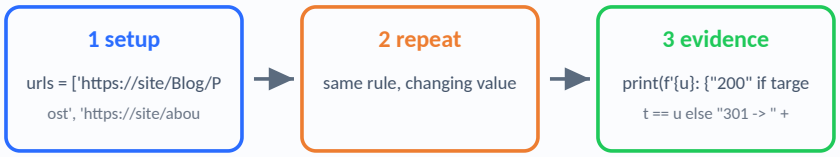
What You'll Build & Learn

Redirect mixed-case URL paths to a lowercase canonical form while preserving the host casing.

- Paths are case-sensitive, hosts are not
- split and partition isolate the path
- Lowercasing only the path component

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 126: enforce a www-to-non-www redirect. Project 128 changes the surface problem while preserving the underlying method.



progress check

Reading target: redirect mixed-case urls to lowercase is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Redirect Mixed-Case URLs to Lowercase: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: urls, https, site, Blog, Post. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: urls = ['https://site/Blog/Post', 'https://site/about', 'https://site/F... | Core: print(f'{u}: {"200" if target == u else "301 -> " + target}') | Evidence: print(f'{u}: {"200" if target == u else "301 -> " + target}')

🛠️ Reader to Writer Bridge

1. Read: explain redirect mixed-case urls to lowercase in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 126.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 128 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{u}: {"200" if target == u else "301 -> " + target}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `urls = ['https://site/Blog/Post', 'https://site/about', 'https://site/FAQ']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of redirect mixed-case urls to lowercase and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Only the path is lowercased while the scheme and host are preserved, since hosts are case-insensitive but lowercasing the whole URL would also corrupt query values.

```
urls = ['https://site/Blog/Post', 'https://site/about', 'https://site/FAQ']
def lower_path(u):
    scheme, rest = u.split('://', 1)
    host, sep, path = rest.partition('/')
    return scheme + '://' + host + sep + path.lower()
for u in urls:
    target = lower_path(u)
    print(f'{u}: {"200" if target == u else "301 -> " + target}')
```

```
output
https://site/Blog/Post: 301 -> https://site/blog/post
https://site/about: 200
https://site/FAQ: 301 -> https://site/faq
```

How it works:

1. urls holds one mixed-case path, one already lowercase, and one uppercase segment.
2. lower_path splits on :// to separate scheme, then partitions the rest into host, separator, and path.
3. It rebuilds the URL with the host unchanged and the path lowercased.
4. Each URL prints 200 when already lowercase or a 301 to the lowercased target.

Try it:

1. Preserve case inside query strings while lowercasing only the path.
2. Also collapse repeated slashes in the path during the rewrite.
3. Leave case-sensitive token segments, such as base64 ids, untouched.
4. Add a URL with an uppercase query value and confirm the path-only fold.

⚠ Common Mistakes

- Lowercasing the entire URL would also fold case-sensitive query parameters.
- Splitting on `/` without `partition` raises when a URL has no path.

- Lowercasing the host is harmless but lowercasing the path of a case-sensitive backend can 404.

Skills gained case canonicalisation | string partition | path lowercasing

→ Where You'll Use This: Mixed-case paths fragment rankings across duplicate URLs; a lowercasing 301 rule consolidates them, and this models the transform before it ships in server config.

⚡ Mental Model

Like a filing clerk who relabels every folder in lowercase so two spellings never end up in separate drawers.

Project 128 Apply a Redirect Map to a URL List

💡 The Idea Behind It

After a migration you hold a map of old URLs to new ones, and applying it rewrites every known old URL while leaving the rest untouched. This code stores the redirect_map as a dictionary and walks a list of URLs, using get to look up each one. A hit prints an arrow to the new target; a miss prints the URL with a no redirect note. It is the lookup at the heart of a migration rollout.

What You'll Build & Learn

Apply a redirect map to a list of URLs, rewriting mapped ones and passing untracked URLs through unchanged.

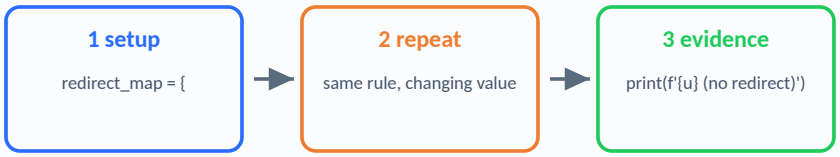
- A redirect map drives migrations
- dict.get returns None on a miss
- Untracked URLs pass through unchanged

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 127: redirect mixed-case urls to lowercase. Project 129 changes the surface problem while preserving the underlying method.

progress check

Reading target: apply a redirect map to a url list is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



🔎 Logic Lens

- Setup: `redirect_map = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from

302 from canonical.

- Evidence: `print(f'{u} (no redirect)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirect_map = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if target:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{u} (no redirect)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if target:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Apply a Redirect Map to a URL List: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: redirect_map, https, old, urls, keep. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: redirect_map = { | Core: if target: | Evidence: print(f'{u} (no redirect)')

🛠️ Reader to Writer Bridge

1. Read: explain apply a redirect map to a url list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 127.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 129 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{u} (no redirect)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `redirect_map = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of apply a redirect map to a url list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A dict lookup with `.get` returns the mapped target when one exists and None otherwise, so unmapped URLs pass through unchanged.

```
redirect_map = {
    'https://old/a': 'https://new/a',
    'https://old/b': 'https://new/b',
}
urls = ['https://old/a', 'https://keep/c', 'https://old/b']
for u in urls:
    target = redirect_map.get(u)
    if target:
        print(f'{u} -> {target}')
    else:
        print(f'{u} (no redirect)')
```

```
output
https://old/a -> https://new/a
https://keep/c (no redirect)
https://old/b -> https://new/b
```

How it works:

1. redirect_map maps two old URLs to their new destinations.
2. urls includes both mapped old URLs plus one that is absent from the map.
3. The loop calls redirect_map.get(u), which returns the target or None.
4. A truthy target prints an arrow to the new URL, otherwise it prints no redirect.

Try it:

1. Report which mapped URLs in the map were never seen in the list.
2. Chase chained map entries so an old target that is itself a key resolves fully.
3. Count how many URLs in the list had no redirect entry.
4. Add a chained entry where a target is also a key and resolve it fully.

⚠ Common Mistakes

- Using `redirect_map[u]` raises KeyError for any URL not in the map.
- Mapping a URL to itself creates a pointless self-redirect.
- Forgetting that a target could itself be a key (a chain) leaves a multi-hop redirect unresolved.

Skills gained redirect map | dict.get lookup | migration rollout

→ Where You'll Use This: Site migrations ship a redirect map; applying it across a URL inventory verifies every old path is covered before launch and shows which URLs still lack a target.

Mental Model

Like a change-of-address book the post office consults for each letter, forwarding the listed ones and delivering the rest as addressed.

Project 129 Find Broken Internal Links

The Idea Behind It

Internal links should point at live pages, and this code cross-checks each link target against the crawl's status map. status holds the code for every crawled URL, links lists source-to-target pairs, and a comprehension keeps any pair whose target status is 404. The output prints each broken link and the total count, surfacing internal links that lead users into a missing page.

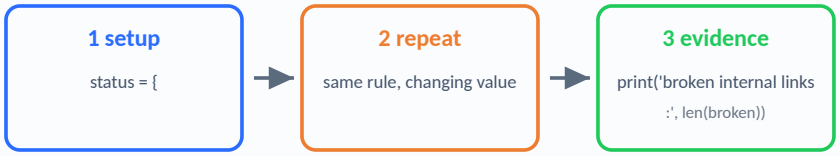
What You'll Build & Learn

Find internal links whose target URL returns 404 by cross-referencing each link against the crawl's status map.

- Internal links should reach live pages
- Joining link pairs to a status map
- Comprehension filtering broken targets

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 128: apply a redirect map to a url list. Project 130 changes the surface problem while preserving the underlying method.



progress check

Reading target: find broken internal links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `status = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('broken internal links:', len(broken))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`status = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`broken = [(s, t) for s, t in links if status.get(t) == 404]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('broken internal links:', len(broken))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `broken = [(s, t) for s, t in links if status.get(t) == 404]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Broken Internal Links: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: status, https, links, broken, get. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: status = { | Core: broken = [(s, t) for s, t in links if status.get(t) == 404] | Evidence: print('broken internal links:', len(broken))

🛠️ Reader to Writer Bridge

1. Read: explain find broken internal links in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 128.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 130 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('broken internal links:', len(broken))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `status = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find broken internal links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Looking up each link's target in the status map and keeping those that return 404 isolates internal links pointing at missing pages.

```
status = {
    'https://a/': 200, 'https://b/': 200,
    'https://c/': 404, 'https://d/': 200,
}
links = [
    ('https://a/', 'https://b/'),
    ('https://a/', 'https://c/'),
```

```
    ('https://b/', 'https://d/'),
]
broken = [(s, t) for s, t in links if status.get(t) == 404]
for s, t in broken:
    print(f'{s} -> {t} (404)')
print('broken internal links:', len(broken))
```

```
output
https://a/ -> https://c/ (404)
broken internal links: 1
```

How it works:

1. status maps four crawled URLs to their codes, one of which is a 404.
2. links is a list of source-to-target tuples representing internal links.
3. A comprehension keeps the pairs whose target status, looked up with get, equals 404.
4. The loop prints each broken link, then prints the total broken count.

Try it:

1. Also flag links whose target returns any 4xx or 5xx status.
2. Group the broken links by their source page in the output.
3. Skip targets missing from the status map rather than treating them as live.
4. Also flag links whose target is a 5xx.

⚠ Common Mistakes

- Checking the source page's status instead of the target's flags the wrong end of the link.
- Using `status[t]` raises KeyError for a target not in the crawl map.
- Treating a 410 target as fine ignores another flavour of dead link.

Skills gained broken link detection | status map join | comprehension filter

→ Where You'll Use This: Internal-link audits run exactly this join, flagging links that point at 404s so editors can repoint or remove them before crawlers waste budget following them.

Mental Model

Like checking every signpost in a building against the room directory and noting which ones point to a room that no longer exists.

Project 130 Build a Status-Code Histogram

The Idea Behind It

A crawl returns thousands of statuses, and a histogram of code-to-count gives the shape of a site's health at a glance. This code feeds a list of statuses to Counter, then iterates the sorted unique codes and prints each beside its frequency. The output reads like the summary line every crawl report opens with, condensing raw responses into a tally per distinct code.

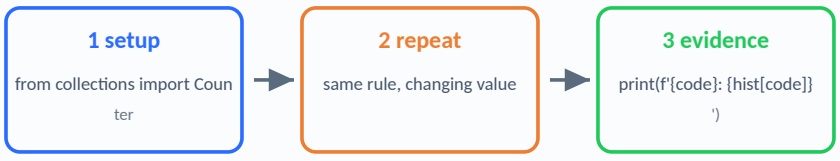
What You'll Build & Learn

Build a per-code frequency histogram of crawl statuses using Counter and print it sorted.

- Counter tallies occurrences automatically
- Histogram shows site health shape
- Sorting keys for ordered output

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 129: find broken internal links. Project 131 changes the surface problem while preserving the underlying method.



progress check

Reading target: build a status-code histogram is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{code}: {hist[code]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`for code in sorted(hist):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{code}: {hist[code]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for code in sorted(hist):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Status-Code Histogram: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: collections, Counter, statuses, hist, code. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: for code in sorted(hist): | Evidence: print(f'{code}: {hist[code]}')

🛠️ Reader to Writer Bridge

1. Read: explain build a status-code histogram in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 129.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 131 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code}: {hist[code]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a status-code histogram and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `Counter` tallies each status code in one pass; sorting the keys before printing makes the histogram deterministic and easy to scan.

```
from collections import Counter
statuses = [200, 200, 301, 200, 404, 301, 200, 500, 404, 200]
hist = Counter(statuses)
for code in sorted(hist):
    print(f'{code}: {hist[code]}')
```

```
output
200: 5
301: 2
404: 2
500: 1
```

How it works:

1. A list of ten statuses with repeats is imported into a Counter as hist.
2. Counter builds a mapping from each distinct code to how many times it appeared.
3. The loop iterates the sorted distinct codes.
4. It prints each code beside its count, yielding an ordered histogram.

Try it:

1. Print a simple bar of hash characters proportional to each count.
2. Sort by frequency descending rather than by code.
3. Show each code's percentage share of the total alongside its count.
4. Print the most common code with `hist.most_common(1)`.

⚠ Common Mistakes

- Iterating an unsorted Counter prints the codes in insertion order, which varies with the data.
- Counting class buckets here would lose the per-code detail a histogram is meant to show.
- Summing the counts and forgetting they should equal the crawl size hides dropped responses.

Skills gained status histogram | collections.Counter | sorted keys

→ Where You'll Use This: Crawl dashboards lead with a per-code histogram so an SEO sees at a glance how many 200s, 301s, and 404s a site returns before drilling into specifics.

Mental Model

Like a tally chart that turns a stack of survey forms into a count beside each possible answer.

Project 131 Tally Permanent Versus Temporary Redirects

The Idea Behind It

Permanent and temporary redirects carry different SEO meaning, and the mix tells you whether a site moves URLs decisively. This code defines permanent as the set 301 and 308 and temporary as 302 and 307, then counts how many codes fall in each using generators inside sum. The output reports four permanent against three temporary, splitting the redirects by their intent.

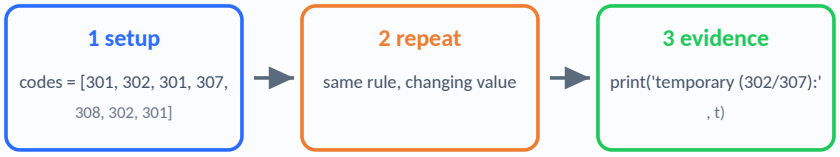
What You'll Build & Learn

Tally permanent versus temporary redirects to gauge how decisively a site moves its URLs.

- 301/308 permanent, 302/307 temporary
- Set membership for classification
- Counting each group with sum

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 130: build a status-code histogram. Project 132 changes the surface problem while preserving the underlying method.



progress check

Reading target: tally permanent versus temporary redirects is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `codes = [301, 302, 301, 307, 308, 302, 301]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('temporary (302/307):', t)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`codes = [301, 302, 301, 307, 308, 302, 301]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

Code Reading Stack

Layer	What to read
Intent	Tally Permanent Versus Temporary Redirects: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: codes, permanent, temporary, sum. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: codes = [301, 302, 301, 307, 308, 302, 301] | Core: p = sum(1 for c in codes if c in permanent) | Evidence: print('temporary (302/307):', t)

🛠️ Reader to Writer Bridge

1. Read: explain tally permanent versus temporary redirects in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 130.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 132 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('temporary (302/307):', t)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `codes = [301, 302, 301, 307, 308, 302, 301]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of tally permanent versus temporary redirects and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Two sets define which codes count as permanent versus temporary, and a pair of generator-sum tallies splits the redirect list by intent.

```
codes = [301, 302, 301, 307, 308, 302, 301]
permanent = {301, 308}
temporary = {302, 307}
p = sum(1 for c in codes if c in permanent)
t = sum(1 for c in codes if c in temporary)
print('permanent (301/308):', p)
print('temporary (302/307):', t)
```

```
output
permanent (301/308): 4
temporary (302/307): 3
```

How it works:

1. codes is a list of seven redirect statuses mixing all four redirect types.
2. permanent is the set {301, 308} and temporary is {302, 307}.
3. p sums one for each code in permanent and t sums one for each in temporary.
4. The code prints the permanent count and the temporary count on separate lines.

Try it:

1. Flag any code that is neither permanent nor temporary as unexpected.
2. Report the ratio of permanent to temporary as a single number.
3. Add 303 and 300 and decide how to classify them.
4. Add a 304 and confirm it counts as neither.

⚠ Common Mistakes

- Forgetting 308 leaves a permanent redirect counted as neither.
- Putting 307 in the permanent set inverts its temporary meaning.
- Counting any 3xx (like 304) as a redirect type pollutes the tally.

Skills gained redirect tally | set membership | sum counting

→ Where You'll Use This: Audits report the permanent-to-temporary split because a site heavy with 302s may be leaking equity on moves that should be permanent 301s.

Mental Model

Like sorting forwarding orders into permanent moves and short holiday holds to see how settled an address book is.

Project 132 Print a Redirect Chain Hop by Hop

The Idea Behind It

Debugging a redirect is easier when you see each hop's status and target on its own line. This printer uses a while True loop: when the current response is a 301 or 302 it prints the URL, its status, and the location it points to, then advances; otherwise it prints the final URL and status and breaks. The result is a readable hop-by-hop trace of the whole chain.

What You'll Build & Learn

Print a redirect chain hop by hop, showing each URL's status and target on its own line.

- Hop-by-hop tracing aids debugging
- while True with an internal break
- Distinguishing a hop from the final stop

Skill Roadmap

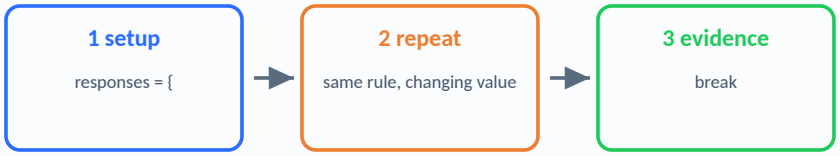
Skill step: moves you from recognition toward independent tracing. It builds on Project 131: tally permanent versus temporary redirects. Project 133 changes the surface problem while preserving the underlying method.

progress check

Reading target: print a redirect chain hop by hop is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `break` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if r['status'] in (301, 302):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`break`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if r['status'] in (301, 302):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Print a Redirect Chain Hop by Hop: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: responses, https, status, location, cur. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = { | Core: if r['status'] in (301, 302): | Evidence: break

🛠️ Reader to Writer Bridge

1. Read: explain print a redirect chain hop by hop in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 131.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 133 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `break`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of print a redirect chain hop by hop and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The loop prints the current URL with its status, and either follows the `location` of a redirect or marks the terminal page and stops.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 302, 'location': 'https://c/'},
    'https://c/': {'status': 200, 'location': None},
}
cur = 'https://a/'
while True:
    r = responses[cur]
```

```
    if r['status'] in (301, 302):
        print(f"{cur} [{r['status']}] -> {r['location']}")
        cur = r['location']
    else:
        print(f"{cur} [{r['status']}] (final)")
        break
```

```
output
https://a/ [301] -> https://b/
https://b/ [302] -> https://c/
https://c/ [200] (final)
```

How it works:

1. The responses dictionary chains a 301 and a 302 into a final 200.
2. cur starts at the first URL inside an unconditional while True loop.
3. When the status is 301 or 302 it prints the URL, status, and location, then advances cur.
4. Otherwise it prints the final URL and status with a final marker and breaks.

Try it:

1. Number each hop with an index as it prints.
2. Add a hop limit so a loop cannot run the trace forever.
3. Include the reason phrase from project 112 beside each status.
4. Add a fourth hop and watch one more line print.

⚠ Common Mistakes

- Printing the target before reading its own status mixes up which hop a code belongs to.
- An infinite `while True` with no terminal branch loops forever on a cyclic chain.
- Using `cur = r['location']` when location is None for a non-redirect would crash the next read.

Skills gained redirect tracing | while True loop | break statement

→ Where You'll Use This: Engineers paste a hop-by-hop trace into bug reports to show exactly where a redirect chain misbehaves, mirroring what curl's verbose follow output reveals.

⚡ Mental Model

Like reading a parcel's tracking history one scan at a time instead of just seeing the final delivery.

Project 133 Check for an Insecure-Protocol Redirect Hop

💡 The Idea Behind It

A redirect chain should not bounce through an insecure step, so this code checks every hop's protocol. is_secure returns whether a URL starts with https://, and a comprehension collects any hop that fails the test. The sample chain hides an insecure:// hop between two https URLs, so the code prints the insecure hops and declares MIXED PROTOCOL, flagging a security and ranking risk.

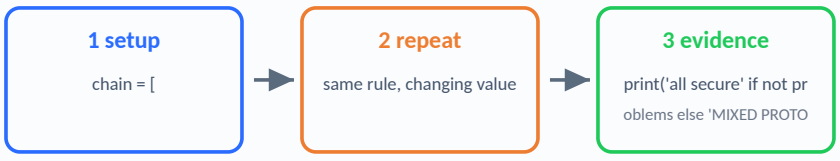
What You'll Build & Learn

Detect an insecure, non-HTTPS hop inside a redirect chain and flag the mixed-protocol risk.

- Chains must stay on HTTPS throughout
- startswith tests the protocol
- Comprehension collects insecure hops

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 132: print a redirect chain hop by hop. Project 134 changes the surface problem while preserving the underlying method.



progress check

Reading target: check for an insecure-protocol redirect hop is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `chain = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('all secure' if not problems else 'MIXED PROTOCOL')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`chain = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`problems = [u for u in chain if not is_secure(u)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('all secure' if not problems else 'MIXED PROTOCOL')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `problems = [u for u in chain if not is_secure(u)]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Check for an Insecure-Protocol Redirect Hop: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: chain, https, insecure, is_secure, startswith. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: chain = [| Core: problems = [u for u in chain if not is_secure(u)] | Evidence: print('all secure' if not problems else 'MIXED PROTOCOL')

🛠️ Reader to Writer Bridge

1. Read: explain check for an insecure-protocol redirect hop in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 132.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 134 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('all secure' if not problems else 'MIXED PROTOCOL')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `chain = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check for an insecure-protocol redirect hop and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Testing each hop's prefix against the secure scheme isolates any step that falls back to an insecure protocol, which weakens the whole chain.

```
chain = [
    'https://a/',
    'insecure://a/',
    'https://b/',
]
def is_secure(u):
    return u.startswith('https://')
problems = [u for u in chain if not is_secure(u)]
print('insecure hops:', problems if problems else 'none')
print('all secure' if not problems else 'MIXED PROTOCOL')
```

```
output
insecure hops: ['insecure://a/']
MIXED PROTOCOL
```

How it works:

1. chain is a list of three URLs where the middle one uses an insecure protocol.

2. is_secure returns True only when a URL starts with https://.
3. A comprehension collects every URL that fails the secure test into problems.
4. The code prints the insecure hops, then all secure or MIXED PROTOCOL depending on whether problems is empty.

Try it:

1. Report the position index of each insecure hop in the chain.
2. Treat http:// specifically and suggest the https:// upgrade target.
3. Fail only when the insecure hop is not the very first entry.
4. Make every hop secure and confirm the 'all secure' verdict.

⚠ Common Mistakes

- Checking only the first and last URL misses an insecure hop in the middle.
- A prefix test that accepts any scheme containing 'https' could be fooled by a lookalike host.
- Treating a protocol-relative URL (`//host`) as secure assumes the page context, which may be wrong.

Skills gained protocol check | startswith test | comprehension filter

→ Where You'll Use This: Audits verify redirect chains never drop to HTTP mid-flight; an insecure hop triggers browser warnings and weakens trust signals, so flagging it is a security and SEO requirement.

Mental Model

Like noticing a secure courier route briefly hands the package to an unmarked van before resuming.

Project 134 Handle 410 Gone Versus 404 Not Found

The Idea Behind It

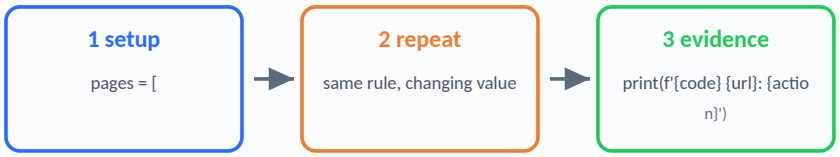
404 means missing, maybe temporarily, while 410 means gone for good, and treating them differently tells a crawler whether to keep retrying or retire a URL. This code walks a list of URL and code pairs, mapping 410 to retire permanently, 404 to recrawl later, and anything else to keep. The output assigns each page its action, encoding the gone-versus-not-found distinction.

What You'll Build & Learn

Assign a crawler action per page by distinguishing a permanent 410 Gone from a recheckable 404 Not Found.

- 410 is permanent, 404 may recover
- if-elif-else action selection
- Status drives recrawl behaviour

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 133: check for an insecure-protocol redirect hop. Project 135 changes the surface problem while preserving the underlying method. *progress check*

Reading target: handle 410 gone versus 404 not found is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `pages = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{code} {url}: {action}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Names	Watch these names first: pages, https, url, code, action. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = [| Core: if code == 410: | Evidence: print(f'{code} {url}: {action}')

Reader to Writer Bridge

1. Read: explain handle 410 gone versus 404 not found in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 133.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 135 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{code} {url}: {action}')`. Then compare punctuation, spacing, and order.
2. Explain: point to `pages = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of handle 410 gone versus 404 not found and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Branching on 410 versus 404 encodes the semantic difference: a 410 lets the crawler drop the URL for good, while a 404 leaves room for it to return.

```
pages = [
    ('https://a/', 404),
    ('https://b/', 410),
    ('https://c/', 404),
    ('https://d/', 200),
]
for url, code in pages:
    if code == 410:
        action = 'retire permanently'
    elif code == 404:
        action = 'recrawl later'
    else:
        action = 'keep'
    print(f'{code} {url}: {action}')
```

```
output
404 https://a/: recrawl later
410 https://b/: retire permanently
404 https://c/: recrawl later
200 https://d/: keep
```

How it works:

1. pages is a list of URL and code tuples covering 404, 410, and 200.
2. The loop assigns retire permanently when the code is 410.
3. It assigns recrawl later for 404 and keep for everything else.
4. An f-string prints the code, URL, and chosen action for each page.

Try it:

1. Add a 451 unavailable-for-legal-reasons branch with its own action.
2. Track how many recrawl-later URLs accumulate across the list.
3. Treat repeated 404s over several crawls as an eventual retire.

4. Add a 403 and decide its action.

⚠ Common Mistakes

- Collapsing 410 into the 404 branch loses the 'permanently gone' signal.
- Treating both as a generic 4xx error skips the chance to stop recrawling 410s.
- Assuming a 200 page needs no action when it might still carry a noindex tag.

Skills gained 410 vs 404 | if-elif-else | recrawl logic

→ Where You'll Use This: Crawl schedulers honour 410 by dropping URLs immediately while retrying 404s; modelling this difference keeps a crawler from wasting requests on pages a site has deliberately removed.

⚡ Mental Model

Like a postal service that re-attempts an unanswered house but permanently closes the file on a demolished one.

Project 135 Interpret a 304 Not Modified Response

💡 The Idea Behind It

A 304 says the cached copy is still fresh, so the server sends no body and the client reuses what it has. This code walks a list of responses carrying a status and a body length; for a 304 it notes use cached copy with no body sent, and for a 200 it reports the fresh byte count. Recognising 304 avoids mistaking an empty response for an error.

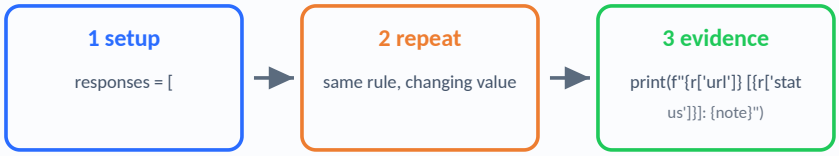
What You'll Build & Learn

Interpret a 304 Not Modified as a cache reuse signal rather than treating its empty body as an error.

- 304 means reuse the cached copy
- An empty body on 304 is normal
- Branching on status for the note

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 134: handle 410 gone versus 404 not found. Project 136 changes the surface problem while preserving the underlying method.



progress check

Reading target: interpret a 304 not modified response is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `responses = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f"{r['url']} [{r['status']}]: {note}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Names	Watch these names first: responses, url, https, status, body_len. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = [| Core: if r['status'] == 304: | Evidence: print(f"{r['url']} [{r['status']}]: {note}")

🛠️ Reader to Writer Bridge

1. Read: explain interpret a 304 not modified response in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 134.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 136 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{r['url']} [{r['status']}]: {note}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `responses = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of interpret a 304 not modified response and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A 304 legitimately carries no body because the client's cached version is still valid, so an empty `body_len` is expected rather than a fault.

```
responses = [
    {'url': 'https://a/', 'status': 200, 'body_len': 1500},
    {'url': 'https://b/', 'status': 304, 'body_len': 0},
    {'url': 'https://c/', 'status': 200, 'body_len': 800},
]
for r in responses:
    if r['status'] == 304:
        note = 'use cached copy (no body sent)'
    else:
        note = f"fresh body, {r['body_len']} bytes"
    print(f"{r['url']} [{r['status']}]: {note}")
```

```
output
https://a/ [200]: fresh body, 1500 bytes
https://b/ [304]: use cached copy (no body sent)
https://c/ [200]: fresh body, 800 bytes
```

How it works:

1. A list of response dictionaries holds a url, status, and body_len.
2. The middle entry is a 304 with a body_len of zero.
3. The loop prints use cached copy for a 304 and a fresh-body byte count otherwise.
4. An f-string shows each URL, status, and its note.

Try it:

1. Add the request headers, such as If-None-Match, that elicit a 304.
2. Count how many responses were served from cache versus fresh.
3. Treat a 304 with a non-zero body length as suspicious.
4. Add another 304 and confirm both reuse the cache.

⚠ Common Mistakes

- Flagging the empty body of a 304 as a broken page misreads a normal cache hit.
- Expecting a `body_len` greater than zero on a 304 contradicts the spec.

- Treating 304 as a redirect because it is a 3xx ignores that it carries no `location`.

Skills gained 304 interpretation | conditional notes | cache awareness

→ Where You'll Use This: Crawlers send conditional requests and honour 304 to save bandwidth; understanding that an empty 304 body is expected prevents tools from flagging healthy cached pages as broken.

Mental Model

Like a librarian replying nothing's changed, keep the copy you have rather than handing over the whole book again.

Project 136 Detect a Redirect Pointing to a Missing Entry

The Idea Behind It

A redirect map can point at a URL that was never crawled, leaving the chain unresolved. This walker guards the loop with a membership check: it advances only while the current URL exists in responses and is a 301 or 302. After the loop it tests whether cur is still present; if not, it reports the dangling target. The guard prevents a KeyError mid-walk when a hop leads off the known set.

What You'll Build & Learn

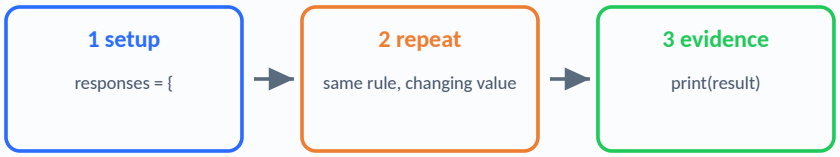
Detect a redirect whose target was never crawled and report it as dangling without raising a KeyError.

- A hop can target an uncrawled URL
- Membership guard prevents KeyError
- Dangling targets stay unresolved

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 135: interpret a 304 not modified response. Project 137 changes the surface problem while preserving the underlying method.

progress check



Reading target: detect a redirect pointing to a missing entry is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(result)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if cur in responses:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(result)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if cur in responses:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Redirect Pointing to a Missing Entry: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: responses, https, status, location, ghost. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: responses = { | Core: if cur in responses: | Evidence: print(result)

🛠️ Reader to Writer Bridge

1. Read: explain detect a redirect pointing to a missing entry in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 135.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 137 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a redirect pointing to a missing entry and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Guarding the loop with `cur in responses` stops the walk safely when a hop points at a URL absent from the map, which the code then reports as dangling.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 301, 'location': 'https://ghost/'},
}
cur = 'https://a/'
result = 'unresolved'
while cur in responses and responses[cur]['status'] in (301, 302):
    cur = responses[cur]['location']
if cur in responses:
    result = f"resolved at {cur} [{responses[cur]['status']}]"
else:
    result = f'DANGLING: {cur} not crawled'
print(result)
```

```
output
DANGLING: https://ghost/ not crawled
```

How it works:

1. The responses dictionary chains two redirects whose final location, a ghost URL, is absent from the map.
2. The while loop advances only while cur is in responses and its status is 301 or 302.
3. After the loop, if cur is still in responses it reports the resolved status.
4. Otherwise it prints DANGLING with the uncrawled target.

Try it:

1. Queue the dangling target for a follow-up crawl pass.
2. Distinguish a dangling external host from an uncrawled internal one.
3. Count how many chains end dangling across a larger map.
4. Add the missing `https://ghost/` entry with status 200 and watch it resolve.

⚠ Common Mistakes

- Dropping the `cur in responses` guard raises KeyError the moment a target is missing.
- Assuming every `location` exists in the map is exactly the bug this guards against.
- Reporting success when the loop exits without confirming the final URL was actually crawled.

Skills gained dangling detection | membership guard | KeyError safety

→ Where You'll Use This: Incomplete crawls leave redirect targets unfetched; guarding lookups lets an audit report unresolved chains gracefully instead of crashing partway through a large URL set.

Mental Model

Like a forwarding chain that points to a street the census never surveyed, so you note the gap rather than insist it exists.

Project 137 Detect a URL That Redirects to Itself

The Idea Behind It

A URL redirecting to itself is the tightest possible loop and an immediate crawl trap. This code scans the sorted response map and, for each URL that is a 301 or 302, checks whether its location equals the URL itself. The first entry points at its own address, so it prints SELF-REDIRECT, while the others read ok. Catching this before any walk begins prevents an instant infinite loop.

What You'll Build & Learn

Flag any URL whose redirect location equals itself, catching the tightest possible loop before a walk.

- A self-redirect is an instant loop
- Comparing location to the URL
- Catching the trap before walking

Skill Roadmap

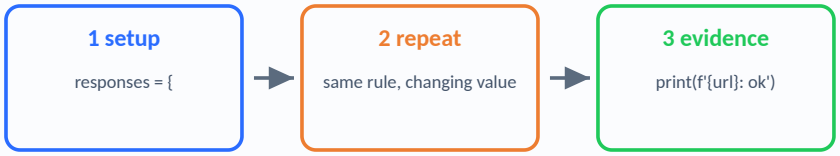
Skill step: pushes the same idea into a less automatic situation. It builds on Project 136: detect a redirect pointing to a missing entry. Project 138 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a url that redirects to itself is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{url}: ok')` exposes the result; match it against the output before changing the program.

output proves the trace

🛠️ Reader to Writer Bridge

1. Read: explain detect a url that redirects to itself in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 136.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 138 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{url}: ok')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect a url that redirects to itself and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A self-redirect is the simplest cycle to spot: a redirect status whose `location` is identical to its own URL, caught without following anything.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://a/'},
    'https://b/': {'status': 301, 'location': 'https://c/'},
    'https://c/': {'status': 200, 'location': None},
}
for url in sorted(responses):
    r = responses[url]
    if r['status'] in (301, 302) and r['location'] == url:
```

```
        print(f'{url}: SELF-REDIRECT')
    else:
        print(f'{url}: ok')
```

```
output
https://a/: SELF-REDIRECT
https://b/: ok
https://c/: ok
```

How it works:

1. The responses dictionary includes one URL whose location points back at itself.
2. The loop iterates the sorted URLs and reads each response.
3. It flags SELF-REDIRECT when the status is 301 or 302 and the location equals the URL.
4. Every other URL prints ok.

Try it:

1. Also catch a URL whose location differs only by a trailing slash.
2. Count how many self-redirects appear across the whole map.
3. Report the status code alongside each self-redirect flag.
4. Add a 302 self-redirect and confirm it is also caught.

⚠ Common Mistakes

- Comparing the URLs after normalising one but not the other can miss a slash-only self-loop.
- Only checking 301 misses a 302 self-redirect.
- Iterating an unsorted dict makes the per-URL output order vary.

Skills gained self-redirect | self-comparison | loop prevention

→ Where You'll Use This: A self-redirect hangs browsers and crawlers immediately; scanning the response map for one is a cheap pre-check that catches the worst misconfiguration before a chain walk even starts.

Mental Model

Like a forwarding note on a door that simply reads see this same door, sending you in circles on the spot.

Project 138 Average the Hop Count Across Chains

The Idea Behind It

One long chain is bad, but the site-wide average tells you whether redirects are a systemic problem. This code stores each chain's pre-counted hops in a dictionary, pulls the values into a list, sums them, and divides by the

count to get a rounded average. The output reports the number of chains, total hops, and the average, summarising the whole redirect map in a single figure.

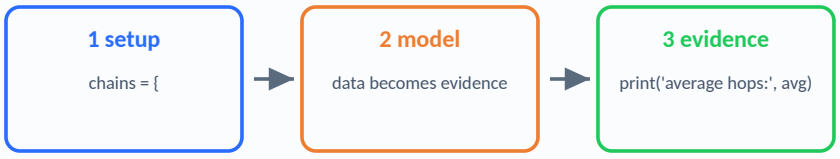
What You'll Build & Learn

Average the hop counts across all redirect chains to judge whether redirects are a systemic issue.

- Average reveals systemic redirect debt
- dict.values feeds a sum
- Rounding the mean to two decimals

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 137: detect a url that redirects to itself. Project 139 changes the surface problem while preserving the underlying method.



progress check

Reading target: average the hop count across chains is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `chains = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('average hops:', avg)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, model applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`chains = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`print('average hops:', avg)`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('average hops:', avg)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('average hops:', avg)`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Average the Hop Count Across Chains: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: chains, https, hops, values, avg. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: chains = { | Core: print('average hops:', avg) | Evidence: print('average hops:', avg)

🛠️ Reader to Writer Bridge

1. Read: explain average the hop count across chains in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 137.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 139 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('average hops:', avg)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `chains = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of average the hop count across chains and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Summing the per-chain hop counts and dividing by the number of chains, then rounding, gives a single comparable redirect-depth metric.

```
chains = {
    'https://a/': 1,
    'https://b/': 3,
    'https://c/': 2,
    'https://d/': 0,
}
hops = list(chains.values())
avg = round(sum(hops) / len(hops), 2)
print('chains:', len(hops))
print('total hops:', sum(hops))
print('average hops:', avg)
```

```
output
chains: 4
total hops: 6
average hops: 1.5
```

How it works:

1. chains maps four starting URLs to their pre-counted hop totals.

2. hops collects the dictionary's values into a list.
3. avg divides the sum of hops by their count and rounds to two decimals.
4. The code prints the chain count, total hops, and the average.

Try it:

1. Also report the maximum and minimum hop count across the chains.
2. Exclude zero-hop chains from the average and compare the result.
3. Compute the median hop count alongside the mean.
4. Drop the zero-hop chain and recompute the average.

⚠ Common Mistakes

- Including chains with zero hops or excluding them changes the average; be explicit about which you mean.
- Integer division would truncate the average to a whole number.
- Forgetting `round` prints a long repeating float.

Skills gained average hops | dict.values | mean rounding

→ Where You'll Use This: Tracking the average hop count across crawls shows whether a redirect cleanup is working; a falling mean signals the site is consolidating chains rather than accumulating them.

Mental Model

Like reporting a fleet's average detour length rather than fixating on the one truck that took the longest way round.

Project 139 Resolve a Redirect Map to Final Targets

The Idea Behind It

A migration map often has chained entries where one target is itself a key, so following it once is not enough. The final function walks the map until the URL is no longer a key, using a seen set to stop if it revisits a URL. The result gives every old URL its true final destination in one pass, even when the map links a to b to c.

What You'll Build & Learn

Resolve a redirect map with chained entries to each URL's true final target, guarding against cycles.

- Map entries can chain together
- Following until the key stops
- A seen set prevents infinite loops

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 138: average the hop count across chains. Project 140 changes the surface problem while preserving the underlying method.

progress check

Reading target: resolve a redirect map to final targets is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `redirect_map = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{start} => {final(start)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirect_map = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`while url in redirect_map and url not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{start} => {final(start)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `while url in redirect_map and url not in seen:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Resolve a Redirect Map to Final Targets: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: redirect_map, https, url, seen, not. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: redirect_map = { | Core: while url in redirect_map and url not in seen: | Evidence: print(f'{start} => {final(start)}')

Reader to Writer Bridge

1. Read: explain resolve a redirect map to final targets in one sentence before touching the code; the goal gives the syntax context.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{start} => {final(start)}')`. Then compare punctuation, spacing, and order.
2. Explain: point to `redirect_map = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of resolve a redirect map to final targets and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Repeatedly replacing a URL with its mapped target until the map runs out (with a seen-set loop guard) flattens any chain into a single final hop.

```
redirect_map = {
    'https://a/': 'https://b/',
    'https://b/': 'https://c/',
    'https://d/': 'https://e/',
}
def final(url, seen=None):
    seen = seen or set()
    while url in redirect_map and url not in seen:
        seen.add(url)
        url = redirect_map[url]
    return url
for start in sorted(redirect_map):
    print(f'{start} => {final(start)}')
```

```
output
https://a/ => https://c/
https://b/ => https://c/
https://d/ => https://e/
```

How it works:

1. redirect_map links a to b to c, with d pointing separately to e.
2. final loops while the URL is still a key and not already in seen.
3. Each step adds the URL to seen and follows the map to the next.
4. The loop prints each starting URL alongside its fully resolved final target.

Try it:

1. Return the full path taken, not just the final target.
2. Report any starting URL that loops back into a cycle.
3. Use the resolved targets to rewrite the map into single hops.

4. Add a cyclic entry and confirm the guard stops it.

⚠ Common Mistakes

- Returning the first target instead of following the chain leaves a multi-hop redirect.
- A default mutable argument shared across calls would accumulate seen URLs; building it per call avoids that.
- Without the seen-set guard a cyclic map would loop forever.

Skills gained map resolution | chained lookup | cycle guard

→ Where You'll Use This: Flattening a chained migration map gives clean one-hop redirects; resolving each old URL to its final target lets an SEO replace multi-step chains with direct 301s that preserve more equity.

⚡ Mental Model

Like following a chain of forwarding addresses until you reach the one nobody has moved on from.

Project 140 Summarise a Crawl by Status Class

💡 The Idea Behind It

Rolling thousands of codes up into 2xx, 3xx, 4xx, and 5xx buckets is the headline a crawl report opens with. This code feeds a generator that formats each status as a family label into Counter, producing a count per family. Iterating the sorted labels prints the four numbers, compressing a full per-code histogram into a single line of site health.

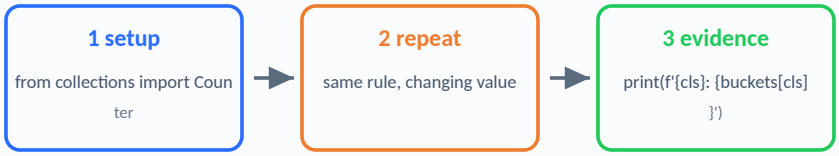
What You'll Build & Learn

Summarise a crawl by counting responses into 2xx, 3xx, 4xx, and 5xx family buckets.

- Family buckets compress the histogram
- Generator builds the class label
- Counter tallies the four families

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 139: resolve a redirect map to final targets. Project 141 changes the surface problem while preserving the underlying method.



progress check

Reading target: summarise a crawl by status class is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{cls}: {buckets[cls]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`buckets = Counter(f'{s // 100}xx' for s in statuses)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{cls}: {buckets[cls]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `buckets = Counter(f'{s // 100}xx' for s in statuses)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Summarise a Crawl by Status Class: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: collections, Counter, statuses, buckets, xx. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: from collections import Counter | Core: buckets = Counter(f'{s // 100}xx' for s in statuses) | Evidence: print(f'{cls}: {buckets[cls]}')

🛠️ Reader to Writer Bridge

1. Read: explain summarise a crawl by status class in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 139.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 141 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{cls}: {buckets[cls]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of summarise a crawl by status class and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Mapping each code to its `Nxx` class string with integer division and counting those strings produces the four-bucket summary directly.

```
from collections import Counter
statuses = [200, 301, 200, 404, 500, 302, 200, 403, 503, 200]
buckets = Counter(f'{s // 100}xx' for s in statuses)
for cls in sorted(buckets):
    print(f'{cls}: {buckets[cls]}')
```

```
output
2xx: 4
3xx: 2
4xx: 2
5xx: 2
```

How it works:

1. statuses is a list of ten codes spanning all four families.
2. A generator formats each status as its family label, like 2xx, via integer division.
3. Counter tallies those labels into buckets.
4. The loop prints each sorted family label beside its count.

Try it:

1. Add a percentage share for each family alongside the count.
2. Include a 1xx bucket and feed it an informational code.
3. List the actual URLs under each family using project 145's approach.
4. Print each bucket as a share of the total.

⚠ Common Mistakes

- Bucketing on `str(s)[0]` works for three-digit codes but is fragile if a code is malformed.
- Forgetting to sort the buckets prints the classes in arbitrary order.
- Treating 304 as an error rather than a 3xx redirect-class code miscounts the buckets.

Skills gained class summary | Counter with generator | family bucketing

→ Where You'll Use This: The four-family rollup is the top-line metric of every crawl report; it lets a stakeholder gauge overall site health in one glance before any URL-level detail.

Mental Model

Like summarising a city's weather report as days of sun, cloud, rain, and storm rather than every hourly reading.

Project 141 Flag a Redirect Chain That Leaves the Domain

The Idea Behind It

A chain that hops to an external domain may signal a hijack or a sloppy migration. The host helper extracts the hostname by splitting off the scheme and then the path. The code takes the first URL's host as the origin and gathers any hop whose host differs. The sample jumps to other.com, so the code prints the origin host and the off-domain hops it found.

What You'll Build & Learn

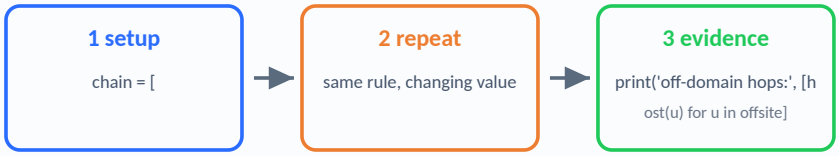
Flag a redirect chain that leaves its origin domain by comparing each hop's host to the first one.

- Off-domain hops can signal a hijack
- Extracting a host from a URL
- Comparing each hop's host to origin

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 140: summarise a crawl by status class. Project 142 changes the surface problem while preserving the underlying method.

progress check



Reading target: flag a redirect chain that leaves the domain is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `chain = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('off-domain hops:', [host(u) for u in offsite] if offsite else 'none')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`chain = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`offsite = [u for u in chain if host(u) != origin]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('off-domain hops:', [host(u) for u in offsite] if offsite else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `offsite = [u for u in chain if host(u) != origin]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Flag a Redirect Chain That Leaves the Domain: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: chain, https, shop, com, other. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: chain = [| Core: offsite = [u for u in chain if host(u) != origin] | Evidence: print('off-domain hops:', [host(u) for u in offsite] if offsite else 'n...

🛠️ Reader to Writer Bridge

1. Read: explain flag a redirect chain that leaves the domain in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 140.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 142 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('off-domain hops:', [host(u) for u in offsite] if offsite else 'none')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `chain = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag a redirect chain that leaves the domain and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Extracting each hop's host and comparing it to the first hop's host isolates any step that leaves the origin domain.

```
chain = [
    'https://shop.com/a',
    'https://shop.com/b',
    'https://other.com/c',
```

```
]
def host(u):
    return u.split('://', 1)[1].split('/', 1)[0]
origin = host(chain[0])
offsite = [u for u in chain if host(u) != origin]
print('origin host:', origin)
print('off-domain hops:', [host(u) for u in offsite] if offsite else 'none')
```

```
output
origin host: shop.com
off-domain hops: ['other.com']
```

How it works:

1. chain lists three URLs where the last belongs to a different domain.
2. host splits a URL on :// then on the first slash to isolate the hostname.
3. origin is the host of the first URL in the chain.
4. A comprehension collects hops whose host differs from origin, then the code prints the origin and any off-domain hosts.

Try it:

1. Allow a list of trusted sibling domains that should not be flagged.
2. Treat a subdomain of the origin as on-domain rather than off.
3. Report the index of the first off-domain hop in the chain.
4. Point the last hop back to `shop.com` and confirm 'none'.

⚠ Common Mistakes

- Splitting only on `://` and forgetting to cut at the first `/` keeps the path in the host.
- Comparing full URLs instead of hosts flags every path change as off-domain.
- Ignoring a port or subdomain difference may over- or under-flag depending on intent.

Skills gained off-domain detection | host extraction | comprehension filter

→ Where You'll Use This: Audits flag chains that drift to foreign domains because they often indicate a compromised redirect or a botched migration; comparing hosts is the check that surfaces the unexpected jump.

Mental Model

Like noticing a forwarded letter suddenly routes through another country before claiming to come back home.

Project 142 Decide Whether a Status Is Retryable

The Idea Behind It

A crawler should retry transient failures but give up on permanent ones. This code defines a retryable set of codes (429 and the common 5xx failures), then classifies each status: a 2xx is done, a member of the retryable set is retry later, and everything else is give up. The output drives a fetch queue's retry logic, deciding which requests deserve another attempt.

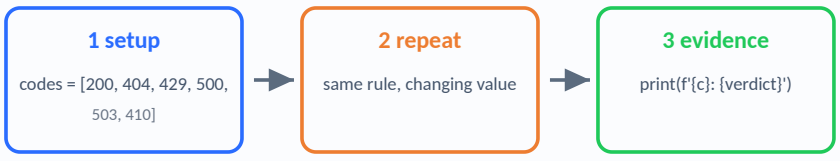
What You'll Build & Learn

Classify each status as done, retry later, or give up to drive a fetch queue's retry decisions.

- Transient failures deserve a retry
- A retryable set encodes the policy
- if-elif-else assigns the verdict

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 141: flag a redirect chain that leaves the domain. Project 143 changes the surface problem while preserving the underlying method.



progress check

Reading target: decide whether a status is retryable is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `codes = [200, 404, 429, 500, 503, 410]` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{c}: {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`codes = [200, 404, 429, 500, 503, 410]`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if 200 <= c < 300:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{c}: {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if 200 <= c < 300:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Decide Whether a Status Is Retryable: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: codes, retryable, verdict, done, retry. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: codes = [200, 404, 429, 500, 503, 410] | Core: if 200 <= c < 300: | Evidence: print(f'{c}: {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain decide whether a status is retryable in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 141.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 143 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{c}: {verdict}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `codes = [200, 404, 429, 500, 503, 410]` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of decide whether a status is retryable and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Success codes finish, a fixed set of transient codes (rate-limit and 5xx) are retried, and everything else is treated as a permanent failure.

```
codes = [200, 404, 429, 500, 503, 410]
retryable = {429, 500, 502, 503, 504}
for c in codes:
    if 200 <= c < 300:
        verdict = 'done'
    elif c in retryable:
        verdict = 'retry later'
    else:
        verdict = 'give up'
    print(f'{c}: {verdict}')
```

```
output
200: done
404: give up
429: retry later
500: retry later
503: retry later
410: give up
```

How it works:

1. codes lists a spread of statuses from 200 through 503 and 410.
2. retryable is a set of transient codes including 429 and several 5xx.
3. The loop assigns done for any 2xx, retry later for a retryable code, and give up otherwise.
4. An f-string prints each code beside its verdict.

Try it:

1. Add a backoff delay that grows with each retry attempt.
2. Cap the number of retries before a retryable code becomes give up.
3. Treat a 403 differently from a 404 in the give-up branch.
4. Add 501 and decide whether it belongs in the retry set.

⚠ Common Mistakes

- Retrying a 404 wastes budget on a page that will not appear by retrying.
- Treating every 5xx as retryable includes 501 (not implemented), which usually will not change.
- Forgetting 429 (too many requests) means ignoring a server explicitly asking you to slow down.

Skills gained retry policy | set membership | if-elif-else

→ Where You'll Use This: Crawl fetchers consult this kind of policy to avoid hammering permanently broken URLs while still retrying rate-limited or temporarily failing ones, keeping crawl budget focused.

⚡ Mental Model

Like a delivery driver who knocks again at a busy house but crosses off an address that no longer exists.

Project 143 Spot a Redirect That Only Strips Query Params

💡 The Idea Behind It

A common redirect drops tracking parameters, sending /page?ref=x to /page. This code compares each redirect's source path, stripped of its query, against the destination. When they match, it is a query-strip that canonicalises rather than moves the page; when they differ, it is a genuine page-move. The output labels each redirect, confirming whether it merely cleans parameters or relocates content.

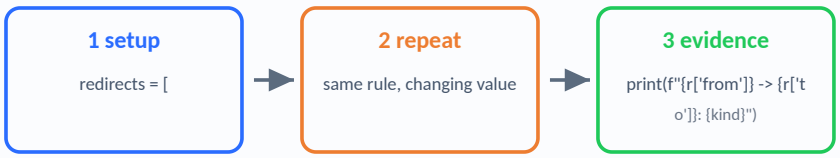
What You'll Build & Learn

Tell a query-stripping canonicalisation redirect apart from a real page-move by comparing paths.

- Query-strip redirects canonicalise URLs
- Splitting off the query string
- Path equality distinguishes the kinds

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 142: decide whether a status is retryable. Project 144 changes the surface problem while preserving the underlying method.



progress check

Reading target: spot a redirect that only strips query params is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `redirects = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f"{r['from']} -> {r['to']}: {kind}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`redirects = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`kind = 'query-strip' if same_path else 'page-move'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{r['from']} -> {r['to']}: {kind}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `kind = 'query-strip' if same_path else 'page-move'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions.    from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{r['from']} -> {r['to']}: {kind}")`. Then compare punctuation, spacing, and order.
2. Explain: point to `redirects = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spot a redirect that only strips query params and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

prediction before proof

same idea, new surface

🔍 From Concept to Code (Python)

Comparing the source URL with its query removed against the target reveals whether the redirect merely strips parameters or actually moves to a different page.

```
redirects = [
    {'from': 'https://s/p?ref=ad', 'to': 'https://s/p'},
    {'from': 'https://s/a', 'to': 'https://s/b'},
]
def path_only(u):
    return u.split('?', 1)[0]
for r in redirects:
    same_path = path_only(r['from']) == r['to']
    kind = 'query-strip' if same_path else 'page-move'
    print(f"{r['from']} -> {r['to']}: {kind}")
```

```
output
https://s/p?ref=ad -> https://s/p: query-strip
https://s/a -> https://s/b: page-move
```

How it works:

1. redirects lists one query-stripping redirect and one that moves to a different page.
2. path_only splits a URL on the question mark and keeps the part before it.
3. same_path is True when the source's path equals the destination exactly.
4. The loop labels each redirect query-strip or page-move and prints it.

Try it:

1. Print which query parameters were removed by the strip.
2. Treat a redirect that adds parameters as its own category.
3. Ignore harmless parameters like a session id when comparing paths.
4. Add a redirect that strips only one of two params and decide how to classify it.

⚠ Common Mistakes

- Comparing the full source URL to the target never matches because the query differs.
- Splitting on `?` and keeping the second half inspects the params instead of the path.
- A target that itself has a query would break the equality even for a pure strip.

Skills gained query stripping | path comparison | redirect classification

→ Where You'll Use This: Distinguishing canonicalising redirects from content moves helps an audit understand intent; a query-strip is healthy housekeeping, while a page-move needs equity-transfer scrutiny.

Mental Model

Like spotting whether a form simply erased a scribbled note in the margin or rewrote the whole address.

Project 144 Validate That Canonicals Point at Live Pages

The Idea Behind It

A canonical tag is wasted if it points at a URL that redirects or 404s. This code holds a status map and a dictionary of page-to-canonical targets, then checks each target's status with get, defaulting to 0 when absent. Only a 200 target counts as OK; a 301 target and a 404 target both read BAD canonical. Verifying targets confirms the consolidation actually works.

What You'll Build & Learn

Validate that every canonical tag points at a live 200 page rather than a redirect or error.

- Canonicals must target live 200 pages
- A redirecting canonical is wasted
- Default status on a missing target

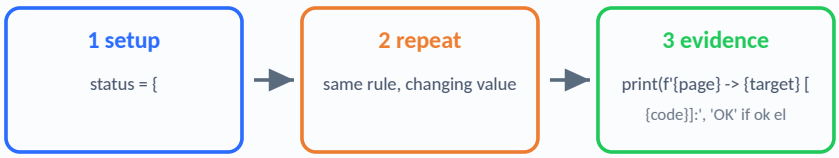
Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 143: spot a redirect that only strips query params. Project 145 changes the surface problem while preserving the underlying method.

progress check

Reading target: validate that canonicals point at live pages is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `status = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`status = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Validate That Canonicals Point at Live Pages: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: status, https, canonicals, page, sorted. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: status = { | Core: print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical') | Evidence: print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')

🛠️ Reader to Writer Bridge

1. Read: explain validate that canonicals point at live pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 143.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 145 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `status = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of validate that canonicals point at live pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A canonical is valid only when its target returns 200; pointing at a 301 or 404 means the declared canonical URL is not the live, indexable page.

```
status = {
    'https://a/': 200, 'https://b/': 301,
    'https://c/': 200, 'https://d/': 404,
}
canonicals = {
    'https://a/': 'https://a/',
    'https://c/': 'https://b/',
    'https://x/': 'https://d/',
}
for page in sorted(canonicals):
    target = canonicals[page]
    code = status.get(target, 0)
    ok = code == 200
    print(f'{page} -> {target} [{code}]:', 'OK' if ok else 'BAD canonical')
```

```
output
https://a/ -> https://a/ [200]: OK
https://c/ -> https://b/ [301]: BAD canonical
https://x/ -> https://d/ [404]: BAD canonical
```

How it works:

1. status maps four URLs to codes including a 301 and a 404.
2. canonicals maps each page to the URL its canonical tag declares.
3. The loop looks up each target's status, defaulting to 0 when it is missing.
4. It prints OK only when the target is 200, otherwise BAD canonical.

Try it:

1. Treat a target outside the status map as an explicit unknown.
2. Also flag a canonical that points at another canonical chain.
3. Report how many canonicals across the set are healthy versus broken.
4. Make `https://b/` return 200 and watch that canonical pass.

⚠ Common Mistakes

- Checking the page's own status instead of the canonical target's misses a bad target.
- Treating a canonical that points at a 301 as fine sends engines on an extra hop.
- Using `status[target]` raises KeyError when the target was never crawled.

Skills gained canonical validation | status lookup | default value

→ Where You'll Use This: SEO audits verify canonical targets resolve to 200; a canonical aimed at a redirect or 404 silently fails to consolidate, so this check confirms each tag does its job.

⚡ Mental Model

Like checking that every Master copy label on a file points to a folder that actually exists and is not just another redirect.

Project 145 Group Crawled URLs by Status Class

💡 The Idea Behind It

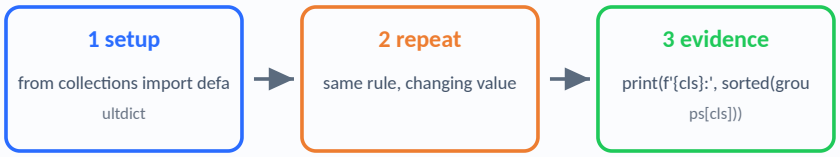
An audit report lists offending URLs under each status class, not just counts. This code uses a defaultdict of lists, appending each crawled URL to the bucket named by its family label. Iterating the sorted classes prints each family followed by its sorted URLs, producing the body of the report rather than the headline numbers project 140 supplies.

What You'll Build & Learn

Group crawled URLs under their 2xx, 3xx, 4xx, and 5xx family classes to form a report body.

- Reports list URLs, not just counts
- defaultdict avoids missing-key checks
- Family label keys the groups

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 144: validate that canonicals point at live pages. Project 146 changes the surface problem while preserving the underlying method. *progress check*

Reading target: group crawled urls by status class is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{cls}:', sorted(groups[cls]))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`for url, code in crawl:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{cls}:', sorted(groups[cls]))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for url, code in crawl:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Group Crawled URLs by Status Class: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: collections, defaultdict, crawl, https, groups. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: for url, code in crawl: | Evidence: print(f'{cls}:', sorted(groups[cls]))

🛠️ Reader to Writer Bridge

1. Read: explain group crawled urls by status class in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 144.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 146 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{cls}:', sorted(groups[cls]))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of group crawled urls by status class and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A `defaultdict(list)` keyed by the `Nxx` class collects URLs into buckets in one pass; sorting both the classes and each bucket keeps the report stable.

```
from collections import defaultdict
crawl = [
    ('https://a/', 200), ('https://b/', 301),
    ('https://c/', 404), ('https://d/', 500),
    ('https://e/', 200), ('https://f/', 404),
]
groups = defaultdict(list)
for url, code in crawl:
    groups[f'{code // 100}xx'].append(url)
for cls in sorted(groups):
    print(f'{cls}:', sorted(groups[cls]))
```

```
output
2xx: ['https://a/', 'https://e/']
3xx: ['https://b/']
4xx: ['https://c/', 'https://f/']
5xx: ['https://d/']
```

How it works:

1. crawl is a list of URL and code tuples spanning all four families.
2. groups is a defaultdict of lists keyed by family label.
3. The loop appends each URL to the bucket named by its status family.
4. It then prints each sorted family label followed by its sorted URLs.

Try it:

1. Sort each family's URLs by some priority instead of alphabetically.
2. Print only the families that contain error URLs.
3. Add the per-family count from project 140 above each list.
4. Print only the 4xx and 5xx buckets (the problems).

⚠ Common Mistakes

- Appending to a plain dict without a default raises KeyError on the first URL of a class.
- Forgetting to sort each bucket's URLs makes the listing order vary.
- Grouping by exact code instead of class produces too many tiny buckets for a summary.

Skills gained `URL grouping` `collections.defaultdict` `family labels`

→ **Where You'll Use This:** The grouped listing forms the detailed body of a crawl report, letting an SEO click into the actual 404 and 5xx URLs behind each family count to plan fixes.

Mental Model

Like filing every complaint into a labelled folder so you can open the Errors drawer and read each case, not just its tally.

Project 146 Diff Two Crawls for Status Regressions

The Idea Behind It

Comparing a fresh crawl against the last one surfaces pages that newly broke. This code holds before and after status maps and walks the before URLs: a page that was 200 and is no longer a 2xx is reported as REGRESSED, while any other change prints as a plain change. The status regression is the alert an audit fires on, distinguishing breakage from harmless shifts.

What You'll Build & Learn

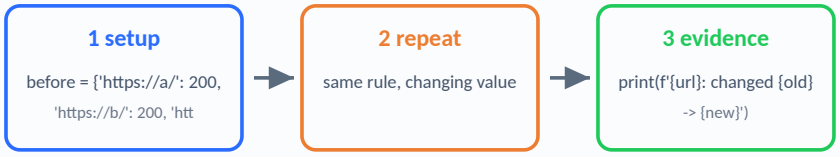
Diff two crawls to surface status regressions where a page that was 200 now returns an error.

- Diffing crawls catches new breakage
- A regression is 200 turned error
- Distinguishing regressions from changes

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 145: group crawled urls by status class. Project 147 changes the surface problem while preserving the underlying method.

progress check



Reading target: diff two crawls for status regressions is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `before = {'https://a/': 200, 'https://b/': 200, 'https://c/': 301}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

- Evidence: `print(f'{url}: changed {old} -> {new}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`before = {'https://a/': 200, 'https://b/': 200, 'https://c/': 301}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if old == 200 and not (200 <= new < 300):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{url}: changed {old} -> {new}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if old == 200 and not (200 <= new < 300):`

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Diff Two Crawls for Status Regressions: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: before, https, after, url, sorted. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: before = {'https://a/': 200, 'https://b/': 200, 'https://c/': 301} | Core: if old == 200 and not (200 <= new < 300): | Evidence: print(f'{url}: changed {old} -> {new}')

🛠️ Reader to Writer Bridge

1. Read: explain diff two crawls for status regressions in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 145.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 147 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{url}: changed {old} -> {new}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `before = {'https://a/': 200, 'https://b/': 200, 'https://c/': 301}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of diff two crawls for status regressions and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

For each URL the prior and current statuses are compared; a page that was 200 and is no longer a success is reported as a regression, other changes are noted.

```
before = {'https://a/': 200, 'https://b/': 200, 'https://c/': 301}
after = {'https://a/': 200, 'https://b/': 404, 'https://c/': 200}
for url in sorted(before):
    old, new = before[url], after.get(url, 0)
    if old == 200 and not (200 <= new < 300):
        print(f'{url}: REGRESSED {old} -> {new}')
    elif old != new:
        print(f'{url}: changed {old} -> {new}')
```

```
output
https://b/: REGRESSED 200 -> 404
https://c/: changed 301 -> 200
```

How it works:

1. before and after are status maps for the same three URLs.
2. The loop reads old from before and new from after, defaulting to 0 if absent.
3. When old was 200 and new is no longer a 2xx it prints REGRESSED.
4. Any other differing pair prints as a plain change.

Try it:

1. Also report URLs present in after but missing from before.
2. Flag a recovery where an error in before is now 200.
3. Group regressions by their new status class in the output.
4. Report URLs that recovered (error before, 200 now).

⚠ Common Mistakes

- Comparing only exact codes flags a harmless 200-to-200 as unchanged but misses class-level regressions.
- Using `after[url]` raises KeyError for a URL dropped from the new crawl.
- Treating a 200-to-301 as a regression may be wrong if the redirect is intentional.

Skills gained crawl diff | regression detection | default lookup

→ Where You'll Use This: Scheduled crawls diff against the prior run so an SEO is alerted the moment a working page breaks, separating genuine regressions from benign status changes like a redirect resolving.

Mental Model

Like comparing today's inventory against yesterday's to spot which shelves emptied overnight.

Project 147 Resolve a Chain but Stop at a Hop Limit

The Idea Behind It

Browsers and crawlers cap redirect depth and abort overly long chains. This walker follows the 301 and 302 hops but stops once a configurable limit is reached, even if more redirects remain. With a limit of two on a three-hop chain, the loop halts at the third URL still redirecting, so the code reports it ABORTED. Modelling a hard hop limit mirrors that real give-up behaviour.

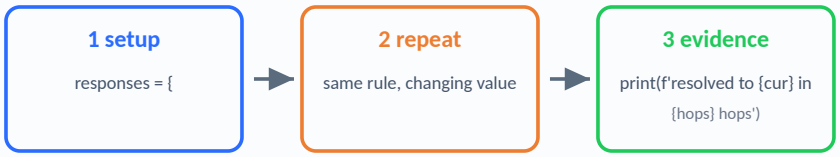
What You'll Build & Learn

Resolve a redirect chain but abort once a configured hop limit is reached, like a real client.

- Clients cap redirect depth
- Combining status and hop guards
- Reporting an abort versus a resolution

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 146: diff two crawls for status regressions. Project 148 changes the surface problem while preserving the underlying method.



progress check

Reading target: resolve a chain but stop at a hop limit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'resolved to {cur} in {hops} hops')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if responses[cur]['status'] in (301, 302):`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'resolved to {cur} in {hops} hops')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Evidence	Entry: responses = { | Core: if responses[cur]['status'] in (301, 302): | Evidence: print(f'resolved to {cur} in {hops} hops')

🛠️ Reader to Writer Bridge

1. Read: explain resolve a chain but stop at a hop limit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 146.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 148 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'resolved to {cur} in {hops} hops')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of resolve a chain but stop at a hop limit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

The walk stops either at a non-redirect page or when the hop limit is hit; checking the final status distinguishes a clean resolution from a forced abort.

```
responses = {
    'https://1/': {'status': 301, 'location': 'https://2/'},
    'https://2/': {'status': 301, 'location': 'https://3/'},
    'https://3/': {'status': 301, 'location': 'https://4/'},
    'https://4/': {'status': 200, 'location': None},
}
```

```
limit, cur, hops = 2, 'https://1/', 0
while responses[cur]['status'] in (301, 302) and hops < limit:
    cur = responses[cur]['location']
    hops += 1
if responses[cur]['status'] in (301, 302):
    print(f'ABORTED after {hops} hops at {cur}')
else:
    print(f'resolved to {cur} in {hops} hops')
```

```
output
ABORTED after 2 hops at https://3/
```

How it works:

1. The responses dictionary defines a three-hop chain ending in 200.
2. limit, cur, and hops are initialised together with limit at 2.
3. The while loop advances only while the status is a redirect and hops is below limit.
4. If the stopping URL is still a redirect it prints ABORTED, otherwise it reports the resolution.

Try it:

1. Make the limit a function argument and try several values.
2. Record the partial chain walked before the abort.
3. Match a specific client's real redirect cap, such as twenty hops.
4. Raise `limit` to 3 and watch the chain resolve.

⚠ Common Mistakes

- Reporting success whenever the loop exits ignores that it may have exited on the hop cap.
- Setting the limit one too low aborts chains that would have resolved on the next hop.
- Counting hops after the limit check lets the walk overshoot by one.

Skills gained hop limit | compound loop guard | abort reporting

→ Where You'll Use This: Crawlers and browsers enforce a maximum redirect depth; modelling it lets an audit predict which chains a search engine will abandon rather than follow to their end.

⚡ Mental Model

Like a courier with a rule that after two forwarding stops they give up and return the parcel undelivered.

Project 148 Trace and Report a Multi-Step Redirect Loop

💡 The Idea Behind It

A loop can span several hops before closing, and reporting the exact looping segment helps an engineer fix it. This walker carries the visited path as a list; when it meets a URL already in the path, it slices from that URL's first appearance to the end and prints the looping segment. A while-else clause prints the destination when no loop is found, so the trace shows precisely where the cycle starts.

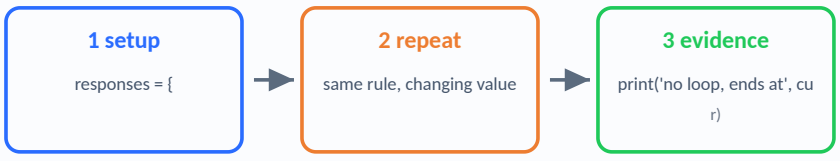
What You'll Build & Learn

Trace a multi-hop redirect loop and print the exact segment of URLs that forms the cycle.

- Loops can span several hops
- A path list locates the cycle start
- while-else runs when no loop occurs

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 147: resolve a chain but stop at a hop limit. Project 149 changes the surface problem while preserving the underlying method.



progress check

Reading target: trace and report a multi-step redirect loop is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('no loop, ends at', cur)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if cur in path:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('no loop, ends at', cur)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if cur in path:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Trace and Report a Multi-Step Redirect Loop: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: responses, https, status, location, cur. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: responses = { | Core: if cur in path: | Evidence: print('no loop, ends at', cur)

🛠️ Reader to Writer Bridge

1. Read: explain trace and report a multi-step redirect loop in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 147.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 149 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('no loop, ends at', cur)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of trace and report a multi-step redirect loop and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Tracking the ordered path of visited URLs lets the code slice out the exact cycle (`b -> c -> b`) the moment a URL recurs, rather than just reporting a loop exists.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 301, 'location': 'https://c/'},
    'https://c/': {'status': 302, 'location': 'https://b/'},
}
cur, path = 'https://a/', []
while responses[cur]['status'] in (301, 302):
    if cur in path:
        seg = path[path.index(cur):] + [cur]
        print('loop:', ' -> '.join(seg))
        break
    path.append(cur)
    cur = responses[cur]['location']
else:
    print('no loop, ends at', cur)
```

```
output
loop: https://b/ -> https://c/ -> https://b/
```

How it works:

1. The responses dictionary chains three redirects whose last hop loops back to the middle URL.
2. cur starts at the first URL and path is an empty list of visited URLs.
3. When cur is already in path, the code slices from its first index to build the looping segment and prints it.
4. The while-else clause prints no loop and the destination if the loop never triggers.

Try it:

1. Also print the prefix of URLs that led into the loop.
2. Add a hop cap as a backstop in case the data has no entry for a URL.
3. Report the length of the looping segment as a number.
4. Break the loop and confirm the else branch prints 'no loop'.

⚠ Common Mistakes

- Using a set instead of an ordered list loses the ability to print the looping segment in order.
- Slicing from the wrong index would include pre-loop URLs in the reported cycle.
- The `while/else` only runs the else branch if the loop ends normally; misplacing it would misreport.

Skills gained loop reporting | path slicing | while-else

→ Where You'll Use This: Reporting the precise cycle segment turns a vague redirect loop alert into an actionable fix, showing an engineer exactly which URLs to break the cycle between.

⚡ Mental Model

Like retracing your steps through a building and marking the exact corridor where the path circles back on itself.

Project 149 Score the Health of a Redirect Audit

💡 The Idea Behind It

Rolling several redirect checks into one score lets you track redirect hygiene over time. This code holds a findings count per defect type and a weights dictionary assigning each defect a severity. It multiplies counts by weights and sums them into a penalty, then subtracts that from a clean baseline of 100, clamped at zero. The output shows the penalty and the resulting health score.

What You'll Build & Learn

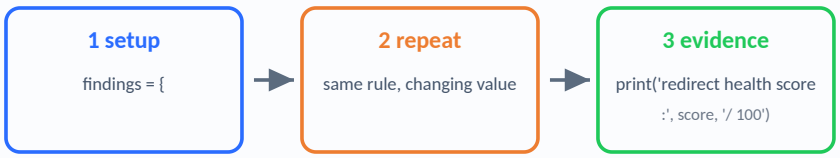
Combine weighted redirect-audit findings into a single health score out of 100.

- Weighted defects roll into one score
- Severity weights rank defect types

- max clamps the score at zero

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 148: trace and report a multi-step redirect loop. Project 150 changes the surface problem while preserving the underlying method.



progress check

Reading target: score the health of a redirect audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `findings = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print('redirect health score:', score, '/ 100')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`findings = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`penalty = sum(findings[k] * weights[k] for k in findings)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print('redirect health score:', score, '/ 100')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `penalty = sum(findings[k] * weights[k] for k in findings)`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score the Health of a Redirect Audit: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: findings, loops, over_limit_chains, ends_in_4xx, temp_should_be_perm. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: findings = { | Core: penalty = sum(findings[k] * weights[k] for k in findings) | Evidence: print('redirect health score:', score, '/ 100')

Reader to Writer Bridge

1. Read: explain score the health of a redirect audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 148.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 150 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('redirect health score:', score, '/ 100')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `findings = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score the health of a redirect audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each defect type is weighted by severity, multiplied by its count, summed into a penalty, and subtracted from 100 with a floor at zero to give a single health score.

```
findings = {
    'loops': 1,
    'over_limit_chains': 2,
    'ends_in_4xx': 1,
    'temp_should_be_perm': 3,
}
weights = {'loops': 10, 'over_limit_chains': 3, 'ends_in_4xx': 5,
'temp_should_be_perm': 2}
penalty = sum(findings[k] * weights[k] for k in findings)
score = max(0, 100 - penalty)
print('penalty:', penalty)
print('redirect health score:', score, '/ 100')
```

```
output
penalty: 27
redirect health score: 73 / 100
```

How it works:

1. findings counts each defect type, like loops and over-limit chains.
2. weights assigns a severity to each defect type.
3. penalty sums findings times weights across the shared keys.
4. score subtracts penalty from 100 and clamps at zero with max, then both are printed.

Try it:

1. Add a new defect type with its own weight and count.

2. Cap each defect's contribution so one category cannot dominate.
3. Convert the score into a letter grade for the report.
4. Set every finding to zero and confirm a perfect 100.

⚠ Common Mistakes

- Letting the score go negative without a `max(0, ...)` floor produces a meaningless number.
- Weighting a minor defect as heavily as a loop hides which problems matter most.
- Summing counts without weights treats every defect as equally severe.

Skills gained health scoring | weighted sum | max clamp

→ Where You'll Use This: A single redirect health score lets teams track hygiene across releases and set a quality gate; weighting defects by severity ensures a loop hurts the score more than an extra hop.

Mental Model

Like a credit score that starts clean and deducts points weighted by how serious each blemish is.

Project 150 Run a Full Status and Redirect Audit

The Idea Behind It

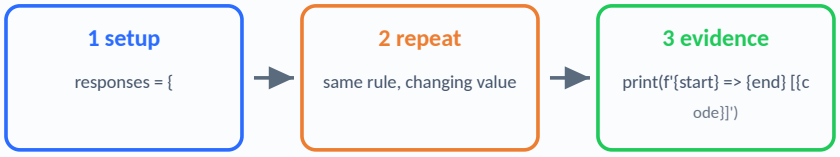
This capstone ties the chapter together over one response map. The resolve function walks each URL's chain with a seen set, returning the looping URL when a cycle is found or otherwise the final URL and status. Looping over the sorted map, the code resolves every URL and prints its destination with a status class or a loop marker. The sample surfaces a clean 200, a 404 dead-end, and a self-loop in a single pass.

What You'll Build & Learn

Run a combined audit that resolves every URL's redirect chain and reports its final status or loop.

- A resolver unifies the chapter's checks
- seen set handles loops inside resolve
- One pass reports status and breakage

Skill Roadmap



Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 149: score the health of a redirect audit. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run a full status and redirect audit is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `responses = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
- Evidence: `print(f'{start} => {end} [{code}]')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`responses = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
2. Apply the rule	`if cur in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{start} => {end} [{code}]')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: HTTP Status Codes and Redirects becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if cur in seen:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Run a Full Status and Redirect Audit: connect the surface task to the chapter skill, classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.
Names	Watch these names first: responses, https, status, location, resolve. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: responses = { | Core: if cur in seen: | Evidence: print(f'{start} => {end} [{code}]')

🛠️ Reader to Writer Bridge

1. Read: explain run a full status and redirect audit in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 149.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{start} => {end} [{code}]')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `responses = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run a full status and redirect audit and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

One resolver walks each URL's redirects with a seen-set guard, returning either the terminal status or a loop marker, and the loop over sorted starts produces the full audit line by line.

```
responses = {
    'https://a/': {'status': 301, 'location': 'https://b/'},
    'https://b/': {'status': 200, 'location': None},
    'https://c/': {'status': 301, 'location': 'https://d/'},
    'https://d/': {'status': 404, 'location': None},
    'https://e/': {'status': 301, 'location': 'https://e/'},
}
def resolve(start):
    cur, seen = start, set()
    while responses[cur]['status'] in (301, 302):
        if cur in seen:
            return cur, 'loop'
        seen.add(cur)
        cur = responses[cur]['location']
    return cur, responses[cur]['status']
for start in sorted(responses):
    end, code = resolve(start)
    print(f'{start} => {end} [{code}]')
```

```
output
https://a/ => https://b/ [200]
https://b/ => https://b/ [200]
https://c/ => https://d/ [404]
https://d/ => https://d/ [404]
https://e/ => https://e/ [loop]
```

How it works:

1. The responses dictionary holds a clean chain, a chain ending in 404, and a self-redirect.
2. resolve walks from a start URL, returning loop if it revisits a URL in seen.
3. Otherwise it returns the final URL and its status code.
4. The loop resolves every sorted URL and prints its destination with the status or loop marker.

Try it:

1. Add a hop limit so an unbounded chain aborts cleanly.
2. Roll the per-URL outcomes into the family summary from project 140.

3. Flag chains that end in 4xx or 5xx separately from clean ones.
4. Add a chain ending in 500 and watch it surface as a server error.

⚠ Common Mistakes

- Resolving without the seen-set guard makes the self-redirect on `https://e/` loop forever.
- Reporting only the start URL's status ignores where the chain actually lands.
- Iterating an unsorted map makes the audit output order nondeterministic.

Skills gained full audit | chain resolution | loop handling

→ Where You'll Use This: This resolver is the skeleton of a real redirect audit; pointed at live crawl data it classifies every URL's outcome at once, the engine behind a status-and-redirect report.

Mental Model

Like a single inspection pass that walks every forwarding trail and stamps each one delivered, dead-end, or stuck in a loop.

✅ Chapter Progress Checkpoint

What this chapter added: after 40 mini-projects, HTTP Status Codes and Redirects should feel like a reusable Python move: classify 2xx/3xx/4xx/5xx, trace redirect chains and loops, and tell 301 from 302 from canonical.

chapter checkpoint

1 Read
Open any project from Projects 111-150 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.

transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 5 (On-Page Signals and the HTML Audit) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

8 questions · 4 categories · graded

2 Recall | 2 Meaning | 2 Structure | 2 Transfer

4.1.Q1 Recall MEDIUM Turn back to Project 118 (Detect a Redirect That Dead-Ends in 404). Without running it, what exactly does it print?

4.1.Q2 Meaning MEDIUM Turn back to Project 143 (Spot a Redirect That Only Strips Query Params). Without running it, what exactly does it print?

4.1.Q3 Structure MEDIUM Turn back to Project 123 (Compute the 5xx Error Rate of a Crawl). Without running it, what exactly does it print?

4.1.Q4 Transfer MEDIUM Turn back to Project 113 (Walk a Redirect Chain to the Final URL). Without running it, what exactly does it print?

4.1.Q5 Recall EASY A server returns the code 503. Which class is it, and what should a crawler do?

- A 2xx success — index it
- B 3xx redirect — follow Location
- C 4xx client error — drop the URL
- D 5xx server error — retry later

4.1.Q6 Meaning MEDIUM You permanently move /old-page to /new-page but the redirect returns a 302. Why is that a problem for SEO?

- A 302 is an error code
- B A 302 is temporary, so engines keep the old URL indexed and do not fully transfer ranking signals to the new URL
- C 302 redirects are slower than 301s
- D Browsers ignore 302 redirects

4.1.Q7 Structure MEDIUM A page returns status 200, but its body reads "Sorry, that page no longer exists." What is this called and why does it hurt?

4.1.Q8 Transfer MEDIUM When should you use a canonical tag instead of a 301 redirect to consolidate two duplicate URLs?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 4 – HTTP Status Codes and Redirects

4.1.Q1. `final URL: https://gone/ status 404` then `BROKEN redirect`

4.1.Q2. `https://s/p?ref=ad -> https://s/p: query-strip` then `https://s/a -> https://s/b: page-move`

4.1.Q3. `3/8 server errors = 37.5%`

4.1.Q4. `https://a/ -> https://b/ -> https://c/` then `final: https://c/ status 200`

4.1.Q5. D 503 (Service Unavailable) is a 5xx server error; it is transient, so a well-behaved crawler retries later rather than dropping the page.

4.1.Q6. B a permanent move needs a 301 (or 308); a 302 tells engines the move is temporary, so link equity stays stranded on the old URL.

4.1.Q7. A soft-404: the 200 code says the page is fine while the body admits it is missing, so engines waste crawl budget indexing an empty page. The fix is to return a real 404 or 410.

4.1.Q8. When users still need the duplicate URL to keep working (e.g. a tracking-parameter variant like?ref=ad). A canonical keeps both URLs live but tells engines which to index; a 301 removes the duplicate entirely.

PART II

Intermediate Skills

With the basics in hand, take on functions, data structures, recursion, algorithms and object-oriented design.

Chapter 5 – On-Page Signals and the HTML Audit · Chapter 6 – Keyword Research and Intent as Data · Chapter 7 – Canonicalization, Duplicate and Thin Content · Chapter 8 – Site Speed and Core Web Vitals · Chapter 9 – Structured Data and Rich Results

Chapter 5 · On-Page Signals and the HTML Audit

Audit titles, meta descriptions, header hierarchy, alt text and intent match from an HTML snippet.

Chapter Skill Map

What this chapter adds: In On-Page Signals and the HTML Audit, the focus is audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet. You practise it across 40 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 5 assumes the reading habits from Chapter 4: HTTP Status Codes and Redirects. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 6, Keyword Research and Intent as Data, reuses this chapter's discipline with a new kind of problem.

1 **Projects 151-163**	2 **Projects 164-176**	3 **Projects 177-190**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

On-page SEO lives in a handful of HTML tags. An audit is just reading those tags and asking, for each, "is this what a search engine wants to see?" *the page tells you, if you parse it*

Once the crawler reaches a page and indexes it, ranking is shaped by *on-page signals* — facts the engine reads directly out of your own HTML. The good news for an auditor: every one of these signals is a tag or attribute you can find with a few lines of code. The `title` is one tag. The `meta description` is one tag. The `H1` is one tag. The `canonical` and `robots` directives are link and meta tags in the `<head>`. There is no guessing — you read the markup and compare it to a rule.

Each signal has a *known healthy range*. A title should be roughly 50-60 characters so the search-results page does not truncate it. A meta description should stay under ~155 characters for the same reason. A page should carry `exactly one` `<h1>` — not zero, not three. Headings should step down one level at a time (h1 → h2 → h3), never skip. Every meaningful image needs `alt` text. The whole craft of an HTML audit is encoding these ranges as checks.

The simplest signal is also the strongest: the `<title>`. Reading it is one regular expression, and its length decides whether it survives in the results snippet. Here is the first audit in the chapter — pull the title out of the head and judge its length against the 50-60 sweet spot:

```
import re
html = '<head><title>Best Running Shoes for Marathon Training in 2026</title>
</head>'
m = re.search(r'<title>(.*?)</title>', html, re.S)
title = m.group(1).strip() if m else ''
```

```
n = len(title)
verdict = 'OK' if 50 <= n <= 60 else ('too short' if n < 50 else 'too long')
print(f'title ({n} chars): {verdict}')
print(title)
```

```
output
title (48 chars): too short
Best Running Shoes for Marathon Training in 2026
```

That tiny program is the shape of the entire chapter: extract the signal, measure it, compare it to a rule, print a verdict. Swap the regex and the rule and you have a description-length check, an H1 counter, an alt-text scanner, or a canonical detector. Stack a dozen of them together and you have a real on-page audit report.

extract → measure → judge

One caution runs through the whole chapter: regex is a quick way to read HTML but a brittle one. It does not decode entities like `&`, and it gets confused by nested tags. For robust extraction the standard library ships `html.parser.HTMLParser`, which we reach for when the markup gets real. Most checks here use regex for clarity, but you should know its limits.

TITLE TAG

The `<title>` in the document head. It supplies the clickable headline in search results and is the single strongest on-page relevance signal. Search engines truncate it around 60 characters.

META DESCRIPTION

A `<meta name="description" content="...">` tag whose text often becomes the snippet under the title in results. Not a direct ranking factor, but it drives click-through; clipped near ~155 characters.

HEADING HIERARCHY

The ordered set of `<h1>`–`<h6>` tags. A well-formed page has exactly one H1 (its main topic) and steps levels down one at a time, forming a readable outline.

ALT TEXT

The `alt` attribute on an `<img>`. It describes the image for screen readers and gives crawlers text to index. A *missing* alt is a fault; an intentionally empty `alt=""` marks a decorative image to be skipped.

CANONICAL LINK

A `<link rel="canonical" href="...">` naming the master URL for a page, so duplicate or parameter variants consolidate their ranking signals onto one address instead of competing.

ROBOTS META

A `<meta name="robots" content="...">` carrying crawl/index directives. `noindex` keeps the page out of the index; `nofollow` tells engines not to pass ranking credit through its links.

Title and description: the SERP snippet, measured

The title and meta description are what a searcher actually *sees* in the results — the headline and the blurb. Both get cut off if they run long, so length is the first thing an audit checks. The title's healthy band is 50-60 characters; the description should stay under ~155. Reading the description is the same one-regex move as the title, just a different tag:

```
import re
html = '<meta name="description" content="Shop our full range of trail and road
running shoes with free returns and expert fitting advice for every runner.">'
m = re.search(r'<meta\s+name="description"\s+content="([^"]*)"', html)
desc = m.group(1) if m else ''
n = len(desc)
verdict = 'OK' if n <= 155 else 'too long'
print(f'description ({n} chars): {verdict}')
```

```
output
description (113 chars): OK
```

Length is a proxy, not the truth — SERPs truncate by *pixel width*, not character count, so a short count of wide words can still be clipped. A rough estimate of ~9.5 pixels per character flags titles likely to be cut, catching the wide-word case a character count misses.

characters are a guess; pixels are the rule

The heading outline: one H1, no skipped levels

Headings are the page's table of contents. Two rules matter. First, a page should carry exactly one `<h1>` naming its main topic — zero leaves the page topic-less, several make competing claims. Counting H1s catches both faults at once:

```
import re
html = '<body><h1>Running Shoes</h1><p>Intro</p><h2>Trail</h2><h1>Sale</h1></body>'
h1s = re.findall(r'<h1[^>]*>(.*?)</h1>', html, re.S)
n = len(h1s)
verdict = 'OK' if n == 1 else ('missing H1' if n == 0 else 'multiple H1')
```

```
print(f'h1 count = {n}: {verdict}')
print('h1 texts:', [t.strip() for t in h1s])
```

```
output
h1 count = 2: multiple H1
h1 texts: ['Running Shoes', 'Sale']
```

Second, levels should step down one at a time. Jumping h2 → h4 *skips* a level, which screen readers and crawlers read as a broken outline. Collect the level numbers in document order and look at each adjacent pair: a jump of more than one is a skip.

```
import re
html = '<h1>Guide</h1><h2>Setup</h2><h4>Details</h4><h2>Usage</h2><h3>Tips</h3>'
levels = [int(t) for t in re.findall(r'<h([1-6])[^>]*>', html)]
issues = []
for prev, cur in zip(levels, levels[1:]):
    if cur > prev + 1:
        issues.append(f'h{prev} -> h{cur}')
print('levels:', levels)
print('skips:', issues if issues else 'none')
```

```
output
levels: [1, 2, 4, 2, 3]
skips: ['h2 -> h4']
```

Render the same headings as an indented tree and the structure becomes visible at a glance — that is just printing each heading with two spaces of indent per level above one. A good audit shows the outline *and* names the faults.

Images: missing alt versus deliberately empty

An `<img>` with no `alt` attribute is invisible to screen readers and gives crawlers no text to index. Scanning every image tag for a missing alt is a core check. But there is a subtlety the audit must respect: a *decorative* image (a spacer, a divider) should carry `alt=""` so assistive tech skips it. So three states exist — `missing` (a fault), `empty/decorative` (fine), and `described` (ideal):

```
import re
html = '<img src="a.jpg" alt="Product photo"><img src="spacer.gif" alt=""><img
src="b.png" alt="   ">'
for tag in re.findall(r'<img\b[^>]*>', html):
    m = re.search(r'\balt\s*=\s*"([^"]*)"', tag)
    src = re.search(r'src\s*=\s*"([^"]*)"', tag).group(1)
    if m is None:
        kind = 'MISSING alt'
    elif m.group(1).strip() == '':
        kind = 'empty alt (decorative)'
    else:
```

```
        kind = 'described'
    print(f'{src}: {kind}')
```

```
output
a.jpg: described
spacer.gif: empty alt (decorative)
b.png: empty alt (decorative)
```

Note that `alt=" "` (only whitespace) collapses to empty after `.strip()` — it counts as decorative, not described. Reusing one alt string across many images is its own miss: helpful to nobody, so an audit also tallies alt values to flag copy-pasted descriptions.

Head directives: canonical and robots

Two tags in the `<head>` quietly decide a page's fate in the index. The `canonical` link names the master URL so duplicate variants do not dilute each other. Confirm it exists and read where it points:

```
import re
html = '<head><link rel="stylesheet" href="/s.css"><link rel="canonical"
href="https://example.com/blog/post"></head>'
m = re.search(r'<link\b[^>]*rel\s*=\s*"canonical"[^>]*>', html)
if m:
    href = re.search(r'href\s*=\s*"([^"]*)"', m.group(0)).group(1)
    print('canonical present:', href)
else:
    print('canonical MISSING')
```

```
output
canonical present: https://example.com/blog/post
```

The `robots` meta is more dangerous when wrong: a stray `noindex` silently removes a page from search entirely, and `nofollow` stops its links passing credit. The directives are comma-separated, so split them and test for the two killers:

```
import re
html = '<meta name="robots" content="index, follow, max-snippet:-1">'
m = re.search(r'<meta\s+name="robots"\s+content="([^"]*)"', html)
directives = [d.strip().lower() for d in m.group(1).split(',')] if m else []
indexable = 'noindex' not in directives
followable = 'nofollow' not in directives
print('directives:', directives)
print('indexable:', indexable, '| followable:', followable)
```

```
output
directives: ['index', 'follow', 'max-snippet:-1']
indexable: True | followable: True
```

Keyword placement and intent match

Whether a keyword appears matters; *where* it appears matters as much. A target term should surface in the title, the H1, and ideally the opening paragraph. Checking all three at once shows whether the page's most-read elements actually mention the topic:

```
import re
html = '<title>Trail Running Shoes Review</title><h1>Best Trail Running Shoes</h1>
<p>Our guide covers grip, cushioning and fit for every runner.</p>'
keyword = 'trail running shoes'
title = (re.search(r'<title>(.*?)</title>', html, re.S) or [None, ''])[1].lower()
h1 = (re.search(r'<h1[^>]*>(.*?)</h1>', html, re.S) or [None, ''])[1].lower()
first_p = (re.search(r'<p[^>]*>(.*?)</p>', html, re.S) or [None, ''])[1].lower()
for name, hay in [('title', title), ('h1', h1), ('first paragraph', first_p)]:
    print(f'{name}: {"yes" if keyword in hay else "no"}')
```

```
output
title: yes
h1: yes
first paragraph: no
```

Placement should also fit *intent*. A title leaks the searcher it targets: "how to" and "guide" signal informational intent, "buy" and "price" signal transactional. If a product page's title reads informational, the content and the target are mismatched. Scoring intent cue words in the title classifies it, and comparing that to the page's intended intent flags the clash. Restraint matters too — a description that repeats "best" five times reads as keyword stuffing to engine and reader alike.

right word, right place, right intent

Example 1

A page has `<title>Buy Cheap Running Shoes Online Now Free Shipping Best Deals 2026 Sale</title>` (76 characters). Its character count is over 60, but is that the only reason it will be clipped? Judge it by pixel width too (~9.5px per character; SERPs cut around 600px).

SOLUTION

1. By character count: 76 chars is already over the 50-60 band, so it is too long.
2. Estimate pixel width: 76 × 9.5 ≈ 722px, well past the ~600px the results page shows.
3. Both measures agree it gets clipped — but the pixel estimate is the one that catches wide-word titles a 60-char rule would pass.

Clipped on both counts: 76 chars and ~722px both exceed their limits. The fix is a shorter, front-loaded title.

pixel width is why even a 58-char title of wide words can truncate

Example 2

Audit this `<head>` against four essentials — non-empty title, a description, a canonical, and a viewport: `<head><title>Pricing Plans</title><meta name="description" content="Compare our plans."></head>`. What is the score?

SOLUTION

1. Title: `Pricing Plans` is present and non-empty → pass.
2. Description: the meta description tag is present with content → pass.
3. Canonical: no `<link rel="canonical">` in the head → MISSING.
4. Viewport: no `<meta name="viewport">` → MISSING. Two of four pass.

Score 2/4 — title and description present, canonical and viewport missing. A real audit rolls many such checks into one scorecard. *one HTML string in, one pass/fail tally out*

Example 3

The page targets transactional intent (it is a product page). Its title is `How to Choose Running Shoes: Buying Guide`. Does the title's intent match the page's target?

SOLUTION

1. Score intent cue words in the lowercased title. Informational cues: "how", "guide" → 2 hits. Transactional cues: "buy", "shop", "price" → none of those exact words appear ("buying" is not "buy") → 0 hits.
2. The strongest signal is informational, so the title *reads* informational.
3. But the page is built to be transactional, so detected (informational) ≠ target (transactional).

NO — intent mismatch. The title signals informational while the page targets transactional, a content-versus-target clash worth fixing. *a product page whose title says "how to" is fighting itself*

⚡ Mental-Math Shortcut

Extract, measure, judge. Every on-page check is the same three beats: pull the signal out of the HTML, measure it (a length, a count, a presence), and compare it to a known-healthy rule. If you can name the tag and the rule, you can write the check — and a stack of those checks *is* the audit. When in doubt about the rule of thumb: title 50-60 chars, description under ~155, exactly one H1, no skipped heading levels, every meaningful image alt-described, canonical and viewport present, no stray noindex.

⚠ Common Mistakes

- Trusting a character count for title length when SERPs truncate by pixel width — a short count of wide words still gets clipped, so estimate pixels too.
- Treating an empty `alt=""` as a fault. A *missing* alt is the problem; an intentionally empty alt correctly marks a decorative image for screen readers to skip.

- Reading HTML with regex when entities or nested tags are in play — `&` stays raw and nested markup confuses the pattern. Reach for `html.parser.HTMLParser` when the markup is real.
- Optimising whether a keyword is present while ignoring where and with what intent. A keyword buried at the end of an informational title on a transactional page is a weak, mismatched signal.

This chapter contains 40 hands-on mini-projects (Projects 151–190). Type each one out, run it, and experiment.

Project 151 Check the Title Tag Length

The Idea Behind It

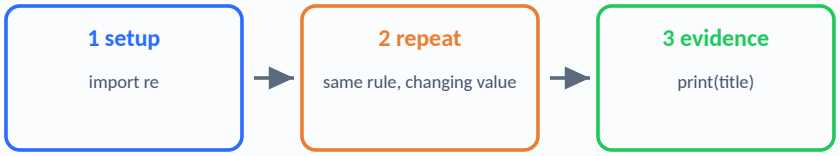
The title tag is the loudest on-page relevance signal you control, and search engines clip it near sixty characters. This project pulls the text between the title tags with a non-greedy regex, strips whitespace, measures its character length, and labels it too short, too long, or inside the fifty-to-sixty sweet spot.

What You'll Build & Learn

Read a page title from raw HTML and judge its length against the range that displays cleanly in a result snippet.

- Why title length matters for snippets
- Non-greedy regex capture with DOTALL
- Three-way verdict from a length comparison

Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 152 changes the surface problem while preserving the underlying method. *progress check*

Reading target: check the title tag length is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(title)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`title = m.group(1).strip() if m else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(title)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `title = m.group(1).strip() if m else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check the Title Tag Length: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, head, title, Best. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: title = m.group(1).strip() if m else '' | Evidence: print(title)

🛠️ Reader to Writer Bridge

1. Read: explain check the title tag length in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 152 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(title)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check the title tag length and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A non-greedy `(.*?)` between `<title>` and `</title>` captures the title text; its length is bucketed against the 50-60 character window that fits before a SERP truncation.

```
import re
html = '<head><title>Best Running Shoes for Marathon Training in 2026</title>
</head>'
m = re.search(r'<title>(.*?)</title>', html, re.S)
title = m.group(1).strip() if m else ''
n = len(title)
verdict = 'OK' if 50 <= n <= 60 else ('too short' if n < 50 else 'too long')
```

```
print(f'title ({n} chars): {verdict}')
print(title)
```

```
output
title (48 chars): too short
Best Running Shoes for Marathon Training in 2026
```

How it works:

1. An HTML string holds a head with one title element containing a marketing-style page name.
2. re.search with the pattern title group and re.S captures whatever sits between the tags, even across line breaks.
3. The match group is stripped, len gives its character count, and a conditional expression maps that count to a verdict string.
4. The script prints the count with its verdict, then the title text itself on a second line.

Try it:

1. Add a verdict for a completely empty title once whitespace is stripped away
2. Loop the same check over a dictionary of several pages and print one line each
3. Warn when the brand name pushes the keyword past character forty
4. Lengthen the title past 60 characters and watch the verdict flip to 'too long'.

⚠ Common Mistakes

- A greedy `(.*)` would run past the first `</title>` into later markup if the page repeated the tag.
- Counting before `.strip()` lets stray whitespace inside the tag inflate the length.
- Treating a missing title (no match) as length 0 silently labels it 'too short' instead of 'absent'.

Skills gained regex extraction | length validation | title audit

→ Where You'll Use This: Every site crawl and SEO dashboard reports title-length warnings; this is the check that flags pages whose titles will read awkwardly or get truncated in the search results page.

Mental Model

The title is the headline on a newspaper stand: too long and the rack cuts it off, too short and it fails to sell the story.

Project 152 Measure the Meta Description Length

The Idea Behind It

A meta description is the snippet copy that argues for the click, and Google rarely renders past roughly one hundred fifty-five characters before trimming it. The code matches the description meta tag with a regex

anchored on the name attribute, captures the content value, counts its characters, and warns only when that count exceeds the cutoff.

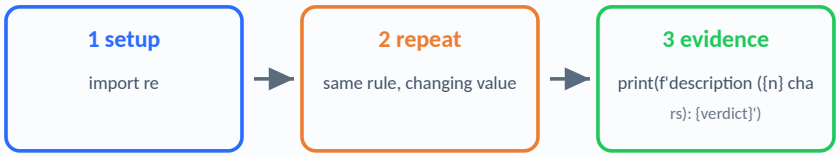
What You'll Build & Learn

Measure a meta description's character length and flag the ones whose closing call to action will be clipped in the snippet.

- The practical meta description length ceiling
- Attribute-anchored regex for a meta tag
- Single-threshold verdict logic

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 151: check the title tag length. Project 153 changes the surface problem while preserving the underlying method.



progress check

Reading target: measure the meta description length is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'description ({n} chars): {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`desc = m.group(1) if m else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'description ({n} chars): {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `desc = m.group(1) if m else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

same idea, new surface

🔍 From Concept to Code (Python)

`[^"]*` captures everything up to the closing quote of the content attribute, and the length is compared against the ~155 character snippet limit.

```
import re
html = '<meta name="description" content="Shop our full range of trail and road running shoes with free returns and expert fitting advice for every runner.">'
m = re.search(r'<meta\s+name="description"\s+content="([^"]*)"', html)
desc = m.group(1) if m else ''
n = len(desc)
verdict = 'OK' if n <= 155 else 'too long'
print(f'description ({n} chars): {verdict}')
```

```
output
description (113 chars): OK
```

How it works:

1. The HTML holds one meta tag whose name is description and whose content is a sentence of shop copy.
2. The regex requires name equals description followed by content, then captures everything inside the content quotes with a negated character class.
3. len measures the captured string and a simple comparison returns OK when at or under one hundred fifty-five, else too long.

4. The print reports the character count alongside the verdict.

Try it:

1. Also warn when the description is shorter than seventy characters and wastes snippet space
2. Handle the case where the description meta tag is entirely absent from the head
3. Switch the attribute order so content precedes name and adjust the pattern
4. Extend the content past 155 characters and watch it flag 'too long'.

⚠ Common Mistakes

- Hard-coding the attribute order (`name` before `content`) misses tags that write `content` first.
- `[^"]*` breaks if the description itself contains an escaped quote entity.
- Treating a missing description as an empty 'OK' hides that the tag is absent entirely.

Skills gained regex matching | meta description | threshold check

→ Where You'll Use This: SEO tools surface truncated descriptions so writers can rewrite snippets that get cut mid-sentence; this length gate is the first thing an audit runs across every indexable page.

⚡ Mental Model

Think of the description as an elevator pitch with a hard time limit: run past the buzzer and the listener only hears half your offer.

Project 153 Count H1 Tags on the Page

💡 The Idea Behind It

A well-formed page carries exactly one H1 naming its main topic, so zero or several is a structural fault. This project uses re.findall to collect the text of every H1 in the markup, counts them, and maps that count to missing, multiple, or OK, then prints the count and the list of captured heading texts.

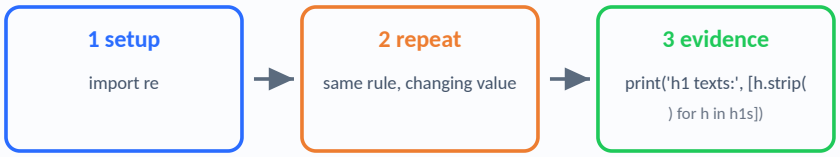
What You'll Build & Learn

Count the H1 elements on a page and report whether there is none, one, or a problematic surplus.

- The single-H1 rule for page topics
- Collecting all matches with re.findall
- Branching on a count of zero, one, or more

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 152: measure the meta description length. Project 154 changes the surface problem while preserving the underlying method.



progress check

Reading target: count h1 tags on the page is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('h1 texts:', [h.strip() for h in h1s])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`verdict = 'OK' if n == 1 else ('missing H1' if n == 0 else 'multiple H1')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('h1 texts:', [h.strip() for h in h1s])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `verdict = 'OK' if n == 1 else ('missing H1' if n == 0 else 'multiple H1')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Count H1 Tags on the Page: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, body, h1, Running. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: verdict = 'OK' if n == 1 else ('missing H1' if n == 0 else 'multiple H1... | Evidence: print('h1 texts:', [h.strip() for h in h1s])

Reader to Writer Bridge

1. Read: explain count h1 tags on the page in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 152.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 154 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('h1 texts:', [h.strip() for h in h1s])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count h1 tags on the page and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`<h1[^>]*>` tolerates attributes on the tag while `(.*?)` grabs the inner text; the count drives a three-way verdict for missing, single, or duplicate headings.

```
import re
html = '<body><h1>Running Shoes</h1><p>Intro</p><h2>Trail</h2><h1>Sale</h1>
</body>'
h1s = re.findall(r'<h1[^>]*>(.*?)</h1>', html, re.S)
n = len(h1s)
verdict = 'OK' if n == 1 else ('missing H1' if n == 0 else 'multiple H1')
print(f'h1 count = {n}: {verdict}')
print('h1 texts:', [h.strip() for h in h1s])
```

```
output
h1 count = 2: multiple H1
h1 texts: ['Running Shoes', 'Sale']
```

How it works:

1. The body markup deliberately contains two H1 elements plus an H2, simulating a common templating mistake.
2. re.findall with a non-greedy capture and re.S returns a list of every H1's inner text.
3. len of that list is the count, and a nested conditional assigns missing, multiple, or OK.
4. The script prints the count with its verdict and then the stripped texts as a Python list.

Try it:

1. Report which H1 text appears first so an editor knows which to keep
2. Extend the check to also count H2 tags on the same page
3. Treat an H1 that is only whitespace as effectively missing
4. Remove the second `<h1>` and confirm the verdict reads 'OK'.

⚠ Common Mistakes

- `<h1[^>]*>` would also match `<h10>`-style invented tags, though those are not valid HTML.
- A multi-line H1 needs the `re.S` flag or the `.*?` stops at the line break.
- Counting opening tags only (without the closing one) over-counts if a stray `<h1>` is unclosed.

Skills gained findall | heading count | structure audit

→ Where You'll Use This: Crawlers routinely flag pages with multiple H1s left over from old templates or page builders; auditors fix these to give each page one unambiguous topic heading.

Mental Model

An H1 is the title page of a book: one is right, none leaves readers lost, and two staple-bound titles confuse everyone.

Project 154 Detect a Skipped Heading Level

The Idea Behind It

An accessible heading outline steps one level at a time, so jumping from H2 straight to H4 leaves a hole that screen readers and crawlers read as broken structure. The code extracts the numeric level of each heading in order, then zips consecutive pairs and records any jump where the next level exceeds the previous by more than one.

What You'll Build & Learn

Walk the heading levels in document order and report every place where a level was skipped.

- Heading levels should increase by one
- Pairwise iteration with zip and a slice
- Capturing only the digit from a heading tag

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 153: count h1 tags on the page. Project 155 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a skipped heading level is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('skips:', issues if issues else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if cur > prev + 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('skips:', issues if issues else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if cur > prev + 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect a Skipped Heading Level: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, h1, Guide, h2. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if cur > prev + 1: | Evidence: print('skips:', issues if issues else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain detect a skipped heading level in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 153.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 155 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('skips:', issues if issues else 'none')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of detect a skipped heading level and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Capturing just the digit in `<h([1-6])>` yields the level sequence, and any adjacent pair where the level jumps by more than one is a skipped-level fault.

```
import re
html = '<h1>Guide</h1><h2>Setup</h2><h4>Details</h4><h2>Usage</h2>
<h3>Tips</h3>'
levels = [int(t) for t in re.findall(r'<h([1-6])[^>]*>', html)]
issues = []
for prev, cur in zip(levels, levels[1:]):
    if cur > prev + 1:
        issues.append(f'h{prev} -> h{cur}')
print('levels:', levels)
print('skips:', issues if issues else 'none')
```

```
output
levels: [1, 2, 4, 2, 3]
skips: ['h2 -> h4']
```

How it works:

1. The HTML has headings at levels one, two, four, two, and three, hiding one skip.
2. re.findall captures just the digit after the h, and a comprehension turns each into an int, giving an ordered levels list.
3. Zipping levels with levels offset by one yields adjacent pairs, and the loop flags any pair where cur exceeds prev plus one.
4. The script prints the levels list and the recorded skips, or none when the outline is clean.

Try it:

1. Also flag when the outline jumps back up more than one level abruptly
2. Record the index position of each skip alongside the level pair
3. Ignore skips inside repeated template sections like a footer if present
4. Insert an `<h3>` before the `<h4>` and watch the skip disappear.

⚠ Common Mistakes

- Only deepening jumps matter; going back up (h4 -> h2) is allowed and must not be flagged.
- `zip(levels, levels[1:])` silently produces nothing for a single-heading page, hiding edge cases.
- Matching `<h[1-6]>` without the digit capture loses the level number you need to compare.

Skills gained zip pairing outline validation regex digits

→ Where You'll Use This: Accessibility and SEO audits check heading order because a jagged outline hurts assistive tech and muddies how engines parse a page's topic hierarchy.

Mental Model

Headings are a staircase: each step should rise one tread, and skipping from the second to the fourth is where someone trips.

Project 155 Build a Heading Outline

The Idea Behind It

The heading hierarchy is effectively a page's table of contents, and rendering it as an indented tree exposes the document's shape at a glance. The code captures each heading's level and inner text together with a backreference, then prints every heading indented by two spaces per level above one, drawing the nesting visually.

What You'll Build & Learn

Turn a page's H1 through H6 tags into a readable indented outline that reveals its structure.

- Visualising structure through indentation
- Backreferences to match opening and closing tags
- Indent width scaled by heading level

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 154: detect a skipped heading level. Project 156 changes the surface problem while preserving the underlying method.

progress check

Reading target: build a heading outline is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print(' ' * (int(lvl) - 1) + text.strip())` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`for lvl, text in heads:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' ' * (int(lvl) - 1) + text.strip())`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for lvl, text in heads:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build a Heading Outline: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, h1, Coffee, Brewing. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: for lvl, text in heads: | Evidence: print(' ' * (int(lvl) - 1) + text.strip())

Reader to Writer Bridge

1. Read: explain build a heading outline in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 154.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 156 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ' * (int(lvl) - 1) + text.strip())`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a heading outline and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

The back-reference `</h\1>` ties each closing tag to its opening level so heading text is captured cleanly; indenting by `level - 1` reconstructs the nesting.

```
import re
html = '<h1>Coffee Brewing</h1><h2>Beans</h2><h3>Roast</h3><h2>Methods</h2>
<h3>Pour Over</h3>'
heads = re.findall(r'<h([1-6])[^>]*>(.*?)</h\1>', html, re.S)
```

```
    for lvl, text in heads:
        print('  ' * (int(lvl) - 1) + text.strip())
```

```
output
Coffee Brewing
  Beans
    Roast
  Methods
    Pour Over
```

How it works:

1. The HTML contains a coffee-themed mix of H1, H2, and H3 headings in a sensible order.
2. re.findall captures the level digit and the inner text, using a backreference so the closing tag matches the opening level.
3. The loop multiplies two spaces by the level minus one to produce indentation, then prints the stripped text.
4. The result reads top to bottom as a nested outline, with deeper headings pushed further right.

Try it:

1. Add the heading level number as a prefix before each indented line
2. Color or mark any heading whose parent level was skipped over
3. Build the same outline from a real page fetched off disk
4. Indent with a '-' bullet prefix instead of spaces for a list-style outline.

⚠ Common Mistakes

- Without the `\1` back-reference, an `<h2>...</h3>` mismatch would still capture and misalign.
- Indenting by `level` instead of `level - 1` pushes the top-level h1 in by one stop.
- Nested inline tags inside a heading would leak into the captured text without extra stripping.

Skills gained backreference regex | indentation | outline rendering

→ Where You'll Use This: Auditors eyeball a rendered outline to spot lopsided nesting, orphaned subsections, or topics buried too deep before recommending a clearer heading structure.

Mental Model

It is the wireframe of a document's skeleton: indentation shows which bones hang off which, so a misshapen spine jumps out.

Project 156 Count Body Words After Stripping Tags

The Idea Behind It

Thin pages with little real text struggle to rank, so counting visible words starts by removing markup. This project replaces every tag with a space using a regex, then extracts runs of letters and apostrophes with findall, and reports the length of that word list as the body word count a reader would actually see.

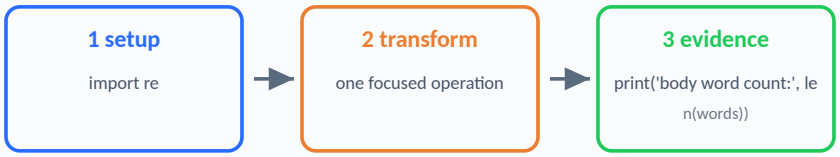
What You'll Build & Learn

Strip all HTML tags from a page and count the words of visible body text that remain.

- Why thin content underperforms in search
- Stripping tags by replacing them with spaces
- Tokenising words with a letter-and-apostrophe pattern

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 155: build a heading outline. Project 157 changes the surface problem while preserving the underlying method.



progress check

Reading target: count body words after stripping tags is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The import tells you the project leans on a tool. Read the imported name as part of the design: the program is choosing a proven operation instead of rebuilding it.
- Writing move: this project practises how to make one intention visible in code. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('body word count:', len(words))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, transform applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`html = '<body><h1>Title</h1><p>The quick brown fox. It jumps over lazy dogs!</p><p>More words here, plenty more.</p></body>'`	This line is the central rule of the tiny program. Slow down here and say what changes from before to after. *slow line*
3. Check the evidence	`print('body word count:', len(words))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
html = '<body><h1>Title</h1><p>The quick brown fox. It jumps over lazy dogs!</p>
<p>More words here, plenty more.</p></body>'
```

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Underline the value being created and circle the operation that makes the final output possible.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Count Body Words After Stripping Tags: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, body, h1, Title. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: import re | Core: html = '<body><h1>Title</h1><p>The quick brown fox. It jumps over lazy... | Evidence: print('body word count:', len(words))

🛠️ Reader to Writer Bridge

1. Read: explain count body words after stripping tags in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 155.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 157 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('body word count:', len(words))`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count body words after stripping tags and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`<[^>]+>` replaces every tag with a space so words never fuse across tag boundaries, then a word regex counts the remaining visible tokens.

```
import re
html = '<body><h1>Title</h1><p>The quick brown fox. It jumps over lazy dogs!
</p><p>More words here, plenty more.</p></body>'
text = re.sub(r'<[^>]+>', ' ', html)
words = re.findall(r"[A-Za-z']+", text)
print('body word count:', len(words))
```

```
output
body word count: 15
```

How it works:

1. The HTML body wraps a heading and two paragraphs of plain sentences.
2. re.sub replaces any run matching a tag pattern with a single space, collapsing markup into separators.

3. re.findall pulls out every token of letters and apostrophes, ignoring punctuation and the former tags.
4. len of that token list is printed as the body word count, which lands at fifteen here.

Try it:

1. Treat hyphenated words as one token rather than splitting them apart
2. Exclude text inside script and style tags before counting
3. Print the words-per-paragraph average alongside the total
4. Replace tags with '' and watch two real words merge into one.

⚠ Common Mistakes

- Replacing tags with '' instead of ' ' glues `</h1><p>` neighbours into one fake word.
- Counting `<script>` or `<style>` contents inflates the total with code, not prose.
- A word pattern of `[A-Za-z]+` alone would split contractions like `don't` into two words.

Skills gained tag stripping | word tokenising | content sizing

→ Where You'll Use This: Word-count thresholds drive thin-content reports; auditors use them to spot pages too light to compete for their target query and flag them for expansion.

⚡ Mental Model

Stripping tags is shaking the packaging off a parcel so you can weigh only the contents the customer actually receives.

Project 157 Confirm the Keyword Appears in Key Spots

💡 The Idea Behind It

A target term ideally appears in the title, the H1, and the opening paragraph, the three spots a reader and an engine weigh most. The code lowercases each of those captured regions using a fallback tuple when no match exists, then loops over the named pairs and prints yes or no for whether the keyword is present in each.

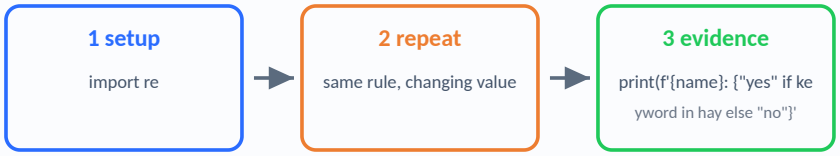
What You'll Build & Learn

Confirm a target keyword shows up in the title, the H1, and the first paragraph of a page.

- Keyword placement across primary elements
- A fallback tuple to avoid None on no match
- Membership testing inside lowercased text

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 156: count body words after stripping tags. Project 158 changes the surface problem while preserving the underlying method.



progress check

Reading target: confirm the keyword appears in key spots is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{name}: {"yes" if keyword in hay else "no"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print(f'{name}: {"yes" if keyword in hay else "no"}')`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print(f'{name}: {"yes" if keyword in hay else "no"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{name}: {"yes" if keyword in hay else "no"}')`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Confirm the Keyword Appears in Key Spots: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, title, Trail, Running. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: print(f'{name}: {"yes" if keyword in hay else "no"}') | Evidence: print(f'{name}: {"yes" if keyword in hay else "no"}')

Reader to Writer Bridge

1. Read: explain confirm the keyword appears in key spots in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 156.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 158 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{name}: {"yes" if keyword in hay else "no"}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of confirm the keyword appears in key spots and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each element is lowercased so the membership test is case-insensitive; the `or [None, '']` fallback keeps the code safe when a tag is missing instead of crashing on `.group`.

```
import re
html = '<title>Trail Running Shoes Review</title><h1>Best Trail Running
Shoes</h1><p>Our guide covers grip, cushioning and fit for every runner.</p>'
keyword = 'trail running shoes'
title = (re.search(r'<title>(.*?)</title>', html, re.S) or [None, '']
)[1].lower()
h1 = (re.search(r'<h1[^>]*>(.*?)</h1>', html, re.S) or [None, '']
)[1].lower()
first_p = (re.search(r'<p[^>]*>(.*?)</p>', html, re.S) or [None, '']
)[1].lower()
for name, hay in [('title', title), ('h1', h1), ('first paragraph', first_p)]:
    print(f'{name}: {"yes" if keyword in hay else "no"}')
```

```
output
title: yes
h1: yes
first paragraph: no
```

How it works:

1. The HTML supplies a title and H1 that mention trail running shoes plus a paragraph that does not.
2. Each region is captured by its own regex, and an or with a two-item fallback list yields an empty string when search returns None.
3. Indexing element one of either the match or the fallback gives the text, which is lowercased for case-insensitive matching.
4. A loop over the named pairs prints yes when the keyword substring is found, no otherwise, exposing the missing first paragraph.

Try it:

1. Add a check for the keyword inside any H2 on the page

2. Match individual keyword words rather than the exact phrase as one
3. Report a single placement score out of the three regions checked
4. Reword the first paragraph to include the keyword and watch its flag flip to 'yes'.

⚠ Common Mistakes

- Comparing without lowercasing makes 'Trail' and 'trail' miss each other.
- A substring test matches the keyword even when it is split across other words, which can over-report.
- Indexing a failed `re.search` with `[1]` only works because of the fallback list; calling `.group(1)` on `None` would crash.

Skills gained substring search | fallback handling | placement check

→ Where You'll Use This: On-page optimisation guides recommend the keyword in title, H1, and intro; this triad check tells a writer at a glance which prime location still needs the target phrase.

⚡ Mental Model

It is a pre-flight checklist of three gauges; you want all three needles in the green before the page takes off.

Project 158 Find Images Missing an Alt Attribute

💡 The Idea Behind It

An image with no alt attribute is silent to screen readers and gives crawlers no text to index. This project finds every img tag with a word-boundary regex, keeps only those whose tag has no alt assignment, and reports how many images exist, how many lack alt, and prints each offending tag.

What You'll Build & Learn

Scan all image tags on a page and list the ones missing an alt attribute entirely.

- Missing alt hurts accessibility and image SEO
- Matching whole img tags with a word boundary
- Filtering a list by absence of a pattern

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 157: confirm the keyword appears in key spots. Project 159 changes the surface problem while preserving the underlying method. *progress check*

Reading target: find images missing an alt attribute is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(' ', t)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`missing = [t for t in imgs if not re.search(r'\balt\s*=', t)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' ', t)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `missing = [t for t in imgs if not re.search(r'\balt\s*=', t)]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Images Missing an Alt Attribute: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, img, src, hero. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: missing = [t for t in imgs if not re.search(r'\balt\s*=', t)] | Evidence: print(' ', t)

🛠️ Reader to Writer Bridge

1. Read: explain find images missing an alt attribute in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 157.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 159 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' ', t)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of find images missing an alt attribute and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`<img\b[^>]*>` captures each image tag, and the `\balt\s*=` test distinguishes a tag with no alt attribute at all from one that merely has an empty alt.

```
import re
html = '<img src="hero.jpg" alt="Runner on a trail"><img src="logo.png"><img
src="chart.svg" alt="">'
imgs = re.findall(r'<img\b[^>]*>', html)
missing = [t for t in imgs if not re.search(r'\balt\s*=', t)]
print('img tags:', len(imgs))
print('missing alt:', len(missing))
for t in missing:
    print(' ', t)
```

```
output
img tags: 3
missing alt: 1
  <img src="logo.png">
```

How it works:

1. The HTML has three images: one with descriptive alt, one with no alt, and one with an empty alt.
2. re.findall with the img word-boundary pattern returns each full image tag as a string.
3. A comprehension keeps tags where a search for alt equals finds nothing, isolating the truly missing ones.
4. The script prints the total tag count, the missing count, and each offending tag indented underneath.

Try it:

1. Pull the src of each offending image so it is easy to locate
2. Count images that have an alt attribute as a separate total
3. Treat a self-closing slash before the bracket the same way
4. Add `alt="Logo"` to the second image and watch the missing count drop to zero.

⚠ Common Mistakes

- An empty `alt=""` is present (and intentional for decorative images), so it must NOT count as missing.
- Without the `\b` word boundary, an attribute like `data-alt` would falsely satisfy the alt check.
- Self-closing `<img .../>` still matches `[^>]*>` here, but a malformed unclosed tag would not.

Skills gained `img matching` `alt audit` `list filtering`

→ **Where You'll Use This:** Missing-alt reports are a staple of accessibility scans and image-SEO checks; fixing them lets engines understand pictures and serves users on screen readers.

⚡ Mental Model

An image without alt is a photo in an album with no caption: the sighted skim past it, but anyone listening hears only silence.

Project 159 Tell Empty Alt From Decorative Intent

💡 The Idea Behind It

Not every image needs description: a spacer or decoration should carry an empty alt so screen readers skip it, while a missing alt is a real fault. The code inspects each img tag, reads its alt and src, and sorts it into described, decorative empty alt, or missing, distinguishing intentional emptiness from oversight.

What You'll Build & Learn

Classify each image as described, intentionally decorative, or missing its alt attribute outright.

- Empty alt is valid for decorative images
- Three-way classification beyond present or absent
- Reading two attributes from one tag

🧭 Skill Roadmap

`Skill step:` adds one small variation while the chapter pattern is still new. It builds on Project 158: find images missing an alt attribute. Project 160 changes the surface problem while preserving the underlying method.

progress check

`Reading target:` tell empty alt from decorative intent is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- `Writing move:` this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print(f'{src}: {kind}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if m is None:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{src}: {kind}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m is None:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Tell Empty Alt From Decorative Intent: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, img, src, jpg. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if m is None: | Evidence: print(f'{src}: {kind}')

🛠️ Reader to Writer Bridge

1. Read: explain tell empty alt from decorative intent in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 158.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 160 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{src}: {kind}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of tell empty alt from decorative intent and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A captured alt value that is `None` means the attribute is absent, while a captured value that strips to nothing is a deliberate decorative marker; only non-blank text counts as described.

```
import re
html = '<img src="a.jpg" alt="Product photo"><img src="spacer.gif" alt=""><img
src="b.png" alt="   ">'
for tag in re.findall(r'<img\b[^>]*>', html):
    m = re.search(r'\balt\s*=\s*"([^"]*)"', tag)
    src = re.search(r'src\s*=\s*"([^"]*)"', tag).group(1)
    if m is None:
        kind = 'MISSING alt'
    elif m.group(1).strip() == '':
        kind = 'empty alt (decorative)'
    else:
        kind = 'described'
    print(f'{src}: {kind}')
```

```
output
a.jpg: described
spacer.gif: empty alt (decorative)
b.png: empty alt (decorative)
```

How it works:

1. The HTML holds a described product photo, a spacer with empty alt, and an image whose alt is only spaces.
2. For each img tag the code searches for an alt value and separately captures the src.
3. When the alt search is None the kind is missing, when its stripped value is empty the kind is decorative, otherwise described.
4. Each image's src and classification are printed, with the whitespace-only alt correctly read as decorative.

Try it:

1. Add a fourth category for alt text that is suspiciously long
2. Flag a decorative image whose filename suggests it is actually meaningful
3. Count how many images fall into each of the three buckets
4. Give `spacer.gif` real alt text and watch it move to 'described'.

⚠ Common Mistakes

- Whitespace-only alt (`alt=" "`) is effectively empty; not stripping it would mislabel it 'described'.
- Distinguishing `None` (no attribute) from `''` (empty attribute) is the whole point; collapsing them loses the decorative signal.
- An alt with only a stray entity like ` ` would be treated as text here even though it renders blank.

Skills gained attribute parsing alt classification intent detection

→ Where You'll Use This: Mature accessibility audits separate genuine omissions from valid decorative markup so teams fix the real problems without flooding reports with intentional empty alts.

Mental Model

It is triage at a clinic: the described patients are fine, the decorative ones are deliberately resting, and only the missing ones need urgent care.

Project 160 Verify a Canonical Link Is Present

The Idea Behind It

A canonical link tells engines which URL is the master copy, heading off duplicate-content dilution. The code searches for a link tag whose rel is canonical, and when found it digs the href value out of that exact tag and prints the canonical URL; otherwise it reports the canonical as missing.

What You'll Build & Learn

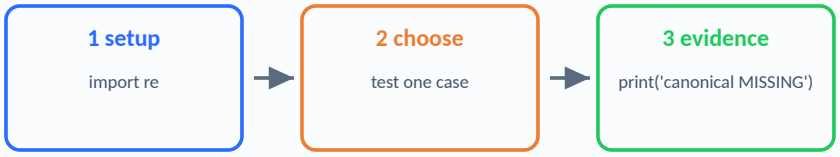
Confirm a page declares a canonical link and read the URL it points to.

- What a canonical tag prevents
- Matching one specific link among several
- Two-stage extraction of tag then attribute

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 159: tell empty alt from decorative intent. Project 161 changes the surface problem while preserving the underlying method.

progress check



Reading target: verify a canonical link is present is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print('canonical MISSING')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if m:`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('canonical MISSING')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m:`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Verify a Canonical Link Is Present: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, head, link, rel. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if m: | Evidence: print('canonical MISSING')

Reader to Writer Bridge

1. Read: explain verify a canonical link is present in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 159.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 161 should feel like a variation, not a brand-new mystery.

from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('canonical MISSING')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of verify a canonical link is present and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

From Concept to Code (Python)

The outer regex isolates the single `<link>` tag whose rel is canonical (ignoring the stylesheet link), then a second pass pulls the href out of just that tag.

```
import re
html = '<head><link rel="stylesheet" href="/s.css"><link rel="canonical"
href="https://example.com/blog/post"></head>'
m = re.search(r'<link\b[^>]*rel\s*=\s*"canonical"[^>]*>', html)
if m:
    href = re.search(r'href\s*=\s*"([^"]*)"', m.group(0)).group(1)
    print('canonical present:', href)
```

```
else:
    print('canonical MISSING')
```

```
output
canonical present: https://example.com/blog/post
```

How it works:

1. The head holds a stylesheet link and a canonical link pointing at a blog post URL.
2. The first regex matches a link tag that contains rel equals canonical, returning the whole tag.
3. A second regex run over that matched tag captures the href value between its quotes.
4. The script prints the canonical URL when present, or a missing message when the first search fails.

Try it:

1. Warn when the canonical URL points to a different domain than expected
2. Detect more than one canonical tag, which is itself an error
3. Compare the canonical against the page's own address for self-reference
4. Remove the canonical link and confirm the 'MISSING' branch runs.

⚠ Common Mistakes

- Searching the whole document for any href would grab the stylesheet's href instead of the canonical's.
- A canonical pointing at a relative path still matches, but search engines prefer an absolute URL.
- Matching `rel="canonical"` exactly misses a tag that lists multiple rel values like `rel="canonical alternate"`.

Skills gained canonical check | nested extraction | link tag regex

→ Where You'll Use This: Duplicate-content audits verify every page declares a sensible canonical; a missing or wrong canonical is a frequent cause of the wrong URL being indexed or ranking.

Mental Model

The canonical is a redirect signpost among identical doors saying this one is the real entrance, so visitors do not split across copies.

Project 161 Parse the Meta Robots Directives

The Idea Behind It

A meta robots tag governs whether a page may be indexed and its links followed. This project captures the robots content value, splits it on commas into lowercased directives, then derives indexable and followable booleans by checking for noindex and nofollow, surfacing whether the page is quietly being suppressed.

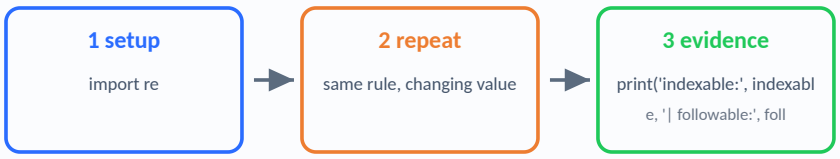
What You'll Build & Learn

Parse a meta robots tag into directives and report whether the page is indexable and followable.

- How meta robots controls indexing
- Splitting a comma list into clean tokens
- Deriving booleans from membership tests

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 160: verify a canonical link is present. Project 162 changes the surface problem while preserving the underlying method.



progress check

Reading target: parse the meta robots directives is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('indexable:', indexable, '| followable:', followable)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit

Move	Code to inspect	Why it matters
		titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`directives = [d.strip().lower() for d in m.group(1).split(',')] if m else []`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('indexable:', indexable, '| followable:', followable)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `directives = [d.strip().lower() for d in m.group(1).split(',')] if m else []`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Parse the Meta Robots Directives: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, meta, name, robots. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: directives = [d.strip().lower() for d in m.group(1).split(',')] if m el... | Evidence: print('indexable:', indexable, '| followable:', followable)

Reader to Writer Bridge

1. Read: explain parse the meta robots directives in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 160.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 162 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('indexable:', indexable, '| followable:', followable)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of parse the meta robots directives and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The content value is split on commas and normalised, then indexability is decided by the absence of `noindex` and `nofollow` rather than the presence of their positive opposites.

```
import re
html = '<meta name="robots" content="index, follow, max-snippet:-1">'
m = re.search(r'<meta\s+name="robots"\s+content="([^"]*)"', html)
directives = [d.strip().lower() for d in m.group(1).split(',')] if m else []
indexable = 'noindex' not in directives
followable = 'nofollow' not in directives
print('directives:', directives)
print('indexable:', indexable, '| followable:', followable)
```

```
output
directives: ['index', 'follow', 'max-snippet:-1']
indexable: True | followable: True
```

How it works:

1. The HTML has a robots meta whose content lists index, follow, and a max-snippet directive.
2. The regex captures the content value, which is split on commas with each piece stripped and lowercased into a directives list.
3. indexable is true when noindex is absent and followable is true when nofollow is absent.
4. The script prints the directive list and the two derived booleans.

Try it:

1. Also surface the max-snippet value as a separate number
2. Default to indexable and followable when the robots tag is absent
3. Recognise the all and none shorthand directives explicitly
4. Change the content to `noindex, nofollow` and watch both flags go False.

⚠ Common Mistakes

- A missing robots tag means default index/follow, so an empty directive list must read as indexable.
- Checking for `index` to decide indexability is wrong; the real rule is the absence of `noindex`.
- Forgetting to strip and lowercase makes ` Noindex` slip past the membership test.

Skills gained directive parsing | string split | boolean logic

→ Where You'll Use This: A stray noindex left in a template can silently de-index whole sections; auditors parse robots directives to catch pages accidentally hidden from search.

⚡ Mental Model

The robots tag is a doorman's note: index and follow waves engines in, while noindex quietly tells them to walk on by.

Project 162 Detect Open Graph and Twitter Card Tags

💡 The Idea Behind It

Open Graph and Twitter Card meta tags decide how a page looks when shared on social platforms. The code collects the set of og properties and the set of twitter card names with two findall calls, prints each sorted set, then checks specifically whether the commonly forgotten og:description property is present.

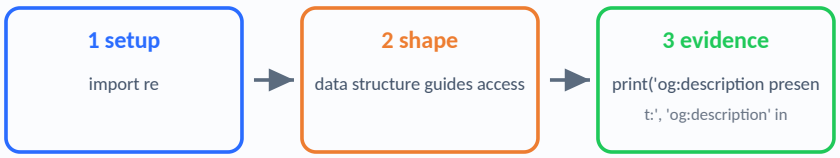
What You'll Build & Learn

List a page's Open Graph and Twitter Card meta tags and point out a commonly missing one.

- Social meta tags shape share previews
- Deduplicating matches with a set
- Checking for one expected key by membership

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 161: parse the meta robots directives. Project 163 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect open graph and twitter card tags is the surface task; the transferable Python move is to mark setup, rule, and output before running. setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The data structure is doing part of the thinking. Ask what the collection stores, how items are found, and what order or uniqueness it promises.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('og:description present:', 'og:description' in og)` exposes the result; match it against the output before changing the program. output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, shape applies the chapter idea, and evidence proves your trace against the output. visual trace

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`'<meta property="og:image" content="https://example.com/a.jpg">'`	This line depends on the chosen data shape. Ask how items are stored, found, or ordered. slow line
3. Check the evidence	`print('og:description present:', 'og:description' in og)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `'<meta property="og:image" content="https://example.com/a.jpg">'`

Construction pattern

The construction begins by importing tools. Read imported names as dependencies that the rest of the file relies on.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Name the collection shape, then ask how an item is added, selected, transformed, or counted.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Detect Open Graph and Twitter Card Tags: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, meta, property, og. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: '<meta property="og:image" content="https://example.com/a.jpg">' | Evidence: print('og:description present:', 'og:description' in og)

🛠️ Reader to Writer Bridge

1. Read: explain detect open graph and twitter card tags in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 161.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 163 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('og:description present:', 'og:description' in og)`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect open graph and twitter card tags and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Open Graph tags live in the `property` attribute while Twitter tags use `name`; collecting each into a set lets the audit check coverage and spot a missing recommended tag.

```
import re
html = ('<meta property="og:title" content="Trail Shoes">'
        '<meta property="og:image" content="https://example.com/a.jpg">'
        '<meta name="twitter:card" content="summary_large_image">')
og = set(re.findall(r'property="(og:[^"]+)"', html))
tw = set(re.findall(r'name="(twitter:[^"]+)"', html))
print('open graph:', sorted(og))
print('twitter card:', sorted(tw))
print('og:description present:', 'og:description' in og)
```

```
output
open graph: ['og:image', 'og:title']
twitter card: ['twitter:card']
og:description present: False
```

How it works:

1. A multi-line string concatenates og:title, og:image, and a twitter:card meta tag.
2. One findall captures every og property name into a set, another captures twitter names into a second set.
3. Both sets are printed sorted so the present tags read in order.
4. A membership test reports og:description as absent, the typical gap in social markup.

Try it:

1. Report which required og tags are missing rather than just one
2. Also capture the content value behind each og:image tag
3. Add detection for the twitter:image and twitter:title tags
4. Add an `og:description` meta and watch the final check flip to True.

⚠ Common Mistakes

- Searching `name=` for Open Graph misses them because OG uses the `property` attribute.
- Printing the raw sets without sorting makes the output order vary between runs.
- A page can have OG tags but no Twitter card, which still shares acceptably via OG fallbacks.

Skills gained set building | social tags | presence check

→ Where You'll Use This: Social-sharing audits verify Open Graph and card tags so links render with a title, image, and description instead of a bare URL across Facebook, LinkedIn, and X.

⚡ Mental Model

Social tags are the trading-card art for your link: leave a slot blank and the card shows up dull where rivals look vivid.

Project 163 Flag Empty or Missing Titles Across Pages

💡 The Idea Behind It

A title that is absent or blank squanders the strongest on-page lever, and the two faults look different in markup. This project loops over a small set of pages, searches each for a title, and distinguishes no title tag at all from a present-but-empty title, printing a clear verdict per path.

What You'll Build & Learn

Audit several pages and separate the ones missing a title tag from the ones whose title is empty.

- Absent versus empty are distinct title faults
- Iterating a dictionary of pages by sorted key
- Branching on None versus a blank capture

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 162: detect open graph and twitter card tags. Project 164 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag empty or missing titles across pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{path}: ok ({m.group(1)!r})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if m is None:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{path}: ok ({m.group(1)!r})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m is None:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Empty or Missing Titles Across Pages: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, pages, head, title, Welcome. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if m is None: | Evidence: print(f'{path}: ok ({m.group(1)!r})')

🛠️ Reader to Writer Bridge

1. Read: explain flag empty or missing titles across pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 162.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 164 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{path}: ok ({m.group(1)!r})')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag empty or missing titles across pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A failed match (`None`) means the tag is absent, while a match whose stripped text is empty means the tag exists but is blank; the two faults need different fixes so the audit keeps them distinct.

```
import re
pages = {
    '/a': '<head><title>Welcome</title></head>',
    '/b': '<head><title></title></head>',
    '/c': '<head><meta charset="utf-8"></head>',
}
for path in sorted(pages):
    m = re.search(r'<title>(.*?)</title>', pages[path], re.S)
    if m is None:
        print(f'{path}: NO title tag')
    elif m.group(1).strip() == '':
        print(f'{path}: EMPTY title')
    else:
        print(f'{path}: ok ({m.group(1)!r})')
```

```
output
/a: ok ('Welcome')
/b: EMPTY title
/c: NO title tag
```

How it works:

1. A pages dictionary maps three paths to markup: a good title, an empty title, and a head with no title.
2. Iterating the sorted keys, each page is searched for a title with re.S so newlines do not break it.
3. When search returns None the path has no title tag; when the stripped capture is empty the title is blank.
4. Otherwise the path prints ok with the title shown via the repr conversion.

Try it:

1. Add a fourth case flagging a title that is only whitespace
2. Collect the offending paths into a list and print a summary count
3. Read the page markup from files in a directory instead of a literal dict
4. Add a page whose title is just spaces and confirm it reads EMPTY.

⚠ Common Mistakes

- Collapsing 'no tag' and 'empty tag' into one bucket hides that the fixes differ.

- Iterating the dict without sorting the keys makes the report order nondeterministic.
- A title of only whitespace passes a truthiness check but is still effectively empty.

Skills gained multi-page audit | None handling | empty detection

→ Where You'll Use This: Site-wide title checks are core to any crawl report; both blank and absent titles leave engines guessing a page's topic, so audits surface each separately for fixing.

⚡ Mental Model

Scanning titles is checking name tags at a conference: some are missing entirely, some are pinned on blank, and both leave you unintroduced.

Project 164 Compute Keyword Density

💡 The Idea Behind It

Keyword density is the share of body words equal to the target term, where a modest level signals focus and a sky-high one reads as stuffing. The code strips tags, lowercases the text, tokenises letter runs, counts occurrences of the keyword, and computes density as a rounded percentage of the total word count.

What You'll Build & Learn

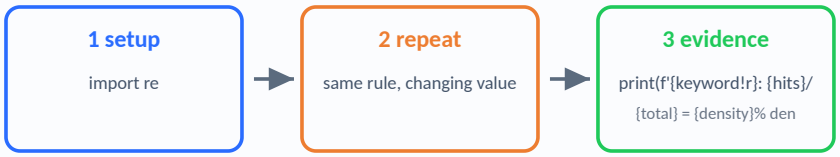
Compute the percentage of body words that equal a target keyword to gauge topical focus.

- Density as keyword hits over total words
- Lowercasing before counting for case fairness
- Rounding a percentage with round

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 163: flag empty or missing titles across pages. Project 165 changes the surface problem while preserving the underlying method.

progress check



Reading target: compute keyword density is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{keyword!r}: {hits}/{total} = {density}% density')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`html = '<h1>Running Shoes</h1><p>These running shoes suit road and trail runners. Shoes built for speed.</p>'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{keyword!r}: {hits}/{total} = {density}% density')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
html = '<h1>Running Shoes</h1><p>These running shoes suit road and trail runners. Shoes built for speed.</p>'
```

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute Keyword Density: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, collections, Counter, html, h1. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: html = '<h1>Running Shoes</h1><p>These running shoes suit road and trai... | Evidence: print(f'{keyword!r}: {hits}/{total} = {density}% density')

🛠️ Reader to Writer Bridge

1. Read: explain compute keyword density in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 163.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 165 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{keyword!r}: {hits}/{total} = {density}% density')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute keyword density and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

After stripping tags and lowercasing, density is simply the keyword's count divided by total word count; rounding keeps the printed float stable and deterministic.

```
import re
from collections import Counter
html = '<h1>Running Shoes</h1><p>These running shoes suit road and trail
runners. Shoes built for speed.</p>'
text = re.sub(r'<[^>]+>', ' ', html).lower()
words = re.findall(r"[a-z]+", text)
total = len(words)
keyword = 'shoes'
hits = words.count(keyword)
density = round(100 * hits / total, 1)
print(f'{keyword!r}: {hits}/{total} = {density}% density')
```

```
output
'shoes': 3/14 = 21.4% density
```

How it works:

1. The HTML mixes a heading and paragraph where the word shoes appears three times.
2. re.sub removes tags and the text is lowercased, then findall pulls every lowercase letter run as a word.
3. total is the word count, hits is the list count of the keyword, and density is one hundred times hits over total, rounded.
4. The script prints the keyword with its hit ratio and the density percentage.

Try it:

1. Count a two-word phrase rather than a single keyword token
2. Flag the density as stuffed once it climbs above a chosen threshold
3. Report the densities of the three most frequent content words
4. Switch the keyword to a two-word phrase and count phrase occurrences instead.

⚠ Common Mistakes

- Including tag names or attribute text in the word list distorts the denominator.
- Counting `shoes` would also catch `shoeshine` with a substring test; `==` on tokens avoids that.

- Dividing without rounding prints a long, noisy float that varies in appearance.

Skills gained density calc | word counting | Counter-free tally

→ Where You'll Use This: Content tools report keyword density so writers avoid both starving a page of its target term and overusing it to the point that engines see manipulation.

Mental Model

Density is seasoning in a dish: a pinch of the keyword brings out the flavour, but dumping the whole jar ruins the meal.

Project 165 Measure the Stop-Word Ratio

The Idea Behind It

When most of a page's words are filler like the and of, there is little substance for a crawler to digest. This project defines a stop-word set, strips tags and tokenises the lowercased text, keeps only the words found in that set, and reports their share of the total as a stop-word ratio that proxies content richness.

What You'll Build & Learn

Calculate the fraction of a page's words that are stop words as a quick richness proxy.

- Stop words carry little topical meaning
- Membership filtering against a set
- Ratio of a subset to the whole

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 164: compute keyword density. Project 166 changes the surface problem while preserving the underlying method. *progress check*

Reading target: measure the stop-word ratio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print(f'stop words: {len(stops)}/{len(words)} = {ratio}%')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`stops = [w for w in words if w in stop]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'stop words: {len(stops)}/{len(words)} = {ratio}%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure the Stop-Word Ratio: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, The, best, of. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: stops = [w for w in words if w in stop] | Evidence: print(f'stop words: {len(stops)}/{len(words)} = {ratio}%')

🛠️ Reader to Writer Bridge

1. Read: explain measure the stop-word ratio in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 164.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 166 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'stop words: {len(stops)}/{len(words)} = {ratio}%')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure the stop-word ratio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering the lowercased word list against a stop-word set and dividing by the total gives the proportion of low-information words on the page.

```
import re
html = '<p>The best of the running shoes are on the shelf and in the store
today.</p>'
stop = {'the', 'of', 'are', 'on', 'and', 'in', 'a', 'to', 'is'}
words = re.findall(r"[a-z]+", re.sub(r'<[^>]+>', ' ', html).lower())
stops = [w for w in words if w in stop]
ratio = round(100 * len(stops) / len(words), 1)
print(f'stop words: {len(stops)}/{len(words)} = {ratio}%')
```

```
output
stop words: 9/15 = 60.0%
```

How it works:

1. The HTML paragraph is deliberately padded with articles and prepositions.
2. A stop set lists common function words, and the text is stripped of tags, lowercased, and tokenised into words.
3. A comprehension keeps only words present in the stop set, building the stops list.
4. The ratio is one hundred times the stop count over the total word count, rounded, and printed with the raw counts.

Try it:

1. Expand the stop set with more common English function words
2. Print the most frequent non-stop word as the apparent topic
3. Invert the metric to report the content-word ratio instead
4. Add 'for' and 'with' to the stop set and watch the ratio rise.

⚠ Common Mistakes

- A short or incomplete stop list undercounts and makes a stuffed page look content-rich.
- Case sensitivity makes a capitalised 'The' at a sentence start slip past the set.
- Dividing by zero crashes on an empty body, so an empty page needs a guard.

Skills gained stop words | set membership | ratio calc

→ Where You'll Use This: A high stop-word ratio hints at fluffy or padded copy; content audits use it as a fast signal to mark pages that say very little of substance.

Mental Model

Stop words are the foam on a poured beer: a little is normal, but a glass that is mostly froth leaves you barely any drink.

Project 166 Estimate Readability by Sentence Length

The Idea Behind It

Long sentences read harder, and readability is itself an on-page quality signal. The code strips tags, splits the text on sentence-ending punctuation while discarding empty fragments, tokenises the words, and divides word count by sentence count to give an average words-per-sentence figure with no external dependency.

What You'll Build & Learn

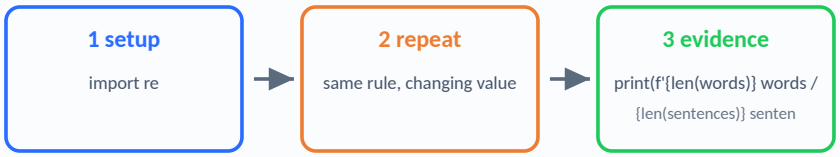
Estimate prose readability by averaging the number of words per sentence on a page.

- Average sentence length as a readability proxy
- Splitting on sentence-ending punctuation
- Discarding empty fragments after a split

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 165: measure the stop-word ratio. Project 167 changes the surface problem while preserving the underlying method.

progress check



Reading target: estimate readability by sentence length is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{len(words)} words / {len(sentences)} sentences = {avg} words/sentence')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`sentences = [s for s in re.split(r'[.!?]+', text) if s.strip()]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{len(words)} words / {len(sentences)} sentences = {avg} words/sentence')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `sentences = [s for s in re.split(r'[.!?]+', text) if s.strip()]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Estimate Readability by Sentence Length: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, Running, is, great. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: sentences = [s for s in re.split(r'[.!?]+', text) if s.strip()] | Evidence: print(f'{len(words)} words / {len(sentences)} sentences = {avg} words/s...

🛠️ Reader to Writer Bridge

1. Read: explain estimate readability by sentence length in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 165.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 167 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{len(words)} words / {len(sentences)} sentences = {avg} words/sentence')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of estimate readability by sentence length and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Splitting on sentence-ending punctuation and discarding empty fragments counts sentences, and dividing the word total by that count yields average sentence length.

```
import re
html = '<p>Running is great. It builds endurance and strength over time! Are
you ready to start today?</p>'
text = re.sub(r'<[^>]+>', ' ', html)
```

```
sentences = [s for s in re.split(r'[.!?]+', text) if s.strip()]
words = re.findall(r"[A-Za-z']+", text)
avg = round(len(words) / len(sentences), 1)
print(f'{len(words)} words / {len(sentences)} sentences = {avg}
words/sentence')
```

```
output
16 words / 3 sentences = 5.3 words/sentence
```

How it works:

1. The HTML paragraph holds three short sentences ended by a period, exclamation, and question mark.
2. re.sub strips tags, then re.split on one or more of period, bang, or question breaks the text into sentence fragments.
3. A comprehension drops fragments that are only whitespace, and findall counts the words across the text.
4. Dividing words by sentences and rounding gives the average, printed as words per sentence.

Try it:

1. Flag the page as hard to read above a chosen average length
2. Count syllables to approximate a fuller readability grade
3. Report the single longest sentence found on the page
4. Add a much longer sentence and watch the average climb.

⚠ Common Mistakes

- Splitting on '.' alone treats 'Inc.' or '3.5' as a sentence break and inflates the count.
- An empty trailing fragment after the final '!' would count as a sentence without the strip filter.
- Abbreviations and ellipses can fool the naive punctuation split in real text.

Skills gained sentence split | readability | averaging

→ Where You'll Use This: Readability scores guide editors toward shorter, scannable sentences; this dependency-free average stands in for heavier formulas when a quick signal is enough.

Mental Model

Sentence length is the gear you climb a hill in: short ones let readers keep pace, while one endless clause stalls them on the slope.

Project 167 Count Internal Versus External Links

The Idea Behind It

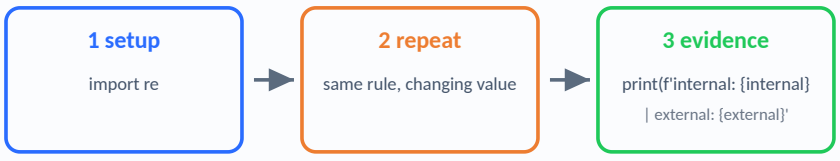
The mix of internal links within your site versus external ones shapes how authority flows. This project walks every href, counts a leading slash as internal, and for absolute URLs extracts the domain and treats it as internal when it equals the host or is a subdomain of it, otherwise external, revealing whether a page hoards or leaks equity.

What You'll Build & Learn

Classify each link on a page as internal or external and tally the two counts.

- Link equity flow between internal and external
- Recognising relative versus absolute URLs
- Subdomain matching with endswith

🧭 Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 166: estimate readability by sentence length. Project 168 changes the surface problem while preserving the underlying method. *progress check*

Reading target: count internal versus external links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'internal: {internal} | external: {external}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if href.startswith('/'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'internal: {internal} | external: {external}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Evidence	Entry: import re | Core: if href.startswith('/'): | Evidence: print(f'internal: {internal} | external: {external}')

🛠️ Reader to Writer Bridge

1. Read: explain count internal versus external links in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 166.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 168 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'internal: {internal} | external: {external}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count internal versus external links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A leading-slash href is internal by definition, and an absolute URL is internal when its host equals the site domain or is a subdomain of it (the `.` + host suffix test).

```
import re
host = 'example.com'
html = ('<a href="https://example.com/about">About</a>'
        '<a href="/blog">Blog</a>'
        '<a href="https://other.com/ref">Partner</a>'
        '<a href="https://shop.example.com/cart">Cart</a>')
internal = external = 0
for href in re.findall(r'href\s*=\s*"([^"]*)"', html):
    if href.startswith('/'):
        internal += 1
    else:
        dom = href.split('://', 1)[1].split('/', 1)[0]
        if dom == host or dom.endswith('.' + host):
            internal += 1
        else:
            external += 1
print(f'internal: {internal} | external: {external}')
```

```
output
internal: 3 | external: 1
```

How it works:

1. The HTML lists four anchors: an absolute same-domain link, a relative link, an external link, and a subdomain link.
2. Each href is examined; one starting with a slash is internal immediately.
3. For absolute URLs the domain is sliced out after the scheme and before the next slash, then compared to the host.
4. A domain equal to the host or ending in a dot plus the host counts as internal, else external, and both totals are printed.

Try it:

1. Print the actual external domains that the page links out to
2. Handle protocol-relative URLs that begin with two slashes
3. Separately count links that point back to the page itself
4. Add a `mailto:` link and decide which bucket (or neither) it belongs in.

⚠ Common Mistakes

- Treating a subdomain like `shop.example.com` as external miscounts your own pages.
- A naive `host in href` test wrongly counts `notexample.com` as internal.
- Protocol-relative or mailto links would need their own branch before the split.

Skills gained link classification | URL parsing | host matching

→ Where You'll Use This: Internal-linking audits use this split to ensure pages distribute authority through the site rather than bleeding it all to outside domains or hoarding it.

⚡ Mental Model

Internal links are pipes routing water around your own house; external ones drain it to the neighbours, so you watch the balance.

Project 168 Flag Links With Empty Anchor Text

💡 The Idea Behind It

Anchor text tells engines what a linked page is about, so a link with no readable text wastes that signal, though an image link can rescue it through alt text. The code captures each anchor's href and inner markup, strips tags from the inner to get text, falls back to an image alt, and flags the link when neither yields a label.

What You'll Build & Learn

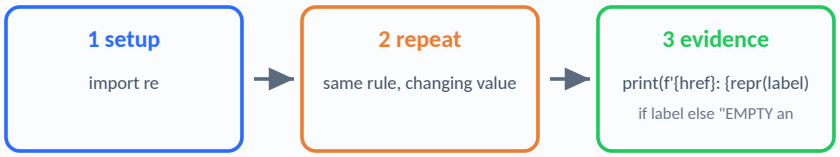
Find links whose anchor text is empty, crediting an image link whose alt supplies a label.

- Anchor text as a relevance signal
- Falling back to image alt for a label
- Stripping inner tags to recover text

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 167: count internal versus external links. Project 169 changes the surface problem while preserving the underlying method.

progress check



Reading target: flag links with empty anchor text is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{href}: {repr(label) if label else "EMPTY anchor text"}')` exposes the result; match it against the output before changing the program.

output proves the trace

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 169 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{href}: {repr(label) if label else "EMPTY anchor text"}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag links with empty anchor text and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Inner tags are stripped to find visible text, and when that is blank the alt text of a contained image is used as a fallback label before declaring the anchor empty.

```
import re
html = ('<a href="/shoes">Trail shoes</a>'
        '<a href="/sale"></a>'
        '<a href="/img"><img src="x.jpg" alt="Boot guide"></a>'
        '<a href="/blank">   </a>')
for m in re.finditer(r'<a\b[^>]*href="([^"]*)"[^>]*>(.*?)</a>', html, re.S):
    href, inner = m.group(1), m.group(2)
    text = re.sub(r'<[^>]+>', '', inner).strip()
    alt = re.search(r'<img\b[^>]*\balt="([^"]*)"', inner)
    label = text or (alt.group(1).strip() if alt else '')
    print(f'{href}: {repr(label) if label else "EMPTY anchor text"}')
```

```
output
/shoes: 'Trail shoes'
/sale: EMPTY anchor text
/img: 'Boot guide'
/blank: EMPTY anchor text
```

How it works:

1. The HTML has four anchors: a text link, an empty one, an image link with alt, and a whitespace-only link.
2. finditer captures each anchor's href and its inner content between the tags.
3. The inner markup is stripped of tags and trimmed to text, and an image alt is searched as a fallback label.
4. label takes the text or the alt, and the script prints the href with its label or an empty-anchor warning.

Try it:

1. Warn on generic anchor text like click here or read more
2. Collect every empty-anchor href into a list for a summary
3. Strip extra inline tags like span inside the anchor text
4. Remove the image's alt and watch `/img` become an empty anchor.

⚠ Common Mistakes

- Treating an image-only link as empty ignores that its alt text is the effective anchor.
- A non-greedy `(.*?)` is essential so the regex stops at the first `</a>`, not the last.
- Whitespace-only inner text must be stripped or `/blank` would look labelled.

Skills gained anchor audit | finditer | alt fallback

→ Where You'll Use This: Link audits flag bald links so editors add descriptive anchor text; correctly crediting image-link alt keeps the report from false-flagging legitimate icon and logo links.

⚡ Mental Model

Anchor text is the label on a hallway door; a blank one leaves engines guessing the room, while the image's alt is a handwritten sticky note.

Project 169 Count Nofollow Versus Followed Links

💡 The Idea Behind It

A nofollow link asks engines not to pass ranking credit, so counting followed against nofollow shows how much equity actually flows onward. This project reads each anchor's rel attribute, splits it into tokens, and increments nofollow when that token appears, otherwise treating the link as a followed, equity-passing link.

What You'll Build & Learn

Count how many links are nofollow versus followed to see how much link equity flows on.

- Nofollow withholds ranking credit
- Splitting a rel value into multiple tokens

- Counting two outcomes in one loop

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 168: flag links with empty anchor text. Project 170 changes the surface problem while preserving the underlying method.

progress check

Reading target: count nofollow versus followed links is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'nofollow: {nofollow} | followed (pass equity): {followed}')` exposes the result; match it against the output before changing the program.

Code Reading Stack

Layer	What to read
Intent	Count Nofollow Versus Followed Links: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, href, rel, nofollow. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: rels = rel.group(1).lower().split() if rel else [] | Evidence: print(f'nofollow: {nofollow} | followed (pass equity): {followed}')

Reader to Writer Bridge

1. Read: explain count nofollow versus followed links in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 168.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 170 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'nofollow: {nofollow} | followed (pass equity): {followed}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count nofollow versus followed links and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The rel attribute can list several space-separated tokens, so splitting it and testing for `nofollow` membership correctly catches `rel="sponsored nofollow"` as well as a bare nofollow.

```
import re
html = ('<a href="/a" rel="nofollow">A</a>'
        '<a href="/b">B</a>'
        '<a href="https://x.com" rel="sponsored nofollow">Ad</a>'
        '<a href="/c">C</a>')
nofollow = followed = 0
for tag in re.findall(r'<a\b[^>]*>', html):
    rel = re.search(r'rel\s*=\s*"([^"]*)"', tag)
    rels = rel.group(1).lower().split() if rel else []
    if 'nofollow' in rels:
        nofollow += 1
    else:
        followed += 1
print(f'nofollow: {nofollow} | followed (pass equity): {followed}')
```

```
output
nofollow: 2 | followed (pass equity): 2
```

How it works:

1. The HTML has four anchors, two carrying a rel of nofollow including a sponsored nofollow combination.

2. Each opening anchor tag is matched, and its rel value is captured then lowercased and split into a token list.
3. When nofollow is among the tokens the nofollow counter rises, otherwise the followed counter does.
4. The script prints both totals, labelling the followed ones as passing equity.

Try it:

1. Also tally sponsored and ugc rel values as separate categories
2. List the destination of each nofollow link for review
3. Treat a missing rel as explicitly followed in the output
4. Add a `rel="ugc"` link and decide whether it counts as followed.

⚠ Common Mistakes

- Comparing the whole rel string to `'nofollow'` misses `'sponsored nofollow'`.
- A link with no rel attribute is followed by default and must land in the followed bucket.
- Case sensitivity would miss `rel="NoFollow"` without the lowercasing.

Skills gained rel parsing | nofollow audit | token split

→ Where You'll Use This: Backlink and outbound-link audits separate followed from nofollow links to estimate how much of a page's authority is actually shared with the destinations it points to.

Mental Model

A nofollow is a sealed envelope of credit marked do not deliver; followed links are the ones that actually post your endorsement onward.

Project 170 Check the Mobile Viewport Tag

The Idea Behind It

Without a responsive viewport meta tag a page renders at desktop width on phones and fails mobile-friendliness. The code captures the viewport content value and reports three states: fully OK when it sets width to device-width, present but not responsive when the tag exists without that, and missing when no viewport tag is found at all.

What You'll Build & Learn

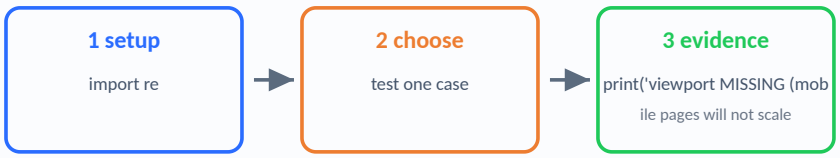
Verify a page has a viewport meta tag that actually sets the width to the device width.

- The viewport tag enables responsive rendering
- Distinguishing present from correctly configured

- A three-branch verdict on one tag

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 169: count nofollow versus followed links. Project 171 changes the surface problem while preserving the underlying method.



progress check

Reading target: check the mobile viewport tag is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('viewport MISSING (mobile pages will not scale)')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if m and 'width=device-width' in m.group(1):`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print('viewport MISSING (mobile pages will not scale)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m and 'width=device-width' in m.group(1):`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Check the Mobile Viewport Tag: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, head, meta, charset. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if m and 'width=device-width' in m.group(1): | Evidence: print('viewport MISSING (mobile pages will not scale)')

Reader to Writer Bridge

1. Read: explain check the mobile viewport tag in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 169.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 171 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('viewport MISSING (mobile pages will not scale)')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check the mobile viewport tag and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Presence of the tag is necessary but not sufficient; the content must include `width=device-width`, so the audit checks both the tag and that specific token.

```
import re
html = '<head><meta charset="utf-8"><meta name="viewport"
content="width=device-width, initial-scale=1"></head>'
m = re.search(r'<meta\s+name="viewport"\s+content="([^"]*)"', html)
if m and 'width=device-width' in m.group(1):
    print('viewport OK:', m.group(1))
elif m:
    print('viewport present but not responsive:', m.group(1))
else:
    print('viewport MISSING (mobile pages will not scale)')
```

```
output
viewport OK: width=device-width, initial-scale=1
```

How it works:

1. The head contains a charset meta and a viewport meta set to width device-width with initial scale one.
2. The regex captures the viewport content value when the tag exists.
3. An if checks that the match exists and that its content contains width equals device-width, printing viewport OK.
4. An elif handles a present but non-responsive tag, and the else reports the tag missing.

Try it:

1. Also warn when initial-scale is set to a value other than one
2. Flag a viewport that disables user zooming as an accessibility issue

3. Default the verdict appropriately when the head has no meta tags
4. Change the content to `width=980` and watch the 'not responsive' branch fire.

⚠ Common Mistakes

- A viewport tag fixed to a pixel width (e.g. `width=980`) is present but not responsive.
- Checking only that the tag exists passes a misconfigured viewport.
- An attribute-order or quoting variation can defeat the rigid regex on real pages.

Skills gained viewport check | mobile audit | branching verdict

→ Where You'll Use This: Mobile-friendliness audits flag pages without a proper viewport because they scale badly on phones, hurting rankings under mobile-first indexing and frustrating most real traffic.

Mental Model

The viewport tag is a pair of reading glasses for the phone; without it the page squints at desktop size and nobody can read the print.

Project 171 Check the HTML Lang Attribute

The Idea Behind It

The lang attribute on the html element tells browsers and engines the page's language, aiding accessibility and international targeting. The code searches the opening html tag for a lang attribute and, when found, prints the declared language code; otherwise it reports lang as missing and notes the cost to accessibility and targeting.

What You'll Build & Learn

Check whether the html element declares a lang attribute and read its value.

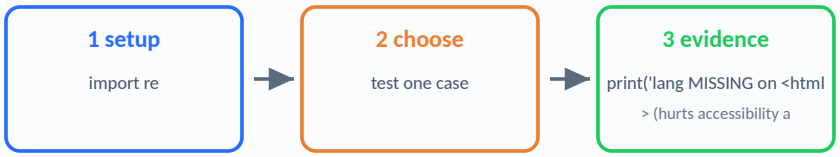
- Lang declares the page language
- Matching an attribute on the html element
- Two-branch present-or-missing report

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 170: check the mobile viewport tag. Project 172 changes the surface problem while preserving the underlying method.

progress check

Reading target: check the html lang attribute is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('lang MISSING on <html> (hurts accessibility and targeting)')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if m:`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('lang MISSING on <html> (hurts accessibility and targeting)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m:`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Check the HTML Lang Attribute: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, lang, en, US. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if m: | Evidence: print('lang MISSING on <html> (hurts accessibility and targeting)')

🛠️ Reader to Writer Bridge

1. Read: explain check the html lang attribute in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 170.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 172 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('lang MISSING on <html> (hurts accessibility and targeting)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of check the html lang attribute and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The regex anchors on the `<html>` opening tag and pulls its `lang` value, so a `lang` on some other element does not produce a false positive.

```
import re
html = '<!DOCTYPE html><html lang="en-US"><head><title>Hi</title></head>
</html>'
m = re.search(r'<html\b[^>]*\blang\s*=\s*"([^"]*)"', html)
if m:
    print('lang declared:', m.group(1))
else:
    print('lang MISSING on <html> (hurts accessibility and targeting)')
```

```
output
lang declared: en-US
```

How it works:

1. The HTML opens with a doctype and an html tag carrying lang equals en-US.
2. The regex anchors on the html tag and captures the lang value with a word boundary so it does not match other attributes.
3. When the search succeeds the declared code is printed.
4. When it fails the script reports the lang as missing along with the impact note.

Try it:

1. Validate that the lang value follows the language-region code format
2. Compare the declared lang against the page's actual text language
3. Detect a lang attribute placed on the body instead of html
4. Remove the lang attribute and confirm the 'MISSING' branch runs.

⚠ Common Mistakes

- Searching the whole document for `lang=` could match a `lang` on a nested element.
- An empty `lang=""` matches the regex but is still effectively undeclared.
- The `\b` before `lang` stops `xml:lang` or `data-lang` from satisfying the check.

Skills gained lang check | attribute regex | presence report

→ Where You'll Use This: Accessibility and international-SEO audits verify the lang attribute so screen readers pick the right voice and engines serve pages to the correct regional audience.

⚡ Mental Model

The lang attribute is the flag on a phrasebook's cover; without it a reader has to guess which language they are even holding.

Project 172 Find Duplicate Titles Across a Page Set

💡 The Idea Behind It

Two pages sharing one title compete with each other and confuse the results page. This project tallies titles across a small set of pages using a Counter, extracting each page's title and incrementing its count, then collects and sorts the titles that appear more than once to reveal which need to be made unique.

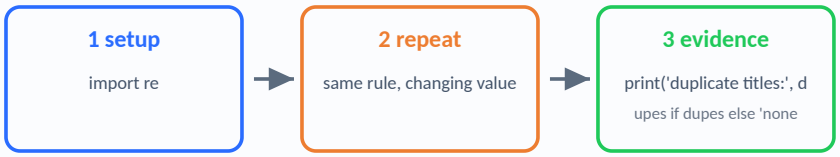
What You'll Build & Learn

Find titles reused across a set of pages so duplicates can be rewritten to be distinct.

- Duplicate titles cause self-competition
- Tallying occurrences with Counter
- Filtering for counts greater than one

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 171: check the html lang attribute. Project 173 changes the surface problem while preserving the underlying method.



progress check

Reading target: find duplicate titles across a page set is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('duplicate titles:', dupes if dupes else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`dupes = sorted(t for t, c in titles.items() if c > 1)`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('duplicate titles:', dupes if dupes else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dupes = sorted(t for t, c in titles.items() if c > 1)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Duplicate Titles Across a Page Set: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, collections, Counter, pages, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: dupes = sorted(t for t, c in titles.items() if c > 1) | Evidence: print('duplicate titles:', dupes if dupes else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain find duplicate titles across a page set in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 171.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 173 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('duplicate titles:', dupes if dupes else 'none')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find duplicate titles across a page set and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A Counter tallies how many pages share each exact title, and any title with a count above one is a duplicate worth flagging; sorting keeps the report stable.

```
import re
from collections import Counter
pages = {
    '/shoes': '<title>Running Shoes</title>',
    '/boots': '<title>Hiking Boots</title>',
```

```
    '/trail': '<title>Running Shoes</title>',
    '/socks': '<title>Wool Socks</title>',
}
titles = Counter()
for body in pages.values():
    t = re.search(r'<title>(.*?)</title>', body).group(1)
    titles[t] += 1
dupes = sorted(t for t, c in titles.items() if c > 1)
print('duplicate titles:', dupes if dupes else 'none')
```

```
output
duplicate titles: ['Running Shoes']
```

How it works:

1. A pages dictionary maps four paths to markup, two of which carry the identical title Running Shoes.
2. A Counter accumulates each extracted title, raising its count each time it recurs.
3. A comprehension keeps titles whose count exceeds one and sorts them into the dupes list.
4. The script prints the duplicate titles, or none when every title is unique.

Try it:

1. Print how many pages share each duplicated title alongside it
2. List the specific paths that carry each repeated title
3. Normalise case and whitespace before comparing titles
4. Lowercase titles before counting so case-only variants are caught.

⚠ Common Mistakes

- Comparing titles case-sensitively treats 'Running Shoes' and 'running shoes' as distinct duplicates.
- Counting tag occurrences rather than per-page titles double-counts a page with two title tags.
- Not sorting the duplicate list makes the printed order vary.

Skills gained Counter tally | duplicate detection | title audit

→ Where You'll Use This: Duplicate-title reports are standard in site crawls; auditors hand editors the list so each page earns a unique title and stops cannibalising its siblings in the rankings.

⚡ Mental Model

Duplicate titles are two shops on one street with the same name: customers and the map both get confused about which to visit.

Project 173 Check Keyword in the First Paragraph

The Idea Behind It

Engines weight the opening words of a page heavily and so do readers deciding whether to stay. The code collects all paragraphs, strips tags from the first to plain lowercased text, and checks whether the keyword appears within its first hundred characters, confirming the target phrase lands early in the intro.

What You'll Build & Learn

Confirm a target keyword appears early in a page's first paragraph.

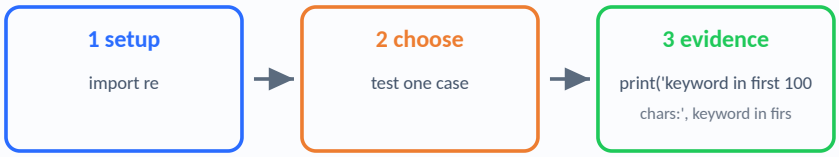
- Early keyword placement carries weight
- Selecting the first paragraph from many
- Slicing to the first hundred characters

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 172: find duplicate titles across a page set. Project 174 changes the surface problem while preserving the underlying method.

progress check

Reading target: check keyword in the first paragraph is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as data -> transformation -> evidence, not as isolated library calls.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('keyword in first 100 chars:', keyword in first[:100])` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`first = re.sub(r'<[^>]+>', '', paras[0]).lower() if paras else ''`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. slow line
3. Check the evidence	`print('keyword in first 100 chars:', keyword in first[:100])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `first = re.sub(r'<[^>]+>', '', paras[0]).lower() if paras else ''`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Check Keyword in the First Paragraph: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, keyword, cold, brew, html. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: first = re.sub(r'<[^>]+>', '', paras[0]).lower() if paras else '' | Evidence: print('keyword in first 100 chars:', keyword in first[:100])

🛠️ Reader to Writer Bridge

1. Read: explain check keyword in the first paragraph in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 172.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 174 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('keyword in first 100 chars:', keyword in first[:100])`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check keyword in the first paragraph and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

The first `<p>` is isolated, stripped of any inner tags, and lowercased before testing whether the keyword appears within its opening characters.

```
import re
keyword = 'cold brew'
html = '<h1>Cold Brew Coffee</h1><p>Making cold brew at home is simple and
cheap.</p><p>Steep coarse grounds.</p>'
paras = re.findall(r'<p[^>]*>(.*?)</p>', html, re.S)
```

```
first = re.sub(r'<[^>]+>', '', paras[0]).lower() if paras else ''
print('first paragraph:', repr(first))
print('keyword in first 100 chars:', keyword in first[:100])
```

```
output
first paragraph: 'making cold brew at home is simple and cheap.'
keyword in first 100 chars: True
```

How it works:

1. The HTML has an H1 and two paragraphs, the first mentioning cold brew right away.
2. findall collects every paragraph's inner content, and the first is stripped of tags and lowercased.
3. An empty-paragraph guard yields an empty string if there are no paragraphs.
4. The script prints the first paragraph and reports whether the keyword sits within its first hundred characters.

Try it:

1. Make the early window configurable rather than fixed at a hundred
2. Match the keyword as separate words rather than an exact phrase
3. Report the character position where the keyword first appears
4. Move the keyword to a later paragraph and watch the early check fail.

⚠ Common Mistakes

- Treating the H1 as the first paragraph mixes the heading signal with the body signal.
- Forgetting to strip inline tags inside the paragraph can hide the keyword behind markup.
- Slicing `[:100]` on a short paragraph is harmless, but on a long one it enforces the 'early' requirement.

Skills gained intro check | string slice | keyword placement

→ Where You'll Use This: On-page optimisation expects the target phrase near the top; this check tells a writer whether the opening sentence actually leads with the topic readers and engines look for first.

Mental Model

The first paragraph is a shop window: the keyword belongs on the front display, not buried on a shelf in the back room.

Project 174 Measure Heading Keyword Coverage

The Idea Behind It

Headings structure a page's topic, so a target keyword should recur across them rather than sitting only in the H1. The code captures every heading's text, tokenises each into a lowercased word set, counts the headings

that intersect the keyword set, and reports coverage as the share of headings mentioning a keyword term.

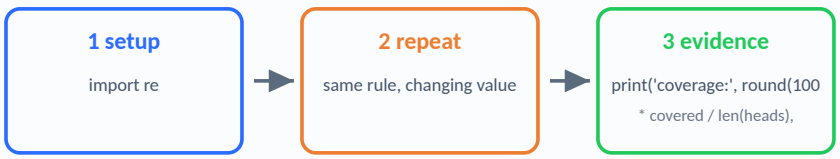
What You'll Build & Learn

Measure what fraction of a page's headings mention any of the target keyword terms.

- Keywords should span multiple headings
- Set intersection to test for any shared term
- Coverage as a percentage of headings

🧭 Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 173: check keyword in the first paragraph. Project 175 changes the surface problem while preserving the underlying method.



progress check

`Reading target:` measure heading keyword coverage is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The code is a small AI-engineering pipeline: prepare a value or dataset, apply a model/math step, then inspect a measurable result. Read it as `data -> transformation -> evidence`, not as isolated library calls.
- `Writing move:` this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- `Evidence:` `print('coverage:', round(100 * covered / len(heads), 1), '%')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: `setup` creates the facts, `repeat` applies the chapter idea, and `evidence` proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if keyword & words:`	This is where raw data becomes evidence: a model, metric, tensor, or pipeline step turns inputs into something measurable. *slow line*
3. Check the evidence	`print('coverage:', round(100 * covered / len(heads), 1), '%')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if keyword & words:`

Construction pattern

The construction is pipeline-shaped: data preparation -> model or transformation -> metric, prediction, or inspection output.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Separate the model step from the data step: one prepares evidence, the other learns, predicts, or scores.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Measure Heading Keyword Coverage: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, keyword, running, shoes, html. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Model pipeline data: features, labels, tensors, prompts, embeddings, predictions, or metrics.
Evidence	Entry: import re | Core: if keyword & words: | Evidence: print('coverage:', round(100 * covered / len(heads), 1), '%')

🛠️ Reader to Writer Bridge

1. Read: explain measure heading keyword coverage in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 173.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 175 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('coverage:', round(100 * covered / len(heads), 1), '%')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of measure heading keyword coverage and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Each heading's word set is intersected with the keyword term set; a non-empty intersection means the heading is on-topic, and the share of such headings is the coverage.

```
import re
keyword = {'running', 'shoes'}
html = '<h1>Running Shoes Guide</h1><h2>Choosing Shoes</h2><h2>Care Tips</h2>
<h3>Cleaning</h3>'
heads = re.findall(r'<h[1-6][^>]*>(.*?)</h[1-6]>', html, re.S)
covered = 0
for h in heads:
    words = set(re.findall(r'[a-z]+', h.lower()))
    if keyword & words:
        covered += 1
print(f'headings: {len(heads)} | mentioning keyword: {covered}')
print('coverage:', round(100 * covered / len(heads), 1), '%')
```

```
output
headings: 4 | mentioning keyword: 2
coverage: 50.0 %
```

How it works:

1. The keyword is a set of two words and the HTML has an H1, two H2s, and an H3.
2. findall captures every heading's inner text across levels one through six.
3. Each heading's words become a lowercased set, and the intersection with the keyword set is truthy when any term matches.
4. covered counts the matching headings, and coverage is one hundred times covered over the heading total, rounded and printed.

Try it:

1. Require every keyword term rather than any single one for a hit
2. Weight the H1 and H2 matches more heavily than deeper headings
3. List which headings missed the keyword entirely
4. Require the full phrase in a heading rather than any single term.

⚠ Common Mistakes

- Mismatched open/close levels (`<h2>...</h3>`) are tolerated by `</h[1-6]>` but can capture wrong text.
- Requiring all keyword terms instead of any makes coverage unrealistically strict.
- Counting a keyword inside a longer word needs token sets, not a raw substring.

Skills gained set intersection | heading coverage | percentage

→ Where You'll Use This: Topic-coverage audits check that headings reinforce the target theme throughout the page, not just at the top, which helps engines read the page as thoroughly on-topic.

Mental Model

Headings are signposts down a trail; if only the first mentions the destination, hikers lose confidence they are still on the right path.

Project 175 Flag Image-Heavy Thin Pages

The Idea Behind It

A page that is mostly images with little surrounding text gives crawlers thin content to index. This project counts the image tags and the visible words after stripping markup, computes a words-per-image ratio guarding against division by zero, and flags the page as thin when that ratio falls below fifty.

What You'll Build & Learn

Flag image-heavy pages with too little text by computing a words-per-image ratio.

- Galleries can be content-thin for crawlers

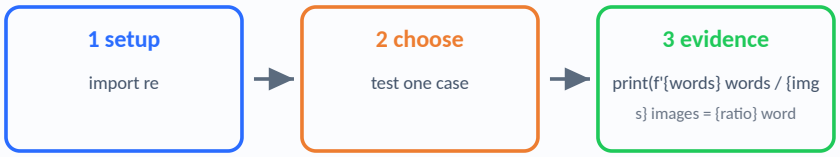
- Guarding a ratio against zero images
- Threshold flag on words per image

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 174: measure heading keyword coverage. Project 176 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag image-heavy thin pages is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{words} words / {imgs} images = {ratio} words per image -> {flag}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output.

visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

Move	Code to inspect	Why it matters
2. Apply the rule	`ratio = round(words / imgs, 1) if imgs else 0`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(f'{words} words / {imgs} images = {ratio} words per image -> {flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `ratio = round(words / imgs, 1) if imgs else 0`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Flag Image-Heavy Thin Pages: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, h1, Gallery, img. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: ratio = round(words / imgs, 1) if imgs else 0 | Evidence: print(f'{words} words / {imgs} images = {ratio} words per image -> {fla...

Reader to Writer Bridge

1. Read: explain flag image-heavy thin pages in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 174.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 176 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{words} words / {imgs} images = {ratio} words per image -> {flag}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag image-heavy thin pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Dividing visible word count by image count yields a words-per-image ratio; a low ratio means the images dominate and the page is light on indexable text.

```
import re
html = '<h1>Gallery</h1><img src="1.jpg" alt="a"><img src="2.jpg" alt="b">
<p>Few words here only.</p>'
imgs = len(re.findall(r'<img\b', html))
words = len(re.findall(r'[A-Za-z]+', re.sub(r'<[^>]+>', ' ', html)))
ratio = round(words / imgs, 1) if imgs else 0
flag = 'thin (image-heavy)' if ratio < 50 else 'OK'
print(f'{words} words / {imgs} images = {ratio} words per image -> {flag}')
```

```
output
5 words / 2 images = 2.5 words per image -> thin (image-heavy)
```

How it works:

1. The HTML is a gallery with a heading, two images, and one short paragraph.
2. findall counts the img tags, and stripping tags then tokenising letters counts the visible words.
3. The ratio is words over images, rounded, falling back to zero when there are no images.
4. A ratio under fifty prints the thin image-heavy flag, and the figures are reported together.

Try it:

1. Make the thinness threshold adjustable per page type
2. Count words inside image alt text toward the total

3. Report the ratio bucketed into thin, borderline, and healthy
4. Add a paragraph of copy and watch the ratio cross the threshold to OK.

⚠ Common Mistakes

- Counting words inside alt attributes would inflate the prose total and mask thinness.
- Dividing by zero on a text-only page needs the `if imgs` guard.
- Background images set via CSS are invisible to an `<img>` count and slip past this check.

Skills gained thin content | ratio guard | image count

→ **Where You'll Use This:** Product galleries and portfolio pages often trip thin-content checks; this ratio tells auditors which image-heavy pages need descriptive copy to rank for their queries.

Mental Model

Words per image is the caption-to-photo balance in a catalogue: all pictures and no copy leaves shoppers and engines without the details.

Project 176 Check Title and Description Uniqueness

The Idea Behind It

Both titles and descriptions should be distinct across a site, so counting unique values per field exposes duplicates dragging pages down. The code defines a helper that extracts either the title or description for a page, gathers all values per field, and compares the unique count to the total to declare all unique or duplicates.

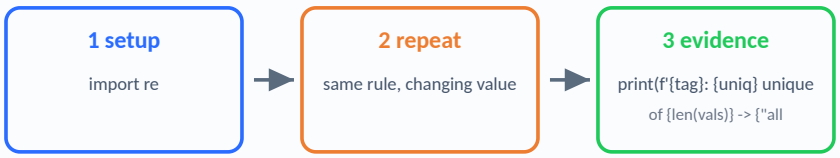
What You'll Build & Learn

Check whether titles and descriptions are unique across a set of pages in one pass.

- Both title and description need uniqueness
- A helper that switches on a field name
- Comparing unique count to total count

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 175: flag image-heavy thin pages. Project 177 changes the surface problem while preserving the underlying method.



progress check

Reading target: check title and description uniqueness is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{tag}: {uniq} unique of {len(vals)} -> {"all unique" if uniq == len(vals) else "DUPLICATES"}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if tag == 'title':`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{tag}: {uniq} unique of {len(vals)} -> {"all unique" if uniq == len(vals) else "DUPLICATES"}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if tag == 'title':`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Check Title and Description Uniqueness: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, pages, title, Trail, Shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: if tag == 'title': | Evidence: print(f'{tag}: {uniq} unique of {len(vals)} -> {"all unique" if uniq ==...

Reader to Writer Bridge

1. Read: explain check title and description uniqueness in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 175.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 177 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{tag}: {uniq} unique of {len(vals)} -> {"all unique" if uniq == len(vals) else "DUPLICATES"}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check title and description uniqueness and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Collecting each field's values into a set and comparing the set size to the page count detects duplication in titles and descriptions with the same generic logic.

```
import re
pages = {
    '/a': '<title>Trail Shoes</title><meta name="description" content="Buy trail shoes.">',
    '/b': '<title>Road Shoes</title><meta name="description" content="Buy trail shoes.">',
    '/c': '<title>Trail Shoes</title><meta name="description" content="Fast road shoes.">',
}
def field(body, tag):
    if tag == 'title':
        return re.search(r'<title>(.*?)</title>', body).group(1)
    return re.search(r'name="description"\s+content="([^"]*)"', body).group(1)
for tag in ('title', 'description'):
    vals = [field(b, tag) for b in pages.values()]
    uniq = len(set(vals))
    print(f'{tag}: {uniq} unique of {len(vals)} -> {"all unique" if uniq == len(vals) else "DUPLICATES"}')
```

```
output
title: 2 unique of 3 -> DUPLICATES
description: 2 unique of 3 -> DUPLICATES
```

How it works:

1. A pages dictionary holds three pages where some titles and descriptions repeat.
2. The field helper returns the title or the description for a page depending on the tag argument.
3. For each field the values are gathered into a list and the unique count comes from wrapping them in a set.
4. When unique count equals the total the field is all unique, otherwise duplicates, printed per field.

Try it:

1. Name the specific duplicated values rather than just declaring duplicates
2. Add the H1 as a third field checked for uniqueness
3. Lowercase and trim values before testing for duplicates
4. Make all three titles distinct and watch that field report 'all unique'.

⚠ Common Mistakes

- A page missing the field would crash `.group`, so real audits need a None-safe extractor.
- Case or trailing-whitespace differences make near-duplicates look unique.
- Counting unique tags instead of per-page values misattributes duplicates on multi-tag pages.

Skills gained uniqueness check | helper function | set count

→ Where You'll Use This: Crawl reports flag duplicate titles and descriptions together; auditors use this dual check to find pages sharing snippet copy that should each be written fresh.

⚡ Mental Model

It is roll call for two attributes at once: every page should answer with its own name for both title and description, not echo a neighbour.

Project 177 Extract a Title With HTMLParser

💡 The Idea Behind It

Regex is brittle around entities and nested markup, so the standard library HTMLParser is the robust way to read element text. This project subclasses HTMLParser to track when it is inside a title and accumulate the data, correctly decoding an ampersand entity that a naive regex would have left raw, then prints the title and its length.

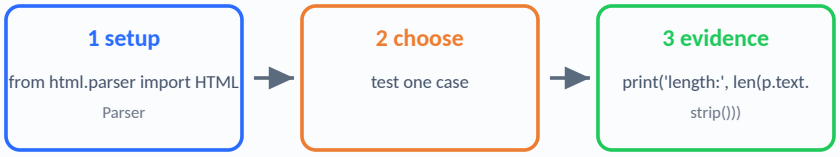
What You'll Build & Learn

Extract title text reliably with HTMLParser, decoding entities a regex would miss.

- HTMLParser is robust where regex is brittle
- Tracking state across start and end tags
- Accumulating text in handle_data

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 176: check title and description uniqueness. Project 178 changes the surface problem while preserving the underlying method.



progress check

Reading target: extract a title with htmlparser is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from html.parser import HTMLParser` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The code is about responsibility: data and behaviour are grouped under a name, so read methods as actions that belong to that object.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('length:', len(p.text.strip()))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from html.parser import HTMLParser`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if tag == 'title':`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('length:', len(p.text.strip()))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if tag == 'title':`

Construction pattern

The construction groups state and behavior under names. Read the class/record/interface header, then ask what each method is responsible for.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Semicolon: Ends many Java/C/JavaScript statements or CSS declarations; missing one can join two ideas accidentally. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

List the fields or attributes first, then read methods as behavior attached to that stored state.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Extract a Title With HTMLParser: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: html, parser, HTMLParser, TitleGrab, __init__. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; classes/records group responsibilities; functions/methods create reusable boundaries; conditions choose a route.
Data shape	Object data: state is bundled with the methods that operate on it.
Evidence	Entry: from html.parser import HTMLParser | Core: if tag == 'title': | Evidence: print('length:', len(p.text.strip()))

🛠️ Reader to Writer Bridge

1. Read: explain extract a title with htmlparser in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 176.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 178 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('length:', len(p.text.strip()))`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `from html.parser import HTMLParser` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of extract a title with htmlparser and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

HTMLParser fires `handle_data` only between the title's start and end tags, and it automatically converts `&` to `&`, giving the true rendered length a regex would miscount.

```
from html.parser import HTMLParser
class TitleGrab(HTMLParser):
    def __init__(self):
        super().__init__()
        self.intitle = False
        self.text = ''
    def handle_starttag(self, tag, attrs):
        if tag == 'title':
            self.intitle = True
    def handle_endtag(self, tag):
        if tag == 'title':
            self.intitle = False
    def handle_data(self, data):
        if self.intitle:
            self.text += data
p = TitleGrab()
p.feed('<head><title>Espresso &amp; Cold Brew Basics</title></head>')
print('title:', p.text.strip())
print('length:', len(p.text.strip()))
```

```
output
title: Espresso & Cold Brew Basics
length: 27
```

How it works:

1. A TitleGrab class subclasses HTMLParser with an intitle flag and a text accumulator.
2. handle_starttag sets intitle true on a title tag and handle_endtag clears it.
3. handle_data appends incoming text only while intitle is true, building up the title content.
4. Feeding markup with an encoded ampersand yields the decoded title, and the script prints it and its stripped length.

Try it:

1. Extend the parser to also capture the meta description content
2. Handle multiple title tags by recording only the first
3. Add handling for numeric character references beyond named entities

4. Add an `©` entity to the title and confirm it decodes to a single character.

⚠ Common Mistakes

- A regex on the raw string would count `&` as five characters, overstating the title length.
- Forgetting to flip `intitle` off in `handle_endtag` would capture text from later tags too.
- Concatenating without resetting `text` between parses would accumulate across multiple feeds.

Skills gained HTMLParser | entity decoding | stateful parsing

→ Where You'll Use This: Production audits prefer a real parser over regex for pulling text because entities, attributes with brackets, and nested tags break naive patterns on messy real-world HTML.

Mental Model

Regex reads HTML by squinting at the shapes; HTMLParser actually understands the grammar, so it never mistakes an encoded ampersand for literal text.

Project 178 Estimate Title Pixel Width

The Idea Behind It

Result pages truncate titles by pixel width rather than character count, so a short count of wide words can still be cut. This project counts the title's words, estimates its rendered width by multiplying character length by a per-character pixel figure, and warns when the estimate crosses six hundred pixels as likely to be clipped.

What You'll Build & Learn

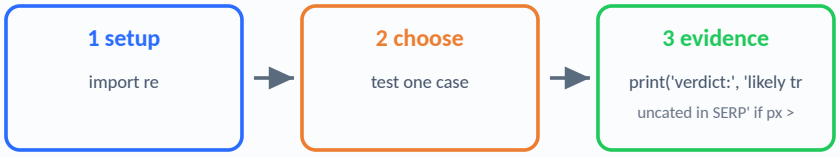
Estimate a title's pixel width to flag whether it will be truncated in the results page.

- Truncation is by pixels not characters
- A rough pixels-per-character estimate
- Threshold verdict on estimated width

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 177: extract a title with htmlparser. Project 179 changes the surface problem while preserving the underlying method.

progress check



Reading target: estimate title pixel width is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Estimate Title Pixel Width: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, title, Buy, Cheap. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits') | Evidence: print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')

🛠️ Reader to Writer Bridge

1. Read: explain estimate title pixel width in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 177.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 179 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of estimate title pixel width and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Multiplying character count by an average glyph width approximates rendered pixels; comparing against the ~600px SERP budget catches titles that fit by character count but overflow visually.

```
import re
html = '<title>Buy Cheap Running Shoes Online Now Free Shipping Best Deals 2026 Sale</title>'
title = re.search(r'<title>(.*?)</title>', html, re.S).group(1)
words = re.findall(r'[A-Za-z0-9]+', title)
px = round(len(title) * 9.5)
print(f'title: {len(words)} words, ~{px}px wide')
print('verdict:', 'likely truncated in SERP' if px > 600 else 'fits')
```

```
output
title: 12 words, ~656px wide
verdict: likely truncated in SERP
```

How it works:

1. The HTML title is a long, keyword-laden marketing string.
2. The title is captured, and findall counts its alphanumeric words.
3. Pixel width is approximated as character length times nine and a half, rounded to a whole number.
4. The script prints the word count and estimated width, then warns of likely truncation when the width exceeds six hundred.

Try it:

1. Weight wide characters like m more than narrow ones like i
2. Make the pixel-per-character and limit values configurable
3. Apply the same pixel estimate to the meta description
4. Shorten the title under 60px-equivalent and watch the verdict flip to 'fits'.

⚠ Common Mistakes

- A flat pixels-per-character figure ignores that 'W' is far wider than 'i'.
- Counting only words misses that long words still consume width.
- The 600px budget is approximate and varies by device and font.

Skills gained `pixel estimate` `truncation check` `width heuristic`

→ **Where You'll Use This:** Snippet-preview tools approximate pixel width so writers know whether a title survives the results page; this heuristic catches wide titles that pass a character-count test yet still get cut.

Mental Model

Counting characters is measuring a suitcase by its number of items; pixel width measures whether the whole thing actually fits through the overhead bin.

Project 179 Find Duplicate Alt Text on Images

The Idea Behind It

Reusing one alt string across many images helps neither accessibility nor image search. The code extracts every alt value, lowercases and trims them, tallies the non-empty ones with a Counter, and surfaces the alt strings used more than once, treating case-only differences as the same copy-pasted description.

What You'll Build & Learn

Find alt text repeated across multiple images so duplicated descriptions get rewritten.

- Duplicate alt text is unhelpful
- Case-insensitive duplicate detection
- Excluding empty alts from the tally

Skill Roadmap

`Skill step:` pushes the same idea into a less automatic situation. It builds on Project 178: estimate title pixel width. Project 180 changes the surface problem while preserving the underlying method. *progress check*

`Reading target:` find duplicate alt text on images is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- `Setup:` `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The comprehension compresses a loop into a readable noun phrase: `make this` for `each item` if `it qualifies`. Expand it mentally when it feels dense.
- `Writing move:` this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print('duplicate alt text:', dupes if dupes else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`c = Counter(a for a in alts if a)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('duplicate alt text:', dupes if dupes else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `c = Counter(a for a in alts if a)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Duplicate Alt Text on Images: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, collections, Counter, html, img. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: c = Counter(a for a in alts if a) | Evidence: print('duplicate alt text:', dupes if dupes else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain find duplicate alt text on images in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 178.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 180 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('duplicate alt text:', dupes if dupes else 'none')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find duplicate alt text on images and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Lowercasing and stripping alt values before counting catches case-only variants as duplicates, and any value used more than once (ignoring empty alts) is reported.

```
import re
from collections import Counter
html = ('<img src="a.jpg" alt="Trail running shoe on rocks">'
        '<img src="b.jpg" alt="Trail running shoe on rocks">'
```

```
        '<img src="c.jpg" alt="Logo">'
        '<img src="d.jpg" alt="trail running shoe on rocks">')
alts = [m.lower().strip() for m in re.findall(r'\balt="([^"]*)"', html)]
c = Counter(a for a in alts if a)
dupes = sorted(t for t, n in c.items() if n > 1)
print('duplicate alt text:', dupes if dupes else 'none')
```

```
output
duplicate alt text: ['trail running shoe on rocks']
```

How it works:

1. Four images include three with variations of the same trail running shoe description, one differing only in case.
2. findall captures each alt value, and a comprehension lowercases and strips them into the alts list.
3. A Counter tallies only the non-empty alts, so a case difference collapses into one bucket.
4. Alts with a count above one are sorted into dupes and printed, or none when all are distinct.

Try it:

1. Report how many images share each duplicated alt string
2. Treat near-identical alts differing by one word as duplicates
3. List the src filenames that carry each repeated alt
4. Make the third repeat's alt unique and watch the duplicate vanish.

⚠ Common Mistakes

- Case-sensitive counting would miss the 'Trail…' vs 'trail…' duplicate.
- Counting empty alts as duplicates floods the report; decorative empties are filtered out.
- Not stripping whitespace lets ' Logo' and 'Logo' look distinct.

Skills gained alt duplicate | Counter tally | normalisation

→ Where You'll Use This: Image-SEO audits flag duplicated alt text because identical descriptions across a gallery dilute relevance and bore screen-reader users; auditors push for unique, specific captions.

Mental Model

Copy-pasted alt text is a museum where every painting wears the same label: visitors and the catalogue learn nothing distinct about any piece.

Project 180 Confirm the Outline Starts at H1

The Idea Behind It

A document outline should open with its single H1, so leading with an H2 signals styling chosen over meaning. The code captures the heading levels in document order, takes the first one, and reports whether the outline starts at level one, exposing a page whose first heading is not the H1.

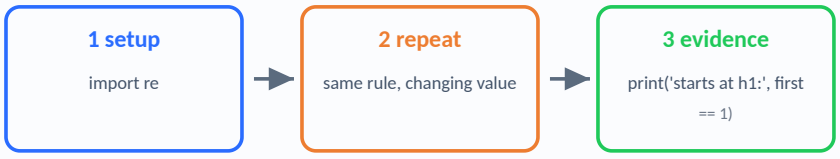
What You'll Build & Learn

Report whether a page's first heading is its H1, as a proper outline should begin.

- Outlines should open with the H1
- Reading the first element of a list safely
- Comparing the first level to one

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 179: find duplicate alt text on images. Project 181 changes the surface problem while preserving the underlying method.



progress check

Reading target: confirm the outline starts at h1 is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('starts at h1:', first == 1)` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`first = levels[0] if levels else None`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('starts at h1:', first == 1)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `first = levels[0] if levels else None`

Construction pattern

Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Confirm the Outline Starts at H1: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, h2, Recipes, h1. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: first = levels[0] if levels else None | Evidence: print('starts at h1:', first == 1)

Reader to Writer Bridge

1. Read: explain confirm the outline starts at h1 in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 179.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 181 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('starts at h1:', first == 1)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of confirm the outline starts at h1 and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Capturing heading levels in document order and inspecting the first element tells whether the outline opens at the top level or dives in mid-hierarchy.

```
import re
html = '<h2>Recipes</h2><h1>Sourdough Bread</h1><h2>Ingredients</h2>
<h3>Flour</h3>'
levels = [int(t) for t in re.findall(r'<h([1-6])', html)]
first = levels[0] if levels else None
print('heading levels in order:', levels)
print('starts at h1:', first == 1)
```

```
output
heading levels in order: [2, 1, 2, 3]
starts at h1: False
```

How it works:

1. The HTML places an H2 before the H1, an order built for appearance rather than structure.
2. findall captures each heading digit, and a comprehension turns them into an ordered levels list.
3. first takes the leading level, guarded to None when the list is empty.
4. The script prints the ordered levels and whether first equals one, reporting false here.

Try it:

1. Also confirm exactly one H1 exists anywhere in the document

2. Report at what index the first H1 actually appears
3. Warn when the page has no headings at all
4. Move the `<h1>` to the front and watch the check pass.

⚠ Common Mistakes

- Document order, not DOM nesting, is what `findall` returns; a CSS-reordered page can still mislead a reader.
- A page with no headings yields an empty list, so `first` must guard against an index error.
- Matching `<h([1-6])` without a boundary could catch an invented `<h7>`-like tag if present.

Skills gained outline start | first element | level check

→ Where You'll Use This: Heading-structure audits verify the first heading is the H1; pages that open on an H2 because it looked right in a template confuse the document outline engines build.

Mental Model

An outline starting on H2 is a book that opens on chapter two: readers and engines wonder where the missing first chapter went.

Project 181 Spot a Stuffed Meta Description

The Idea Behind It

A description that repeats one term over and over reads as spam to engines and users. The code extracts the description, removes stop words, finds the single most common remaining content word with a Counter, computes its share of the content words, and flags the description as keyword-stuffed when that share exceeds twenty percent.

What You'll Build & Learn

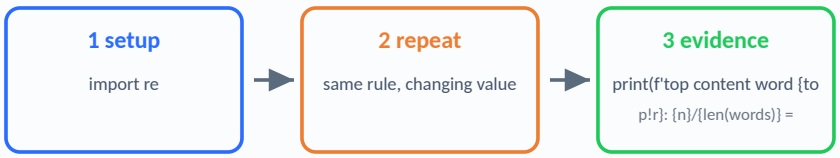
Detect a keyword-stuffed meta description by finding its most repeated content word's share.

- Repetition in a description reads as spam
- most_common to find the top word
- Share threshold for stuffing

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 180: confirm the outline starts at h1. Project 182 changes the surface problem while preserving the underlying method.

progress check



Reading target: spot a stuffed meta description is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'top content word {top!r}: {n}/{len(words)} = {ratio}% -> {flag}')` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`words = [w for w in re.findall(r'[a-z]+', desc.lower()) if w not in stop]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'top content word {top!r}: {n}/{len(words)} = {ratio}% -> {flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `words = [w for w in re.findall(r'[a-z]+', desc.lower()) if w not in stop]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Spot a Stuffed Meta Description: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, collections, Counter, html, meta. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: words = [w for w in re.findall(r'[a-z]+', desc.lower()) if w not in sto... | Evidence: print(f'top content word {top!r}: {n}/{len(words)} = {ratio}% -> {flag}...

Reader to Writer Bridge

1. Read: explain spot a stuffed meta description in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 180.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 182 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'top content word {top!r}: {n}/{len(words)} = {ratio}% -> {flag}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of spot a stuffed meta description and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Filtering out stop words first ensures the most-common word is a meaningful term, not 'the'; a content word claiming a large share of the text signals stuffing.

```
import re
from collections import Counter
html = '<meta name="description" content="The best running shoes, the best
deals, the best brands, the best fit, best value.">'
desc = re.search(r'content="([^"]*)"', html).group(1)
stop = {'the', 'for', 'and', 'a', 'of', 'to', 'who', 'want', 'on'}
words = [w for w in re.findall(r'[a-z]+', desc.lower()) if w not in stop]
top, n = Counter(words).most_common(1)[0]
ratio = round(100 * n / len(words), 1)
flag = 'keyword-stuffed' if ratio > 20 else 'OK'
print(f'top content word {top!r}: {n}/{len(words)} = {ratio}% -> {flag}')
```

```
output
top content word 'best': 5/11 = 45.5% -> keyword-stuffed
```

How it works:

1. The description hammers the word best across a comma-laden sentence.
2. After capturing the content, a comprehension keeps lowercased words that are not in the stop set.
3. Counter most_common returns the top content word and its count, and the ratio is its share of all content words, rounded.
4. A ratio above twenty percent prints the keyword-stuffed flag along with the figures.

Try it:

1. Apply the same stuffing check to the page title
2. Make the stuffing threshold percentage configurable
3. Report the top three content words and their shares
4. Vary the repeated word with synonyms and watch the ratio fall to OK.

⚠ Common Mistakes

- Skipping the stop-word filter makes 'the' the top word and hides the real stuffing.
- A threshold set too high never flags genuine over-repetition.
- `most_common(1)` on an all-stop-word description would crash on an empty list.

Skills gained stuffing detection | Counter most_common | stop filtering

→ Where You'll Use This: Spam and quality audits flag stuffed snippets so writers rework descriptions into natural sentences, since overt repetition can suppress a snippet or read as manipulative to engines.

Mental Model

A stuffed description is a salesperson who only shouts best, best, best: the word loses meaning and the pitch starts to sound desperate.

Project 182 Compare Title and H1 Word Overlap

The Idea Behind It

The title and the H1 should describe the same thing, so a wide gap between them is a relevance smell. This project lowercases both, reduces each to a set of words, and intersects them to find the shared words, reporting an empty overlap as a sign the two signals are disconnected rather than reinforcing.

What You'll Build & Learn

Measure the shared words between a page's title and H1 to test whether they agree.

- Title and H1 should reinforce each other
- Word sets and their intersection
- Empty overlap as a warning sign

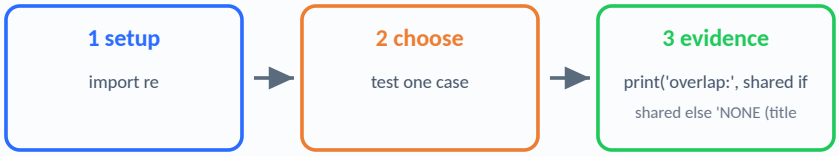
Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 181: spot a stuffed meta description. Project 183 changes the surface problem while preserving the underlying method.

progress check

Reading target: compare title and h1 word overlap is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Compare Title and H1 Word Overlap: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, title, Home, h1. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print('overlap:', shared if shared else 'NONE (title and h1 disconnecte... | Evidence: print('overlap:', shared if shared else 'NONE (title and h1 disconnecte...

🛠️ Reader to Writer Bridge

1. Read: explain compare title and h1 word overlap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 181.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 183 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of compare title and h1 word overlap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Reducing each element to a lowercase word set and intersecting them surfaces shared vocabulary; an empty intersection means the title and H1 are sending different topic signals.

```
import re
html = '<title>Home</title><h1>Welcome to Acme Running Co</h1>'
title = re.search(r'<title>(.*?)</title>', html, re.S).group(1).lower()
h1 = re.search(r'<h1[^>]*>(.*?)</h1>', html, re.S).group(1).lower()
tset = set(re.findall(r'[a-z]+', title))
hset = set(re.findall(r'[a-z]+', h1))
shared = sorted(tset & hset)
print('title words:', sorted(tset))
print('h1 words:', sorted(hset))
print('overlap:', shared if shared else 'NONE (title and h1 disconnected)')
```

```
output
title words: ['home']
h1 words: ['acme', 'co', 'running', 'to', 'welcome']
overlap: NONE (title and h1 disconnected)
```

How it works:

1. The HTML pairs a vague title Home with a specific H1 about Acme Running Co.
2. Both are captured and lowercased, then findall reduces each to a set of words.
3. The intersection of the two sets is sorted into the shared list.
4. The script prints each word set and the overlap, reporting none here since the two share no words.

Try it:

1. Report the overlap as a percentage of the title's words
2. Ignore stop words before computing the shared set
3. Extend the comparison to include the first H2 as well
4. Rewrite the title to include 'Acme Running' and watch the overlap appear.

⚠ Common Mistakes

- Comparing raw strings instead of word sets reports a mismatch even for reordered same-word phrases.
- Not lowercasing makes 'Home' and 'home' fail to overlap.
- Stop words inflate apparent overlap, so a shared 'the' can mask a real topic gap.

Skills gained set overlap title-h1 match relevance check

→ Where You'll Use This: Relevance audits compare title and H1 wording because a disconnect suggests a templated or careless title; aligning them helps both signals point engines at the same topic.

Mental Model

Title and H1 are two witnesses to the same event; when their stories share no details, you suspect one of them was not really there.

Project 183 Score a Page Against an On-Page Checklist

The Idea Behind It

Real audits roll many checks into one score, and this one tallies four essentials in a single pass. The code tests for a non-empty title, a non-empty description, a canonical link, and a viewport tag, stores each result as a boolean in a dictionary, sums them for a score, and prints present or missing per check.

What You'll Build & Learn

Score one page against four on-page essentials and print a pass-fail tally.

- Bundling checks into one score
- Storing boolean results in a dictionary
- Summing booleans to get a total

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 182: compare title and h1 word overlap. Project 184 changes the surface problem while preserving the underlying method.

progress check

Reading target: score a page against an on-page checklist is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print(f'score: {score}/{len(required)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print(f'{k}: {"present" if required[k] else "MISSING"}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'score: {score}/{len(required)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'{k}: {"present" if required[k] else "MISSING"}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score a Page Against an On-Page Checklist: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, head, title, Pricing. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print(f'{k}: {"present" if required[k] else "MISSING"}') | Evidence: print(f'score: {score}/{len(required)}')

🛠️ Reader to Writer Bridge

1. Read: explain score a page against an on-page checklist in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 182.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 184 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'score: {score}/{len(required)}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score a page against an on-page checklist and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each check is a boolean regex search, and the `\S` requirement on title and description ensures a present-but-empty tag does not count; summing the booleans gives the score.

```
import re
html = '<head><title>Pricing Plans</title><meta name="description"
content="Compare our plans."></head>'
required = {
    'title': bool(re.search(r'<title>.*?\S.*?</title>', html, re.S)),
    'description': bool(re.search(r'name="description"\s+content="[^"]*\S',
html)),
    'canonical': bool(re.search(r'rel="canonical"', html)),
    'viewport': bool(re.search(r'name="viewport"', html)),
}
score = sum(required.values())
for k in sorted(required):
    print(f'{k}: {"present" if required[k] else "MISSING"}')
print(f'score: {score}/{len(required)}')
```

```
output
canonical: MISSING
description: present
title: present
viewport: MISSING
score: 2/4
```

How it works:

1. The HTML head supplies a title and description but no canonical or viewport.
2. A required dictionary maps each check name to a boolean from a regex, where the title and description patterns also require a non-whitespace character.
3. score sums the dictionary values, since True counts as one.
4. A sorted loop prints present or missing per check, then the script prints the score out of four.

Try it:

1. Add an H1-present check as a fifth essential
2. Weight the title check more heavily than the others
3. Print only the checks that failed for a terse report
4. Add a canonical and viewport tag and watch the score climb to 4/4.

⚠ Common Mistakes

- A title regex without `\S` would count an empty `<title></title>` as present.
- Summing booleans relies on True equalling 1; mixing in None values would break the count.
- Iterating the dict unsorted makes the per-check lines print in nondeterministic order.

Skills gained scorecard boolean sum checklist audit

→ Where You'll Use This: Audit dashboards condense many on-page checks into a single page score; this pattern is the seed of any report card that ranks pages by how many essentials they pass.

Mental Model

It is a vehicle inspection: four boxes to tick, and the sticker shows how many passed so you know what still needs a repair.

Project 184 Score Keyword Placement Across Elements

The Idea Behind It

Where a keyword appears matters as much as whether it appears, so this scores its presence across four prime spots. The code captures the title, H1, an H2, and the first paragraph into a dictionary, lists the keys whose text contains the keyword, and reports both the placements found and a score out of four.

What You'll Build & Learn

Score a keyword's presence across the title, H1, an H2, and the first paragraph.

- Placement spread strengthens a keyword
- Building a dictionary of page regions
- Listing keys whose value matches

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 183: score a page against an on-page checklist. Project 185 changes the surface problem while preserving the underlying method.

progress check

Reading target: score keyword placement across elements is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print('placement score:', len(hits), 'of', len(spots))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`hits = [k for k, v in spots.items() if keyword in v.lower()]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('placement score:', len(hits), 'of', len(spots))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `hits = [k for k, v in spots.items() if keyword in v.lower()]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Keyword Placement Across Elements: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, keyword, standing, desk, html. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: hits = [k for k, v in spots.items() if keyword in v.lower()] | Evidence: print('placement score:', len(hits), 'of', len(spots))

🛠️ Reader to Writer Bridge

1. Read: explain score keyword placement across elements in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 183.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 185 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('placement score:', len(hits), 'of', len(spots))`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score keyword placement across elements and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each element is extracted into a dict and tested for the lowercased keyword; the count of element types containing it is the placement score across the most weighted on-page spots.

```
import re
keyword = 'standing desk'
html = '<title>Adjustable Standing Desk</title><h1>The Best Standing Desk</h1>
<h2>Standing Desk Setup</h2><p>A standing desk improves posture.</p>'
spots = {
    'title': re.search(r'<title>(.*?)</title>', html, re.S).group(1),
    'h1': re.search(r'<h1[^>]*>(.*?)</h1>', html, re.S).group(1),
    'h2': re.search(r'<h2[^>]*>(.*?)</h2>', html, re.S).group(1),
    'first_p': re.search(r'<p[^>]*>(.*?)</p>', html, re.S).group(1),
}
hits = [k for k, v in spots.items() if keyword in v.lower()]
print('keyword placement:', sorted(hits))
print('placement score:', len(hits), 'of', len(spots))
```

```
output
keyword placement: ['first_p', 'h1', 'h2', 'title']
placement score: 4 of 4
```

How it works:

1. The HTML mentions standing desk in the title, H1, H2, and the opening paragraph.
2. A spots dictionary captures the inner text of each of the four regions with its own regex.
3. A comprehension collects the keys whose lowercased text contains the keyword into the hits list.
4. The script prints the sorted placements and a score of how many of the four spots matched.

Try it:

1. Add the meta description as a fifth scored placement
2. Weight the title and H1 hits above the H2 and paragraph
3. Match keyword words individually rather than the whole phrase
4. Drop the keyword from the H2 and watch the score fall to 3 of 4.

⚠ Common Mistakes

- Each extraction assumes the tag exists; a missing H2 would crash on `.group(1)`.
- Only the first H2 is checked, so a keyword in a later H2 is missed.
- A substring match counts the keyword even inside an unrelated longer phrase.

Skills gained placement score | region dict | keyword spread

→ Where You'll Use This: On-page scoring tools reward keyword spread across key elements; this placement score gives an optimiser a concrete number for how well a page surfaces its target term.

⚡ Mental Model

Keyword placement is planting the same flag at four checkpoints: scattering it across the map proves you really hold the territory.

Project 185 Infer Search Intent From the Title

💡 The Idea Behind It

Titles leak the searcher intent they target, so cue words classify a page's likely intent from its title alone. The code defines word lists for informational, transactional, and navigational intents, scores each by summing how often its cue words occur in the lowercased title, and picks the highest-scoring intent as the inferred one.

What You'll Build & Learn

Infer a page's likely search intent by scoring intent cue words in its title.

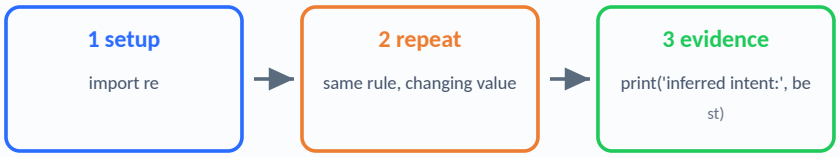
- Titles signal the searcher's intent
- Scoring categories by cue word counts
- Choosing the max-scoring category

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 184: score keyword placement across elements. Project 186 changes the surface problem while preserving the underlying method.

progress check

Reading target: infer search intent from the title is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('inferred intent:', best)` exposes the result; match it against the output before changing the program.

output proves the trace

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`scores = {kind: sum(title.count(w) for w in words) for kind, words in intents.items()}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('inferred intent:', best)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `scores = {kind: sum(title.count(w) for w in words) for kind, words in intents.items()}`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Infer Search Intent From the Title: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, intents, informational, how, what. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: scores = {kind: sum(title.count(w) for w in words) for kind, words in i... | Evidence: print('inferred intent:', best)

🛠️ Reader to Writer Bridge

1. Read: explain infer search intent from the title in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 184.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 186 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('inferred intent:', best)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of infer search intent from the title and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each intent category accumulates a score from its cue words, and the highest-scoring category (with sorted keys to break ties deterministically) is the inferred intent.

```
import re
intents = {
    'informational': ('how', 'what', 'guide', 'tips', 'why'),
    'transactional': ('buy', 'price', 'cheap', 'order', 'shop'),
    'navigational': ('login', 'official', 'website'),
}
```

```
title = re.search(r'<title>(.*?)</title>', '<title>How to Brew Cold Brew: A
Beginner Guide</title>', re.S).group(1).lower()
scores = {kind: sum(title.count(w) for w in words) for kind, words in
intents.items()}
best = max(sorted(scores), key=lambda k: scores[k])
print('signals:', {k: scores[k] for k in sorted(scores)})
print('inferred intent:', best)
```

```
output
signals: {'informational': 2, 'navigational': 0, 'transactional': 0}
inferred intent: informational
```

How it works:

1. An intents dictionary maps three intent types to tuples of cue words.
2. The title how to brew cold brew a beginner guide is captured and lowercased inline.
3. A dict comprehension scores each intent by summing the title's counts of its cue words.
4. max over the sorted keys picks the top intent, and the script prints the per-intent signals and the inferred intent.

Try it:

1. Add a commercial-investigation intent with cues like best and review
2. Break ties by preferring the intent with the rarest matched cue
3. Score the H1 alongside the title for a stronger signal
4. Swap the title to 'Buy Cold Brew Maker' and watch intent flip to transactional.

⚠ Common Mistakes

- `title.count('how')` also fires inside 'however', so cue words can over-match.
- Calling `max` over the unsorted dict makes ties resolve unpredictably.
- A title with no cue words returns the first category by sort order, not a real 'unknown'.

Skills gained intent inference | cue scoring | max selection

→ Where You'll Use This: Intent classification helps match content to the queries it should target; auditors use title cues to spot pages aimed at the wrong stage of a searcher's journey.

Mental Model

Intent cues are tells in a card game: how to whispers a curious browser while buy now shows a wallet already out.

Project 186 Check Title Intent Against Page Intent

The Idea Behind It

A product page should read transactional, not informational, so comparing signalled intent against intended intent flags a mismatch. The code scores informational and transactional cue words in the title, picks the detected intent, compares it to the declared page intent, and reports whether the two match or clash.

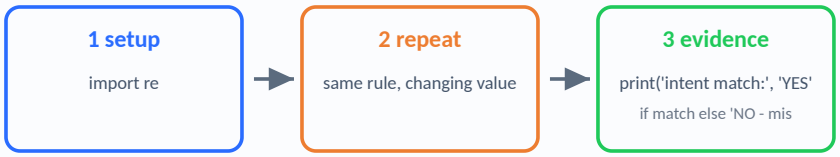
What You'll Build & Learn

Compare the intent a title signals against the intent the page targets and flag mismatches.

- Title intent should match page intent
- Selecting a detected category by max score
- Equality test for a mismatch verdict

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 185: infer search intent from the title. Project 187 changes the surface problem while preserving the underlying method.



progress check

Reading target: check title intent against page intent is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('intent match:', 'YES' if match else 'NO – mismatch')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print('intent match:', 'YES' if match else 'NO – mismatch')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('intent match:', 'YES' if match else 'NO – mismatch')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('intent match:', 'YES' if match else 'NO – mismatch')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Title Intent Against Page Intent: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, page_intent, transactional, title, search. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: import re | Core: print('intent match:', 'YES' if match else 'NO - mismatch') | Evidence: print('intent match:', 'YES' if match else 'NO - mismatch')

🛠️ Reader to Writer Bridge

1. Read: explain check title intent against page intent in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 185.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 187 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('intent match:', 'YES' if match else 'NO – mismatch')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check title intent against page intent and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The detected intent comes from the highest-scoring cue category, and comparing it to the page's declared target reveals when the title chases a different intent than the page serves.

```
import re
page_intent = 'transactional'
title = re.search(r'<title>(.*?)</title>', '<title>How to Choose Running Shoes:
Buying Guide</title>', re.S).group(1).lower()
intent_words = {'informational': ('how', 'guide', 'what', 'tips'),
                'transactional': ('buy', 'shop', 'price', 'order')}
detected = max(sorted(intent_words), key=lambda k: sum(title.count(w) for w in
intent_words[k]))
match = detected == page_intent
print(f'page targets: {page_intent}')
```

```
print(f'title signals: {detected}')
print('intent match:', 'YES' if match else 'NO — mismatch')
```

```
output
page targets: transactional
title signals: informational
intent match: NO — mismatch
```

How it works:

1. The page intent is declared transactional but the title reads how to choose running shoes buying guide.
2. An intent words dictionary maps two intents to cue tuples, and the title is captured and lowercased.
3. max over the sorted keys picks the detected intent by summed cue counts, landing on informational.
4. match compares detected to the declared intent, and the script prints both and a yes or no mismatch verdict.

Try it:

1. Add navigational and commercial intents to the comparison
2. Report by how many cue words the detected intent led
3. Let the page intent be inferred from the URL pattern instead
4. Rewrite the title as 'Buy Running Shoes Online' and watch the match become YES.

⚠ Common Mistakes

- 'Buying Guide' scores informational here because 'guide' outweighs no transactional cue word.
- A title with zero cues defaults to the first sorted category, faking a confident detection.
- Substring counting lets 'buying' miss the cue word 'buy' if you required whole words.

Skills gained intent mismatch | max scoring | equality check

→ Where You'll Use This: Content-to-intent audits catch pages whose copy fights their purpose, like a shop page written as a guide; aligning the two improves both rankings and conversion.

Mental Model

It is matching a label to its contents: a jar marked jam that smells of pickles tells you something got mixed up on the line.

Project 187 Detect Structured Data Types

The Idea Behind It

JSON-LD structured data unlocks rich results like FAQ panels and review stars. The code finds every JSON-LD script block, joins their contents, extracts each declared schema type from the at-type fields, and reports how

many blocks exist and which schema types the page declares, deduplicated and sorted.

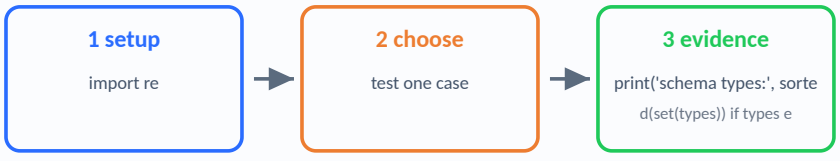
What You'll Build & Learn

Find embedded JSON-LD blocks and report which schema types the page declares.

- JSON-LD enables rich results
- Matching script blocks by their type attribute
- Pulling the at-type values from the payload

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 186: check title intent against page intent. Project 188 changes the surface problem while preserving the underlying method.



progress check

Reading target: detect structured data types is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print('schema types:', sorted(set(types)) if types else 'none')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print('schema types:', sorted(set(types)) if types else 'none')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print('schema types:', sorted(set(types)) if types else 'none')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print('schema types:', sorted(set(types)) if types else 'none')`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Detect Structured Data Types: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, head, title, script. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.

Layer	What to read
Evidence	Entry: import re | Core: print('schema types:', sorted(set(types)) if types else 'none') | Evidence: print('schema types:', sorted(set(types)) if types else 'none')

🛠️ Reader to Writer Bridge

1. Read: explain detect structured data types in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 186.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 188 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('schema types:', sorted(set(types)) if types else 'none')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect structured data types and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The script-tag regex isolates JSON-LD payloads, and a second regex harvests every `@type` value so the audit lists the structured-data kinds present without fully parsing the JSON.

```
import re
html = '<head><title>FAQ</title><script type="application/ld+json">
{"@type":"FAQPage"}</script></head>'
blocks = re.findall(r'<script[^>]*application/ld\+json[^>]*>(.*?)</script>',
html, re.S)
types = re.findall(r'"@type"\s*:\s*"([^"]+)"', ' '.join(blocks))
print('JSON-LD blocks:', len(blocks))
print('schema types:', sorted(set(types)) if types else 'none')
```

```
output
JSON-LD blocks: 1
schema types: ['FAQPage']
```

How it works:

1. The head contains one JSON-LD script block declaring an FAQPage type.
2. findall captures the inner content of every script tag whose type is application of the ld plus json kind.
3. The blocks are joined and a second findall pulls each at-type value from them.
4. The script prints the block count and the sorted set of schema types, or none when no types are found.

Try it:

1. Validate that each block is parseable JSON rather than only matching it
2. Detect microdata itemtype attributes in addition to JSON-LD
3. Warn when an expected schema type for the page is absent
4. Add a second JSON-LD block with a `Product` type and watch both types list.

⚠ Common Mistakes

- Escaping the literal `+` in `ld+json` is required, or the regex treats it as a quantifier.
- Reading `@type` by regex misses types written across multiple lines or nested oddly.
- Microdata or RDFa structured data uses different markup and is invisible to this JSON-LD-only check.

Skills gained JSON-LD detection | schema types | script matching

→ Where You'll Use This: Structured-data audits verify pages carry the schema needed for rich results; this scan tells which types a page declares so you can confirm coverage for FAQ, product, or article markup.

⚡ Mental Model

Structured data is a backstage cue card for engines: it spells out this is an FAQ so they can stage the fancy result instead of a plain link.

Project 188 Flag Inconsistent Anchor Text to One URL

💡 The Idea Behind It

Linking to one page with wildly different anchor text muddies the relevance signal that text sends. This project groups anchors by their destination using a defaultdict of sets, collects every distinct trimmed label per href, and flags any URL described with more than one label as inconsistent.

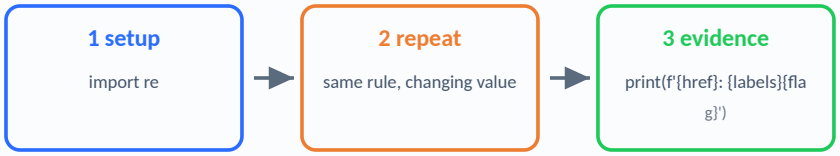
What You'll Build & Learn

Flag any URL on a page that is linked with more than one different anchor text.

- Consistent anchor text sharpens relevance
- Grouping with a defaultdict of sets

- Flagging destinations with multiple labels

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 187: detect structured data types. Project 189 changes the surface problem while preserving the underlying method. *progress check*

Reading target: flag inconsistent anchor text to one url is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'{href}: {labels}{flag}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`flag = ' <- inconsistent' if len(labels) > 1 else ''`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{href}: {labels}{flag}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = ' <- inconsistent' if len(labels) > 1 else ''`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Inconsistent Anchor Text to One URL: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, collections, defaultdict, html, href. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: flag = ' <- inconsistent' if len(labels) > 1 else '' | Evidence: print(f'{href}: {labels} {flag}')

Reader to Writer Bridge

1. Read: explain flag inconsistent anchor text to one url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 187.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 189 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{href}: {labels} {flag}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag inconsistent anchor text to one url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Mapping each destination href to the set of anchor texts that point at it exposes URLs described more than one way; a set size above one is the inconsistency flag.

```
import re
from collections import defaultdict
html = ('<a href="/home">Home</a><a href="/blog">Blog</a>'
        '<a href="/blog">Blog</a><a href="/about">About</a>'
        '<a href="/blog">Read the blog</a>')
texts = defaultdict(set)
for href, txt in re.findall(r'<a[^>]*href="([^"]*)"[^>]*>(.*?)</a>', html,
re.S):
    texts[href].add(txt.strip())
for href in sorted(texts):
    labels = sorted(texts[href])
    flag = ' <- inconsistent' if len(labels) > 1 else ''
    print(f'{href}: {labels}{flag}')
```

```
output
/about: ['About']
/blog: ['Blog', 'Read the blog'] <- inconsistent
/home: ['Home']
```

How it works:

1. The HTML links to the blog twice as Blog and once as Read the blog, plus single links to home and about.
2. A defaultdict of sets maps each href to the distinct trimmed anchor texts pointing at it.
3. findall yields each href and its text, which is stripped and added to the destination's set.
4. Sorted destinations print their labels, appending an inconsistent flag when a URL has more than one label.

Try it:

1. Treat case-only differences in labels as the same anchor text
2. Report the most common label per URL as the suggested standard
3. Count how many distinct labels each inconsistent URL carries

4. Make every link to /blog use 'Blog' and watch the inconsistency clear.

⚠ Common Mistakes

- Using a list instead of a set would report a repeated identical anchor as 'inconsistent'.
- Not stripping anchor text makes ' Blog' and 'Blog' look like two different labels.
- The non-greedy `(.*?)` is needed so each anchor is captured separately, not run together.

Skills gained anchor consistency | defaultdict grouping | label set

→ Where You'll Use This: Internal-link audits flag inconsistent anchors so a destination receives a coherent relevance signal; scattering different labels at one URL weakens the topic it should rank for.

Mental Model

Anchor text is how friends describe a restaurant to others; if everyone calls it something different, no one is sure they all mean the same place.

Project 189 Check Keyword Position Within the Title

The Idea Behind It

A keyword near the front of a title carries more weight and survives truncation, so locating its position tells whether it is front-loaded or buried. The code finds the keyword's character index in the lowercased title, computes that as a percentage of the title length, and labels it front-loaded, early, or buried.

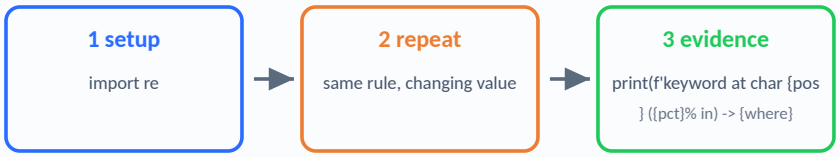
What You'll Build & Learn

Find where a keyword sits within a title and judge whether it is front-loaded or buried.

- Front-loaded keywords carry more weight
- Finding a substring position with find
- Mapping position percentage to a label

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 188: flag inconsistent anchor text to one url. Project 190 changes the surface problem while preserving the underlying method.



progress check

Reading target: check keyword position within the title is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
- Evidence: `print(f'keyword at char {pos} ({pct}% in) -> {where}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: `setup` creates the facts, `repeat` applies the chapter idea, and `evidence` proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`if pos < 0:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'keyword at char {pos} ({pct}% in) -> {where}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if pos < 0:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Check Keyword Position Within the Title: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, keyword, yoga, mat, title. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: if pos < 0: | Evidence: print(f'keyword at char {pos} ({pct}% in) -> {where}')

🛠️ Reader to Writer Bridge

1. Read: explain check keyword position within the title in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 188.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 190 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'keyword at char {pos} ({pct}% in) -> {where}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of check keyword position within the title and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

`str.find` returns the keyword's first index, and converting it to a percentage of title length buckets the placement into front-loaded, early, or buried.

```
import re
keyword = 'yoga mat'
title = re.search(r'<title>(.*?)</title>', '<title>Eco Yoga Mat: Non-Slip Cork Mat for Hot Yoga</title>', re.S).group(1).lower()
pos = title.find(keyword)
if pos < 0:
    print('keyword not in title')
else:
    pct = round(100 * pos / len(title), 1)
    where = 'front-loaded' if pos == 0 else ('early' if pct < 30 else 'buried')
    print(f'keyword at char {pos} ({pct}% in) -> {where}')
```

```
output
keyword at char 4 (9.1% in) -> early
```

How it works:

1. The title Eco Yoga Mat is captured, lowercased, and searched for the keyword yoga mat.
2. find returns the character index, with a negative result printing a not-in-title message.
3. The position is converted to a percentage of the title length, rounded.
4. A position of zero is front-loaded, under thirty percent is early, and beyond that is buried, printed with the figures.

Try it:

1. Make the early versus buried percentage cutoff configurable
2. Report the position of each word of a multi-word keyword
3. Apply the same position check to the H1
4. Move the keyword to the very start and watch it read 'front-loaded'.

⚠ Common Mistakes

- `find` returns -1 when absent, which must be handled before treating it as a position.
- Lowercasing only the title (not the keyword) would miss a capitalised keyword constant.
- Position as a percentage depends on title length, so a long title pushes the 'buried' threshold.

Skills gained keyword position str.find position labelling

→ Where You'll Use This: Title-optimisation tools report keyword position because front-loading the target phrase helps it survive truncation and signals priority; auditors flag buried keywords for rewriting.

Mental Model

Keyword position is seating at a dinner: the head of the table commands attention, while the far end is easy to overlook.

Project 190 Run the Full On-Page Audit Report

The Idea Behind It

This capstone ties the chapter together by running the core on-page checks from one HTML string and printing a single scorecard. The code tests title length, description length, a single H1, a canonical, a lang attribute, and that all images carry alt, appending each result, summing the passes, and printing a checkbox line per check.

What You'll Build & Learn

Run the chapter's core on-page checks on one page and print a combined pass-fail scorecard.

- Combining many checks into a report
- Appending result tuples to a list
- Using all to test every image for alt

Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 189: check keyword position within the title. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*

Reading target: run the full on-page audit report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.

- Evidence: `print(f'on-page score: {passed}/{len(checks)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
2. Apply the rule	`print(f'[{"x" if ok else " "}] {name}')`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'on-page score: {passed}/{len(checks)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: On-Page Signals and the HTML Audit becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `print(f'[{"x" if ok else " "}] {name}')`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Run the Full On-Page Audit Report: connect the surface task to the chapter skill, audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet.
Names	Watch these names first: re, html, lang, en, head. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import re | Core: print(f'[{"x" if ok else " "}] {name}') | Evidence: print(f'on-page score: {passed}/{len(checks)}')

🛠️ Reader to Writer Bridge

1. Read: explain run the full on-page audit report in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 189.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'on-page score: {passed}/{len(checks)}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of run the full on-page audit report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each on-page rule from the chapter is reduced to a boolean and collected in order, so summing the booleans yields a single scorecard that mirrors a real audit summary.

```
import re
html = ('<html lang="en"><head><title>Trail Running Shoes Guide for
Beginners</title>'
        '<meta name="description" content="A clear guide to picking your first
pair of trail running shoes.">'
        '<link rel="canonical" href="https://example.com/guide"></head>'
        '<body><h1>Trail Running Shoes</h1><img src="a.jpg" alt="Shoe"><img
src="b.jpg"></body></html>')
checks = []
t = re.search(r'<title>(.*?)</title>', html, re.S).group(1)
checks.append(('title 50-60', 50 <= len(t) <= 60))
d = re.search(r'description"\s+content="([^"]*)"', html).group(1)
checks.append(('desc <=155', len(d) <= 155))
checks.append(('exactly one h1', len(re.findall(r'<h1', html)) == 1))
checks.append(('canonical', bool(re.search(r'rel="canonical"', html))))
checks.append(('lang set', bool(re.search(r'<html[^>]*lang=', html))))
imgs = re.findall(r'<img\b[^>]*>', html)
checks.append(('all imgs alt', all(re.search(r'\balt=', i) for i in imgs)))
passed = sum(ok for _, ok in checks)
for name, ok in checks:
    print(f'[{"x" if ok else " "}] {name}')
print(f'on-page score: {passed}/{len(checks)}')
```

```
output
[ ] title 50-60
[x] desc <=155
[x] exactly one h1
[x] canonical
[x] lang set
[ ] all imgs alt
on-page score: 4/6
```

How it works:

1. A full HTML string carries a lang, title, description, canonical, an H1, and two images, one without alt.
2. Each check appends a name and boolean tuple, covering title length, description length, single H1, canonical, lang, and image alts.
3. The image check uses all over the img tags so it fails the moment any image lacks alt.
4. passed sums the boolean results, each check prints with an x or blank box, and the final score reads four of six.

Try it:

1. Add checks for a viewport meta and an Open Graph title
2. Print a remediation hint next to each failing check
3. Run the whole scorecard over a dictionary of several pages

4. Lengthen the title into the 50-60 window and watch the score rise.

⚠ Common Mistakes

- A 39-character title fails the 50-60 window, so this sample scores 4 of 6, not a perfect 6.
- Counting `<h1` opening tags assumes well-formed markup; an unclosed tag would still count.
- The second image has no alt, so the 'all imgs alt' check fails as intended.

Skills gained full audit | all aggregation | scorecard report

→ Where You'll Use This: This is the shape of a real on-page audit: many independent checks feeding one page score, which is exactly how crawlers and dashboards summarise a page's health at a glance.

Mental Model

The capstone is a full health checkup: pulse, blood pressure, and the rest measured in one visit, summed into a single chart of what is fine and what needs care.

✅ Chapter Progress Checkpoint

What this chapter added: after 40 mini-projects, On-Page Signals and the HTML Audit should feel like a reusable Python move: audit titles, meta descriptions, header hierarchy, alt text and intent match from an html snippet. *chapter checkpoint*

1 Read
Open any project from Projects 151-190 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.
transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 6 (Keyword Research and Intent as Data) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

9 questions · 4 categories · graded

3 Recall | 2 Meaning | 2 Structure | 2 Transfer

5.1.Q1 Recall MEDIUM Turn back to Project 174 (Measure Heading Keyword Coverage). Without running it, what exactly does it print?

5.1.Q2 Meaning MEDIUM Turn back to Project 160 (Verify a Canonical Link Is Present). Without running it, what exactly does it print?

5.1.Q3 Structure MEDIUM Turn back to Project 185 (Infer Search Intent From the Title). Without running it, what exactly does it print?

5.1.Q4 Transfer MEDIUM Turn back to Project 175 (Flag Image-Heavy Thin Pages). Without running it, what exactly does it print?

5.1.Q5 Recall EASY What is the conventionally healthy length range for a **<title>** tag, and why?

- A 10-20 characters, for brevity
- B 50-60 characters, so search results do not truncate it
- C Exactly 100 characters
- D There is no limit

5.1.Q6 Meaning EASY A page has two **<h1>** tags. Why is that an on-page fault?

- A Two H1s are invalid HTML
- B A page should have exactly one H1 naming its single main topic; multiple H1s make competing topic claims
- C It doubles the page weight
- D Screen readers ignore all H1s

5.1.Q7 Structure EASY An **<img>** has **alt=""** (empty). Is that always a mistake?

- A Yes, every image needs descriptive alt text
- B No — an intentionally empty alt marks a decorative image so screen readers skip it; only a missing alt attribute is a fault
- C Yes, empty alt breaks indexing
- D It depends on the file format

5.1.Q8 Transfer MEDIUM A **<meta name="robots" content="noindex, follow">** is on an important page. What is the consequence?

5.1.Q9 Recall MEDIUM Why prefer **`html.parser.HTMLParser`** over a regex for reading a **`<title>`** containing **`&`**?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 5 – On-Page Signals and the HTML Audit

5.1.Q1. `headings: 4 | mentioning keyword: 2` then `coverage: 50.0 %`

5.1.Q2. `canonical present: https://example.com/blog/post`

5.1.Q3. `signals: {'informational': 2, 'navigational': 0, 'transactional': 0}` then `inferred intent: informational`

5.1.Q4. `5 words / 2 images = 2.5 words per image -> thin (image-heavy)`

5.1.Q5. B roughly 50-60 characters keeps the title from being clipped in the results snippet (and pixel width is the truer limit).

5.1.Q6. B one H1 states the page's main topic; several blur which topic the page is really about.

5.1.Q7. B empty alt is the correct signal for decorative images; the real fault is an image with no alt attribute at all.

5.1.Q8. The `noindex` directive removes the page from the search index entirely — it will not appear in results no matter how good its content. (`follow` only governs whether its links pass credit.)

5.1.Q9. The parser decodes HTML entities (so `&` becomes &) and handles nested/malformed markup, where a naive regex leaves the entity raw and can mis-match nested tags.

Chapter 6 · Keyword Research and Intent as Data

Score, prioritise and cluster keywords; classify SERP intent; model difficulty against volume.

Chapter Skill Map

What this chapter adds: In Keyword Research and Intent as Data, the focus is score, prioritise and cluster keywords; classify serp intent; model difficulty against volume. You practise it across 35 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 6 assumes the reading habits from Chapter 5: On-Page Signals and the HTML Audit. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 7, Canonicalization, Duplicate and Thin Content, reuses this chapter's discipline with a new kind of problem.

1 **Projects 191-201**	2 **Projects 202-212**	3 **Projects 213-225**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

A keyword is not a word — it is a row of data: a query, an intent, a volume, a difficulty.

stop guessing, start scoring

Keyword research feels like brainstorming, but the moment you have a list it becomes a spreadsheet, and a spreadsheet is just rows you can filter, score, and sort. Every keyword carries the same fields: the *phrase* a user types, the *intent* behind it, an estimate of monthly search *volume*, and a *difficulty* score for how hard the first page is to win. Once those four numbers sit in a row, "which keyword should I target?" stops being an opinion and becomes a calculation.

The single most important field is not volume — it is intent. Intent is *why* someone searched. Four classes cover almost everything: informational (they want to learn — "how to clean suede shoes"), navigational (they want a specific site — "nike store login"), commercial (they are comparing before buying — "best running shoes"), and transactional (they are ready to act — "buy nike air max"). Match the wrong content to the intent and you can rank #1 and still convert no one.

The beautiful part: you can often read intent straight off the words, with no SERP and no tool. Certain trigger words give it away. "How", "what", "why", "guide" signal informational. "Buy", "price", "cheap", "order" signal transactional. "Best", "top", "review", "vs" signal commercial. A handful of `if` checks turns a raw phrase into a labelled row:

```
keywords = ['how to clean suede shoes', 'buy nike air max',
            'best running shoes', 'nike store login']
def classify(kw):
```

```
    w = kw.split()
    if any(t in w for t in ('how', 'what', 'why', 'guide')):
        return 'informational'
    if any(t in w for t in ('buy', 'price', 'cheap', 'order')):
        return 'transactional'
    if any(t in w for t in ('best', 'top', 'review', 'vs')):
        return 'commercial'
    return 'navigational'
for kw in keywords:
    print(f'{classify(kw):14} {kw}')
```

```
output
informational  how to clean suede shoes
transactional  buy nike air max
commercial     best running shoes
navigational   nike store login
```

That tiny function is the engine of the whole chapter. Once each keyword has an intent label and a couple of numbers, every "strategy" question — what to write, what to prioritise, which pages compete — reduces to filtering and sorting those rows. *label first, then sort*

SEARCH INTENT

The goal behind a query, usually one of four classes: **informational** (learn), **navigational** (reach a known site), **commercial** (compare before buying), **transactional** (act now). It decides what kind of page can rank.

SEARCH VOLUME

An estimate of how many times a keyword is searched per month. Demand, not difficulty — a big number is worthless if you can never rank for it.

KEYWORD DIFFICULTY

A 0–100 estimate of how hard it is to rank on page one, based on the strength of the pages already there. Higher means more entrenched competition.

PRIORITY SCORE

A single number that combines volume, intent value, and difficulty so a keyword list can be ranked. A common form is `volume × intent_weight ÷ difficulty`.

KEYWORD CLUSTER

A group of keywords that share intent and topic and so belong on one page. Targeting them with separate pages wastes effort and splits authority.

LONG-TAIL KEYWORD

A longer, more specific query (often 4+ words). Lower volume but lower difficulty and higher intent, so it usually converts better.

KEYWORD CANNIBALIZATION

When two or more pages on your own site target the same keyword, competing with each other and splitting rankings instead of one page winning.

Intent is a label you can read off the words

Before volume, before difficulty, decide *why* the searcher is searching, because intent decides what content can rank at all. A page that sells shoes will never win "how to clean suede shoes" — that SERP is full of guides. Intent comes in four flavours, and you can usually guess it from trigger words alone. The same trigger-word idea also maps a keyword to a funnel stage — awareness, consideration, decision — which tells you whether to write a guide, a comparison, or a pricing page:

```
def stage(kw):
    w = set(kw.split())
    if w & {'what', 'how', 'guide', 'is'}: return 'awareness'
    if w & {'best', 'top', 'review', 'vs'}: return 'consideration'
    if w & {'buy', 'price', 'plan', 'demo'}: return 'decision'
    return 'unknown'
for kw in ['what is seo', 'best seo tools', 'buy seo plan']:
    print(f'{stage(kw):14} {kw}')
```

```
output
awareness      what is seo
consideration  best seo tools
decision       buy seo plan
```

Set intersection (`w & {...}`) is the trick: split the phrase into a set of words, intersect with a set of trigger words, and a non-empty result means a match. The same pattern scales to summarising a whole list — count keywords per intent and you get a portfolio check. If a "buy" brand has 70% informational keywords, the content mix is pointed at the wrong stage of the funnel.

Volume versus difficulty: the two-axis trade-off

Every keyword lives at a point on two axes: how much traffic it could send (volume) and how hard it is to win (difficulty). High volume with high difficulty is a trap — "seo" gets 40,000 searches a month and you will never crack page one. A raw 0–100 difficulty is hard to act on, so the first move is to `band` it into easy / medium / hard, turning a number into a decision about where to start:

```
keywords = {'seo': 12, 'best seo tool': 45,
            'enterprise seo platform': 78, 'cheap seo': 30}
def band(d):
    if d < 30: return 'easy'
    if d < 60: return 'medium'
    return 'hard'
for kw in sorted(keywords):
    print(f'{band(keywords[kw]):7} ({keywords[kw]:>2})  {kw}')
```

```
output
medium  (45)  best seo tool
medium  (30)  cheap seo
hard    (78)  enterprise seo platform
easy    (12)  seo
```

The smartest one-line filter combines both axes: rank by a `volume-to-difficulty ratio` for bang-for-buck, but also impose a hard difficulty ceiling so you never chase impossible terms. The ratio alone would rank "seo" first (40000 ÷ 90 = 444), but the ceiling vetoes it — high ratio, still unreachable.

The long tail: where most queries actually live

Search demand is not concentrated in a few fat head terms. It is spread across a vast number of rare, specific phrases — the `long tail`. "Shoes" is a head term: huge volume, brutal difficulty. "Best running shoes for flat feet" is long-tail: small volume, low difficulty, and a searcher who knows exactly what they want. The crudest long-tail detector is just word count:

```
keywords = ['shoes', 'running shoes',
            'best running shoes for flat feet',
            'mens trail running shoes 2026']
for kw in keywords:
    n = len(kw.split())
    tag = 'long-tail' if n >= 4 else 'head'
    print(f'{n} words  {tag:10} {kw}')
```

```
output
1 words  head       shoes
2 words  head       running shoes
6 words  long-tail  best running shoes for flat feet
5 words  long-tail  mens trail running shoes 2026
```

A finer split adds a middle "body" band (head = 1 word, body = 2–3, long-tail = 4+). The strategic point: a hundred long-tail wins can out-traffic one impossible head term, and they convert better because the intent is sharper.

many small, specific wins beat one giant moonshot

Clustering: keywords that belong on one page

A list of 500 keywords is not 500 pages — many of them are the same topic in different words. Grouping them into clusters tells you how many pages you actually need and which keywords share a home. A fast first pass is to group by a shared token (here the last word, the head noun):

```
from collections import defaultdict
keywords = ['running shoes', 'running shorts', 'trail shoes',
            'shoes for kids', 'best shorts']
clusters = defaultdict(list)
for kw in keywords:
    clusters[kw.split()[-1]].append(kw)
for stem in sorted(clusters):
    print(f'{stem}: {sorted(clusters[stem])}')
```

```
output
kids: ['shoes for kids']
shoes: ['running shoes', 'trail shoes']
shorts: ['best shorts', 'running shorts']
```

Each cluster then earns one pillar page targeting its strongest keyword. The deeper test of whether two keywords share a cluster is whether their SERPs look alike: if "seo tools" and "best seo tools" return mostly the same ranking domains, they share intent and should be one page, not two.

Cannibalization: when your own pages compete

The opposite failure of clustering is keyword cannibalization — two of your *own* pages chasing the same keyword. Google does not know which to rank, so it splits signals between them and neither wins. You catch it by inverting your page→keyword map into keyword→pages and flagging any keyword owned by more than one URL:

```
from collections import defaultdict
pages = {'/running-shoes': 'best running shoes',
         '/shoes/running': 'best running shoes',
         '/trail-shoes': 'trail running shoes'}
target = defaultdict(list)
for url, kw in pages.items():
    target[kw].append(url)
for kw in sorted(target):
    urls = sorted(target[kw])
    if len(urls) > 1:
        print(f'CANNIBALIZATION: {kw!r} -> {urls}')
```

```
    else:
        print(f'ok: {kw!r} -> {urls[0]}')
```

```
output
CANNIBALIZATION: 'best running shoes' -> ['/running-shoes', '/shoes/running']
ok: 'trail running shoes' -> /trail-shoes
```

The fix is to merge or redirect: pick one canonical page per keyword and consolidate. The whole chapter now composes — classify intent, weight volume by it, divide by difficulty — into a single ranked decision table, the heart of a keyword strategy:

```
weights = {'informational': 0.5, 'commercial': 1.5,
           'transactional': 2.0, 'navigational': 0.3}
def intent(kw):
    w = set(kw.split())
    if w & {'buy', 'price', 'order'}: return 'transactional'
    if w & {'best', 'top', 'review'}: return 'commercial'
    if w & {'what', 'how', 'why'}: return 'informational'
    return 'navigational'
rows = [('best running shoes', 8000, 45),
        ('buy running shoes online', 3000, 30),
        ('nike store', 12000, 70)]
scored = []
for kw, vol, diff in rows:
    i = intent(kw)
    scored.append((round(vol * weights[i] / diff, 1), i, kw))
for score, i, kw in sorted(scored, reverse=True):
    print(f'{score:>7}  {i:14} {kw}')
```

```
output
  266.7  commercial     best running shoes
  200.0  transactional  buy running shoes online
   51.4  navigational   nike store
```

"nike store" has the most volume (12,000) yet ranks last: it is navigational (people want Nike's own site, weight 0.3) and difficult (70). The score sees what raw volume cannot.

volume is the loudest number and the most misleading

Example 1

Score and rank three keywords with priority = volume × intent_weight ÷ difficulty. "running shoes" (vol 9000, diff 60, weight 2); "best running shoes 2026" (vol 4000, diff 30, weight 3); "what are running shoes" (vol 1200, diff 15, weight 1).

SOLUTION

1. "running shoes": 9000 × 2 ÷ 60 = 18000 ÷ 60 = `300.0`.
2. "best running shoes 2026": 4000 × 3 ÷ 30 = 12000 ÷ 30 = `400.0`.
3. "what are running shoes": 1200 × 1 ÷ 15 = 1200 ÷ 15 = `80.0`.
4. Sort descending by score: 400.0, then 300.0, then 80.0.

Ranked: best running shoes 2026 (400.0) > running shoes (300.0) > what are running shoes (80.0). The high-intent, low-difficulty term beats the higher-volume one. *biggest volume did not win*

Example 2

Two of your pages both target "best running shoes": /running-shoes and /shoes/running. A third page /trail-shoes targets "trail running shoes". Which keyword is cannibalized, and what is the fix?

SOLUTION

1. Invert page→keyword into keyword→pages. "best running shoes" maps to `both /running-shoes and /shoes/running`.
2. "trail running shoes" maps to a single page, /trail-shoes — no conflict.
3. A keyword owned by more than one URL is cannibalized: your pages compete and split rankings.

"best running shoes" is cannibalized (two pages target it). Fix: pick one canonical page and merge or 301-redirect the other into it. *one keyword, one home*

Example 3

Classify the intent of "cheap trainers price" and "how to lace running shoes" using trigger words.

SOLUTION

1. "cheap trainers price" contains `cheap` and `price` — both transactional triggers (ready to buy).
2. "how to lace running shoes" starts with `how` — an informational trigger (wants to learn).
3. Match content to each: a product/category page for the first, a how-to guide for the second.

Transactional and informational respectively. Same product space, opposite content — sell to one, teach the other. *intent, not topic, picks the page type*

Mental-Math Shortcut

One keyword, one row, one home. Read the intent off the words first, then turn the rest into numbers — `volume × intent_weight ÷ difficulty` — and *sort the rows*. The highest-volume keyword is the loudest and the most misleading; let the score, not the big number, pick your targets. And every keyword you keep gets exactly one page that owns it, or your own pages cannibalize each other.

Common Mistakes

- Chasing volume and ignoring intent — ranking #1 for an informational query with a product page converts no one, because the searcher came to learn, not to buy.
- Picking keywords by volume alone, so you target high-volume head terms whose difficulty means you never reach page one.
- Building a separate page for every keyword instead of clustering — you fragment authority and end up with thin, overlapping pages competing with each other.
- Letting two pages target the same keyword (cannibalization) and wondering why neither ranks; the fix is to merge or redirect to one canonical page.

This chapter contains 35 hands-on mini-projects (Projects 191–225). Type each one out, run it, and experiment.

Project 191 Score and Rank Keywords by Priority

The Idea Behind It

This project turns three keyword dicts into a comparable shortlist. A loop computes score as volume times intent_weight divided by difficulty, rounded to one decimal, then sorted with a negative-score key and keyword tiebreak ranks them. The formula deliberately rewards high demand and strong intent while penalising contested terms, so one number captures the trade-off you weigh by hand.

What You'll Build & Learn

Collapse volume, intent, and difficulty into a single priority score, then print keywords ranked best-first.

- Storing keyword metrics in dictionaries
- A weighted scoring formula in code
- Sorting with a negative-key descending order
- Stable tiebreaks using a secondary key

Skill Roadmap

Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 192 changes the surface problem while preserving the underlying method. *progress check*

Reading target: score and rank keywords by priority is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"{k['score']:>6} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for k in keywords:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{k['score']:>6} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for k in keywords:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score and Rank Keywords by Priority: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, running, shoes, volume. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: for k in keywords: | Evidence: print(f"{k['score']:>6} {k['keyword']}")

🛠️ Reader to Writer Bridge

1. Read: explain score and rank keywords by priority in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 192 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{k['score']:>6} {k['keyword']}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of score and rank keywords by priority and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Each keyword gets a derived `score` field, then sorting by negative score (with the keyword as a deterministic tiebreaker) puts the highest-value opportunity first.

```
keywords = [
    {'keyword': 'running shoes', 'volume': 9000, 'difficulty': 60,
'intent_weight': 2},
    {'keyword': 'best running shoes 2026', 'volume': 4000, 'difficulty': 30,
'intent_weight': 3},
    {'keyword': 'what are running shoes', 'volume': 1200, 'difficulty': 15,
'intent_weight': 1},
]
for k in keywords:
    k['score'] = round(k['volume'] * k['intent_weight'] / k['difficulty'], 1)
ranked = sorted(keywords, key=lambda k: (-k['score'], k['keyword']))
for k in ranked:
    print(f"{k['score']:>6}  {k['keyword']}")
```

```
output
 400.0  best running shoes 2026
 300.0  running shoes
  80.0  what are running shoes
```

How it works:

1. A list of dicts holds keyword, volume, difficulty, and intent_weight for three running-shoe terms.
2. The for loop writes a new score key into each dict using the volume times intent_weight over difficulty formula.
3. sorted uses a lambda returning a tuple of negative score then keyword, so higher scores rank first with alphabetical tiebreaks.
4. A final loop prints the right-aligned score beside each keyword in priority order.

Try it:

1. Add an estimated cost-per-click field and fold it into the score formula.
2. Print only keywords scoring above a chosen threshold instead of all of them.
3. Swap the difficulty divisor for the square root of difficulty to soften its effect.
4. Add a keyword with volume 20000 and difficulty 90 and see where it lands.

⚠ Common Mistakes

- Dividing by difficulty without guarding against a zero difficulty would raise ZeroDivisionError.
- Sorting by `k['score']` ascending lists the worst keyword first.
- Dropping the `k['keyword']` tiebreaker makes two equal scores order unpredictably.

Skills gained dict scoring | sorted with lambda | f-string alignment

→ Where You'll Use This: Every keyword research deliverable ends in a ranked shortlist; this scoring pattern is the spine of any prioritisation spreadsheet handed to a content team.

Mental Model

Like a recipe that boils three ingredients down to one flavour score, so you taste-test keywords against each other instead of guessing.

Project 192 Classify Search Intent by Trigger Words

The Idea Behind It

Here a classify function reads the words of each keyword and returns an intent label by checking membership against ordered trigger-word tuples. Question words mean informational, purchase words mean transactional, comparison words mean commercial, and anything left falls through to navigational. Splitting first means whole-word matching, so it never misfires on a substring buried inside another term.

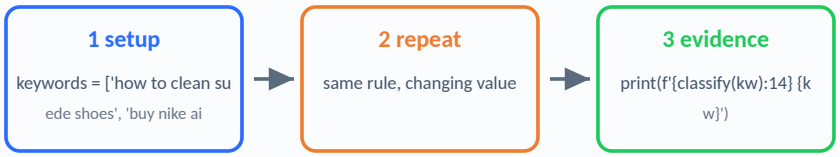
What You'll Build & Learn

Label each keyword with a search intent using only trigger words, no SERP lookup required.

- Search intent from trigger vocabulary
- any() over a tuple of triggers
- Order of checks acts as priority
- A default category for leftovers

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 191: score and rank keywords by priority. Project 193 changes the surface problem while preserving the underlying method.



progress check

Reading target: classify search intent by trigger words is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = ['how to clean suede shoes', 'buy nike air max', 'best running shoes', 'nike store login', 'cheap trainers price']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{classify(kw):14} {kw}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['how to clean suede shoes', 'buy nike air max', 'best running shoes', 'nike store login', 'cheap trainers price']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if any(t in w for t in ('how', 'what', 'why', 'guide', 'tutorial')):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{classify(kw):14} {kw}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if any(t in w for t in ('how', 'what', 'why', 'guide', 'tutorial')):`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Classify Search Intent by Trigger Words: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, how, to, clean, suede. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = ['how to clean suede shoes', 'buy nike air max', 'best runni... | Core: if any(t in w for t in ('how', 'what', 'why', 'guide', 'tutorial')): | Evidence: print(f'{classify(kw):14} {kw}')

🛠️ Reader to Writer Bridge

1. Read: explain classify search intent by trigger words in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 191.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 193 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{classify(kw):14} {kw}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = ['how to clean suede shoes', 'buy nike air max', 'best running shoes', 'nike store login', 'cheap trainers price']` and say

why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of classify search intent by trigger words and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Checking each keyword's words against ordered trigger sets assigns the first matching intent, with navigational as the catch-all default.

```
keywords = ['how to clean suede shoes', 'buy nike air max', 'best running
shoes', 'nike store login', 'cheap trainers price']
def classify(kw):
    w = kw.split()
    if any(t in w for t in ('how', 'what', 'why', 'guide', 'tutorial')):
        return 'informational'
    if any(t in w for t in ('buy', 'price', 'cheap', 'order', 'discount')):
        return 'transactional'
    if any(t in w for t in ('best', 'top', 'review', 'vs', 'compare')):
        return 'commercial'
    return 'navigational'
for kw in keywords:
    print(f'{classify(kw):14} {kw}')
```

```
output
informational  how to clean suede shoes
transactional  buy nike air max
commercial     best running shoes
navigational   nike store login
transactional  cheap trainers price
```

How it works:

1. A list of five mixed keywords feeds the classify function.
2. classify splits the keyword into words, then uses any() to test if any trigger from each tuple appears in that word list.
3. The checks run informational, transactional, then commercial; the first match wins, and unmatched keywords return navigational.
4. The output loop prints each left-padded label beside its keyword.

Try it:

1. Add a transactional trigger for 'coupon' and 'deal' and retest the list.
2. Return all matching intents as a list instead of stopping at the first.
3. Make the navigational fallback only fire when a known brand word is present.

4. Add 'near me' handling to flag local intent separately.

⚠ Common Mistakes

- Order matters: checking 'best' before 'buy' would misclassify 'buy the best phone' as commercial.
- Using `t in kw` (substring) instead of `t in w` (whole word) matches 'how' inside 'show'.
- Forgetting the default return leaves keywords with no trigger word unclassified (None).

Skills gained intent classification | tuple membership | early return

→ Where You'll Use This: Bulk intent tagging is the first column SEOs add to a raw keyword export, deciding whether each term needs a guide, a comparison, or a product page.

Mental Model

Like a postal sorter glancing at one word on each envelope to drop it into the right bin without reading the whole letter.

Project 193 Cluster Keywords by Shared Head Term

The Idea Behind It

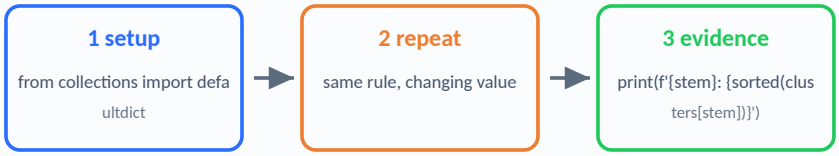
Grouping keywords by their final word is the trick here. A defaultdict of lists takes each keyword, splits it, grabs the last token as a crude head term, and appends the phrase under that stem. Sorting the stems then printing each sorted group reveals topic clusters forming around shared nouns. It is blunt but instantly shows which phrases want to live together.

What You'll Build & Learn

Bucket keywords into emerging topic clusters keyed on their last word.

- defaultdict(list) for grouping
- Using the last token as a stem
- Sorting keys and values for stable output

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 192: classify search intent by trigger words. Project 194 changes the surface problem while preserving the underlying method. *progress check*

Reading target: cluster keywords by shared head term is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{stem}: {sorted(clusters[stem])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`keywords = ['running shoes', 'running shorts', 'trail shoes', 'shoes for kids', 'best shorts']`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{stem}: {sorted(clusters[stem])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
keywords = ['running shoes', 'running shorts', 'trail shoes', 'shoes for kids', 'best shorts']
```

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Cluster Keywords by Shared Head Term: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: collections, defaultdict, keywords, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: keywords = ['running shoes', 'running shorts', 'trail shoes', 'shoes fo... | Evidence: print(f'{stem}: {sorted(clusters[stem])}')

🛠️ Reader to Writer Bridge

1. Read: explain cluster keywords by shared head term in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 192.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 194 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{stem}: {sorted(clusters[stem])}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cluster keywords by shared head term and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A `defaultdict(list)` keyed on the final token groups keywords sharing a head noun; sorting the keys and members keeps the output stable.

```
from collections import defaultdict
keywords = ['running shoes', 'running shorts', 'trail shoes', 'shoes for kids',
'best shorts']
clusters = defaultdict(list)
for kw in keywords:
    stem = kw.split()[-1]
    clusters[stem].append(kw)
for stem in sorted(clusters):
    print(f'{stem}: {sorted(clusters[stem])}')
```

```
output
kids: ['shoes for kids']
shoes: ['running shoes', 'trail shoes']
shorts: ['best shorts', 'running shorts']
```

How it works:

1. A defaultdict(list) named clusters auto-creates an empty list for any new stem.
2. The loop splits each keyword and takes index [-1], the last word, as the grouping stem.
3. Each keyword is appended to the list under its stem.
4. Iterating sorted stems prints each cluster with its members sorted alphabetically.

Try it:

1. Cluster on the first word instead of the last and compare the groupings.
2. Skip keywords whose stem is a stopword like 'the' or 'for'.
3. Print only clusters that contain two or more keywords.
4. Cluster on the first word instead and compare the groupings.

⚠ Common Mistakes

- Using the last word naively misgroups 'shoes for kids' under 'kids' instead of 'shoes'.
- A plain dict would raise KeyError on first insert without `setdefault` or `defaultdict`.

- Forgetting to sort the cluster members leaves their order at the mercy of input order.

Skills gained keyword clustering | defaultdict | string split

→ Where You'll Use This: Quick last-word clustering gives a first-pass map of which keywords belong on the same page before you invest in heavier semantic clustering tools.

Mental Model

Like sorting socks by colour: a rough rule that gets matching pairs near each other fast, even if a few oddballs end up in the wrong pile.

Project 194 Bucket Difficulty into Easy, Medium, Hard

The Idea Behind It

A band function maps a numeric difficulty into easy, medium, or hard using two thresholds at 30 and 60. The keywords dict pairs terms with their scores; iterating the sorted keys looks up each difficulty and prints the band, the padded number, and the keyword. Turning a continuous 0-to-100 metric into three labels makes the data instantly actionable instead of just numeric.

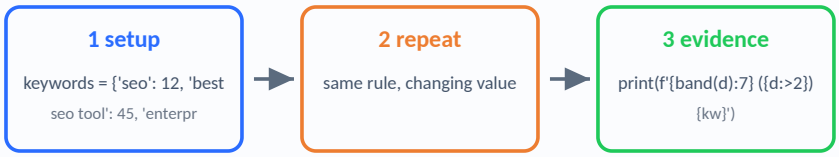
What You'll Build & Learn

Convert raw difficulty scores into easy, medium, and hard labels for fast triage.

- Threshold banding of a numeric metric
- Cascading if checks as boundaries
- Looking up values by sorted key

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 193: cluster keywords by shared head term. Project 195 changes the surface problem while preserving the underlying method. *progress check*



Reading target: bucket difficulty into easy, medium, hard is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = {'seo': 12, 'best seo tool': 45, 'enterprise seo platform': 78, 'cheap seo': 30}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{band(d):7} ({d:>2}) {kw}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = {'seo': 12, 'best seo tool': 45, 'enterprise seo platform': 78, 'cheap seo': 30}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if d < 30: return 'easy'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{band(d):7} ({d:>2}) {kw}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Bucket Difficulty into Easy, Medium, Hard: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, seo, best, tool, enterprise. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = {'seo': 12, 'best seo tool': 45, 'enterprise seo platform':... | Core: if d < 30: return 'easy' | Evidence: print(f'{band(d):7} ({d:>2}) {kw}')

🛠️ Reader to Writer Bridge

1. Read: explain bucket difficulty into easy, medium, hard in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 193.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 195 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{band(d):7} ({d:>2}) {kw}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = {'seo': 12, 'best seo tool': 45, 'enterprise seo platform': 78, 'cheap seo': 30}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of bucket difficulty into easy, medium, hard and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Cascading `if` thresholds map a continuous difficulty into three named bands; the first matching range wins so order of the cutoffs matters.

```
keywords = {'seo': 12, 'best seo tool': 45, 'enterprise seo platform': 78,
'cheap seo': 30}
def band(d):
    if d < 30: return 'easy'
    if d < 60: return 'medium'
    return 'hard'
for kw in sorted(keywords):
    d = keywords[kw]
    print(f'{band(d):7} ({d:>2})  {kw}')
```

```
output
medium  (45)  best seo tool
medium  (30)  cheap seo
hard    (78)  enterprise seo platform
easy    (12)  seo
```

How it works:

1. The keywords dict maps four SEO phrases to integer difficulty scores.
2. band returns 'easy' below 30, 'medium' below 60, otherwise 'hard', using ordered if statements as cut points.
3. The loop walks the dict's sorted keys, reads each difficulty, and calls band on it.
4. Output prints the padded band, the difficulty in parentheses, and the keyword.

Try it:

1. Add a fourth 'very hard' band for scores at or above 80.
2. Make the thresholds function arguments so they can be tuned per client.
3. Sort the output by difficulty instead of alphabetically by keyword.
4. Add a fourth band 'very hard' for difficulty 80 and above.

⚠ Common Mistakes

- A difficulty of exactly 30 lands in 'medium' because the test is `< 30`, not `<= 30`.
- Reordering the `if` checks (hard first) would mislabel low scores.
- Iterating the dict without sorting gives nondeterministic output order.

Skills gained difficulty banding | threshold logic | dict iteration

→ Where You'll Use This: Difficulty bands appear in nearly every keyword report so non-technical stakeholders can see at a glance where the quick wins versus the long campaigns live.

Mental Model

Like a ski slope's green, blue, and black diamond markers: one symbol tells you whether to attempt the run without reading a gradient chart.

Project 195 Detect Long-Tail Keywords by Word Count

The Idea Behind It

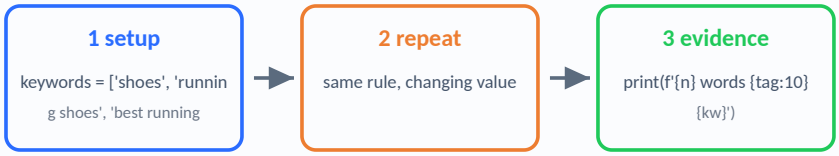
This counts the words in each keyword and tags it long-tail when four or more words are present, otherwise head. The split-and-len pattern is the whole detector: more words means a more specific, lower-competition query. Printing the word count next to the tag and the phrase shows directly why a six-word term reads as long-tail while a two-word phrase stays a head term.

What You'll Build & Learn

Flag long-tail keywords by counting words, separating specific phrases from broad head terms.

- Word count as a length proxy
- Inline conditional expression for tagging
- split() to tokenise a phrase

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 194: bucket difficulty into easy, medium, hard. Project 196 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect long-tail keywords by word count is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = ['shoes', 'running shoes', 'best running shoes for flat feet', 'mens trail running shoes 2026']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{n} words {tag:10} {kw}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['shoes', 'running shoes', 'best running shoes for flat feet', 'mens trail running shoes 2026']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`tag = 'long-tail' if n >= 4 else 'head'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{n} words {tag:10} {kw}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `tag = 'long-tail' if n >= 4 else 'head'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Long-Tail Keywords by Word Count: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, shoes, running, best, flat. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = ['shoes', 'running shoes', 'best running shoes for flat feet... | Core: tag = 'long-tail' if n >= 4 else 'head' | Evidence: print(f'{n} words {tag:10} {kw}')

🛠️ Reader to Writer Bridge

1. Read: explain detect long-tail keywords by word count in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 194.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 196 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{n} words {tag:10} {kw}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = ['shoes', 'running shoes', 'best running shoes for flat feet', 'mens trail running shoes 2026']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect long-tail keywords by word count and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Splitting on whitespace and counting tokens separates short head terms from descriptive long-tail phrases at a four-word threshold.

```
keywords = ['shoes', 'running shoes', 'best running shoes for flat feet', 'mens
trail running shoes 2026']
for kw in keywords:
    n = len(kw.split())
```

```
    tag = 'long-tail' if n >= 4 else 'head'
    print(f'{n} words  {tag:10} {kw}')
```

```
output
1 words  head       shoes
2 words  head       running shoes
6 words  long-tail  best running shoes for flat feet
5 words  long-tail  mens trail running shoes 2026
```

How it works:

1. A list holds four keywords of varying length.
2. For each, len(kw.split()) counts the words into n.
3. An inline conditional sets tag to 'long-tail' when n is four or more, else 'head'.
4. The print shows the count, the padded tag, and the keyword.

Try it:

1. Lower the long-tail threshold to three words and see what flips.
2. Add a third 'mid-tail' tag for exactly two or three words.
3. Count characters instead of words and compare the classifications.
4. Lower the threshold to 3 and see which keywords flip.

⚠ Common Mistakes

- Counting characters instead of words flags any long single word as long-tail.
- A keyword with double spaces would over-count words unless you normalise whitespace.
- Hard-coding the threshold at 3 vs 4 quietly reclassifies three-word terms.

Skills gained long-tail detection | word counting | ternary expression

→ Where You'll Use This: Long-tail flagging steers content planning toward specific, easier-to-rank, higher-converting queries that often beat chasing crowded head terms.

Mental Model

Like judging a question's specificity by its length: 'shoes?' is vague, but 'best trail shoes for flat feet?' tells you exactly what they want.

Project 196 Detect Keyword Cannibalization

The Idea Behind It

Cannibalization happens when several URLs chase the same keyword and split each other's rankings. The code inverts a page-to-keyword dict into a defaultdict mapping each target keyword to the list of URLs aiming at it.

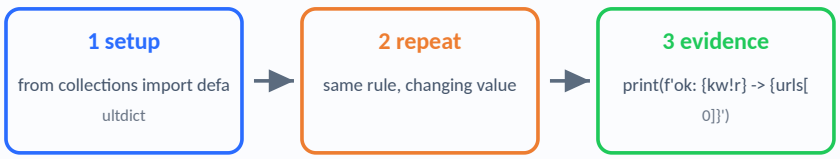
Any keyword with more than one URL is printed with a CANNIBALIZATION warning; single-owner keywords print as ok. The inversion is what surfaces the hidden conflict.

What You'll Build & Learn

Detect keyword cannibalization by finding any keyword targeted by more than one page.

- Inverting a dict to group by value
- defaultdict(list) for many-to-one mapping
- Branching on list length to flag conflicts

🧭 Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 195: detect long-tail keywords by word count. Project 197 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect keyword cannibalization is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'ok: {kw!r} -> {urls[0]}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if len(urls) > 1:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'ok: {kw!r} -> {urls[0]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if len(urls) > 1:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Keyword Cannibalization: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: collections, defaultdict, pages, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: if len(urls) > 1: | Evidence: print(f'ok: {kw!r} -> {urls[0]}')

🛠️ Reader to Writer Bridge

1. Read: explain detect keyword cannibalization in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 195.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 197 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'ok: {kw!r} -> {urls[0]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect keyword cannibalization and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Inverting the page-to-keyword map into keyword-to-URLs reveals any keyword claimed by more than one page, which is the definition of cannibalization.

```
from collections import defaultdict
pages = {
    '/running-shoes': 'best running shoes',
    '/shoes/running': 'best running shoes',
    '/trail-shoes': 'trail running shoes',
}
target = defaultdict(list)
for url, kw in pages.items():
    target[kw].append(url)
for kw in sorted(target):
    urls = sorted(target[kw])
    if len(urls) > 1:
        print(f'CANNIBALIZATION: {kw!r} targeted by {urls}')
    else:
        print(f'ok: {kw!r} -> {urls[0]}')
```

```
output
CANNIBALIZATION: 'best running shoes' targeted by ['/running-shoes',
'/shoes/running']
ok: 'trail running shoes' -> /trail-shoes
```

How it works:

1. The pages dict maps three URLs to the keyword each one targets.
2. A defaultdict(list) called target collects every URL under its keyword as the loop walks pages.items().
3. Sorting keywords, the code checks if a keyword's URL list has more than one entry.
4. Multi-URL keywords print a CANNIBALIZATION line; single-URL keywords print an ok line.

Try it:

1. Report the count of conflicting URLs alongside each warning.
2. Read the page-to-keyword pairs from a CSV file instead of a literal dict.
3. Suggest keeping the shortest URL and redirecting the rest.
4. Add a third page also targeting 'best running shoes' and watch the conflict grow.

⚠ Common Mistakes

- Building the map keyword-first instead of inverting it misses that pages, not keywords, are the keys.
- Comparing raw keyword strings without normalising case treats 'Shoes' and 'shoes' as different targets.
- Reporting a single-URL keyword as a conflict by checking `>= 1` instead of `> 1`.

Skills gained cannibalization audit | dict inversion | conditional reporting

→ Where You'll Use This: Cannibalization checks run during site audits to find pages competing against each other so you can consolidate, redirect, or re-target the weaker ones.

⚡ Mental Model

Like two sales reps cold-calling the same client: instead of one strong pitch, the prospect gets two diluted ones and trust splits between them.

Project 197 Compute Term Frequency for a Seed Across Pages

💡 The Idea Behind It

Term frequency measures how densely a page mentions a seed word, normalised by length so long pages are not unfairly favoured. The code splits each document body, counts how often the term appears, and divides by total word count. Page p1, packed with 'seo', scores 0.6, while p3 that never mentions it scores 0.0, giving a clean on-topic signal per page.

What You'll Build & Learn

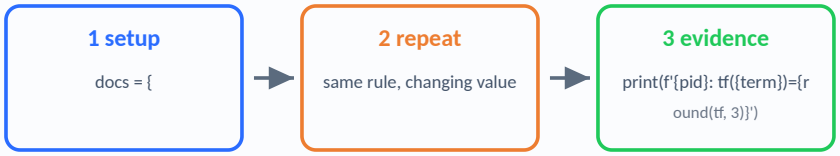
Compute normalised term frequency of a seed keyword across several page bodies.

- Term frequency as count over length
- list.count() for token tallying

- Why normalisation beats raw counts

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 196: detect keyword cannibalization. Project 198 changes the surface problem while preserving the underlying method.



progress check

Reading target: compute term frequency for a seed across pages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `docs = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{pid}: tf({term})={round(tf, 3)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`docs = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for pid in sorted(docs):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

Move	Code to inspect	Why it matters
3. Check the evidence	`print(f'{pid}: tf({term})={round(tf, 3)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for pid in sorted(docs):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute Term Frequency for a Seed Across Pages: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: docs, p1, seo, audit, report. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: docs = { | Core: for pid in sorted(docs): | Evidence: print(f'{pid}: tf({term})={round(tf, 3)}')

Reader to Writer Bridge

1. Read: explain compute term frequency for a seed across pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 196.
   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.

4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 198 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{pid}: tf({term})={round(tf, 3)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `docs = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compute term frequency for a seed across pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Dividing the seed's occurrence count by the document's token count gives term frequency, a length-normalised density that beats a raw count.

```
docs = {
    'p1': 'seo audit seo report seo',
    'p2': 'content marketing seo guide',
    'p3': 'link building tactics',
}
term = 'seo'
for pid in sorted(docs):
    body = docs[pid].split()
    tf = body.count(term) / len(body)
    print(f'{pid}: tf({term})={round(tf, 3)}')
```

```
output
p1: tf(seo)=0.6
p2: tf(seo)=0.25
p3: tf(seo)=0.0
```

How it works:

1. A docs dict maps three page ids to their text bodies, and term is set to 'seo'.
2. For each sorted page id, the body is split into a word list.
3. tf is the body's count of term divided by the body's length.
4. Each page id prints with its rounded term frequency.

Try it:

1. Lowercase each body before counting so 'SEO' and 'seo' both count.
2. Compute term frequency for a list of seed terms at once.

3. Flag any page whose term frequency exceeds a stuffing threshold.
4. Switch the seed to 'building' and re-run.

⚠ Common Mistakes

- Using a raw count instead of dividing by length favours longer documents.
- Counting before lowercasing makes 'SEO' and 'seo' count as different terms.
- Dividing by zero on an empty document body would raise an error.

Skills gained term frequency | text normalisation | string counting

→ Where You'll Use This: Term frequency underpins on-page content scoring, helping you judge whether a page covers its target keyword densely enough without over-stuffing it.

Mental Model

Like measuring the salt concentration of soup rather than total grains: a big pot and a small cup can taste equally salty once you account for volume.

Project 198 Measure Keyword-Set Overlap with Jaccard

The Idea Behind It

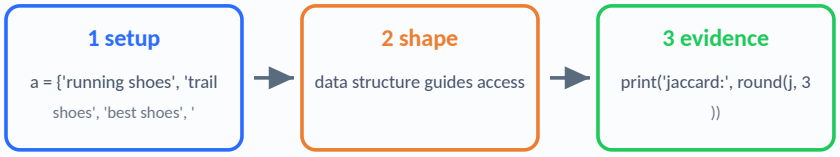
Jaccard similarity compresses how much two keyword sets overlap into one number between zero and one. The code takes set intersection and union, then divides their sizes. With two of five total keywords shared, the result is 0.4. Using Python sets makes the intersection and union operators do all the heavy lifting, and printing the shared members shows exactly what drives the score.

What You'll Build & Learn

Measure overlap between two keyword sets with a single Jaccard similarity number.

- Jaccard as intersection over union
- Set operators & and | in Python
- Quantifying list overlap as a ratio

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 197: compute term frequency for a seed across pages. Project 199 changes the surface problem while preserving the underlying method. *progress check*

Reading target: measure keyword-set overlap with jaccard is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `a = {'running shoes', 'trail shoes', 'best shoes', 'cheap shoes'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The data structure is doing part of the thinking. Ask what the collection stores, how items are found, and what order or uniqueness it promises.
- Writing move: this project practises how to choose a data shape before writing the operation. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('jaccard:', round(j, 3))` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, shape applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`a = {'running shoes', 'trail shoes', 'best shoes', 'cheap shoes'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`j = len(inter) / len(union)`	This line depends on the chosen data shape. Ask how items are stored, found, or ordered. *slow line*
3. Check the evidence	`print('jaccard:', round(j, 3))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `j = len(inter) / len(union)`

Construction pattern

The construction is setup -> operation -> evidence. Name those three parts before worrying about every token.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Name the collection shape, then ask how an item is added, selected, transformed, or counted.

Rewrite drill

Change one literal, name, or argument and explain which later line is affected first.

Code Reading Stack

Layer	What to read
Intent	Measure Keyword-Set Overlap with Jaccard: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: running, shoes, trail, best, cheap. Names are the reader's map of roles and responsibilities.
Flow	Straight-line flow: read top to bottom as setup, operation, evidence.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: a = {'running shoes', 'trail shoes', 'best shoes', 'cheap shoes'} | Core: j = len(inter) / len(union) | Evidence: print('jaccard:', round(j, 3))

Reader to Writer Bridge

1. Read: explain measure keyword-set overlap with jaccard in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 197.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 199 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print('jaccard:', round(j, 3))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `a = {'running shoes', 'trail shoes', 'best shoes', 'cheap shoes'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of measure keyword-set overlap with jaccard and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Set intersection finds shared keywords and set union finds the total distinct keywords; their size ratio is the Jaccard index between 0 and 1.

```
a = {'running shoes', 'trail shoes', 'best shoes', 'cheap shoes'}
b = {'running shoes', 'best shoes', 'walking shoes'}
inter = a & b
union = a | b
j = len(inter) / len(union)
print('shared:', sorted(inter))
print('jaccard:', round(j, 3))
```

```
output
shared: ['best shoes', 'running shoes']
jaccard: 0.4
```

How it works:

1. Two sets a and b hold keyword phrases, with some shared and some unique.
2. inter is a & b, the shared keywords; union is a | b, every keyword across both.
3. j divides the size of inter by the size of union to get the Jaccard score.
4. The code prints the sorted shared keywords and the rounded similarity.

Try it:

1. Print the keywords unique to each set as a gap list.
2. Compare three sets pairwise and report all similarity scores.
3. Lowercase and strip every keyword before building the sets.
4. Add 'trail shoes' to set b and watch the index rise.

⚠ Common Mistakes

- Dividing by `len(a) + len(b)` double-counts the shared keywords in the denominator.
- Using lists instead of sets makes `&` and `|` invalid operations.
- Forgetting to sort the intersection before printing breaks deterministic output.

Skills gained Jaccard similarity | set operations | overlap ratio

→ Where You'll Use This: Set-overlap scores quantify how much your keyword coverage mirrors a competitor's, guiding gap analysis and showing where your strategy diverges.

Mental Model

Like overlapping two Venn-diagram circles and asking what fraction of the total area sits in the shared lens, the bigger the lens the more alike the lists.

Project 199 Group Keywords by Assigned Topic

The Idea Behind It

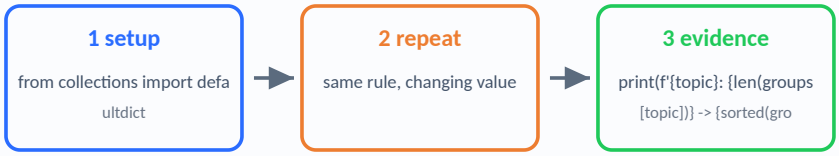
When a keyword export already carries a topic label, rolling keywords up by that label shows which themes have enough demand for a pillar page. A defaultdict of lists appends each keyword under its given topic, and the output prints each topic with its member count and sorted keywords. The grouping is driven entirely by the supplied label, not by guessing the topic.

What You'll Build & Learn

Roll keywords up by a pre-assigned topic label and report the size of each group.

- Grouping by an existing label field
- defaultdict for accumulating members
- Reporting group size alongside contents

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 198: measure keyword-set overlap with jaccard. Project 200 changes the surface problem while preserving the underlying method. *progress check*

Reading target: group keywords by assigned topic is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{topic}: {len(groups[topic])} -> {sorted(groups[topic])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{topic}: {len(groups[topic])} -> {sorted(groups[topic])}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of group keywords by assigned topic and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Iterating the keyword-to-topic map and appending into a `defaultdict(list)` inverts it into topic-to-keywords, the basis of a content cluster plan.

```
from collections import defaultdict
topics = {
    'on page seo': 'on-page',
    'meta description length': 'on-page',
    'backlink audit': 'off-page',
```

```
    'guest posting': 'off-page',
    'core web vitals': 'technical',
}
groups = defaultdict(list)
for kw, topic in topics.items():
    groups[topic].append(kw)
for topic in sorted(groups):
    print(f'{topic}: {len(groups[topic])} -> {sorted(groups[topic])}')
```

```
output
off-page: 2 -> ['backlink audit', 'guest posting']
on-page: 2 -> ['meta description length', 'on page seo']
technical: 1 -> ['core web vitals']
```

How it works:

1. The topics dict maps five keywords to topic labels like on-page or off-page.
2. A defaultdict(list) named groups appends each keyword under its topic as the loop runs.
3. Iterating sorted topics, the code reads each group's list.
4. Each line prints the topic, its member count, and the sorted keywords.

Try it:

1. Sort topics by member count so the biggest theme prints first.
2. Flag any topic with fewer than two keywords as too thin for a pillar.
3. Sum a volume field per topic instead of just counting keywords.
4. Add a 'local' topic with two keywords and see it appear.

⚠ Common Mistakes

- Swapping key and value when iterating groups by keyword instead of topic.
- Printing `groups` directly leaks the defaultdict repr instead of clean lines.
- Not sorting either the topics or the members yields run-to-run variation.

Skills gained topic grouping | defaultdict | group counting

→ Where You'll Use This: Topic roll-ups turn a flat keyword sheet into a content plan, revealing which themes carry enough keywords to justify a dedicated pillar or hub page.

Mental Model

Like tallying votes into party buckets: once each ballot is filed under its label, the size of each pile tells you where the support concentrates.

Project 200 Score Opportunity from Volume and Current Rank

The Idea Behind It

The biggest wins are high-volume keywords where you already rank but not on page one. This opportunity score multiplies volume by rank, but only when rank is worse than ten, otherwise it scores zero because page-one terms need no rescue. 'keyword research' at rank 25 tops the list while a rank-4 term scores zero. Sorting by negative opportunity surfaces the climbable giants first.

What You'll Build & Learn

Score and rank keywords by upside, favouring high-volume terms stuck just off page one.

- Opportunity as volume times poor rank
- Conditional scoring with a rank gate
- Zeroing out already-strong positions

Skill Roadmap

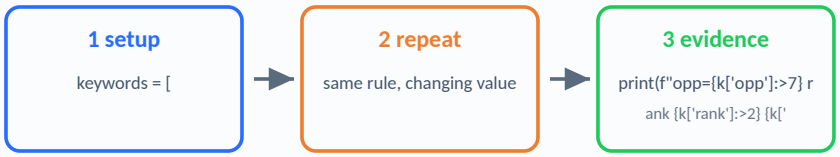
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 199: group keywords by assigned topic. Project 201 changes the surface problem while preserving the underlying method.

progress check

Reading target: score opportunity from volume and current rank is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"opp={k['opp']:>7} rank {k['rank']:>2} {k['keyword']}")` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`k['opp'] = round(k['volume'] * k['rank'] / 100, 1) if k['rank'] > 10 else 0`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"opp={k['opp']:>7} rank {k['rank']:>2} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `k['opp'] = round(k['volume'] * k['rank'] / 100, 1) if k['rank'] > 10 else 0`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Score Opportunity from Volume and Current Rank: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, tools, volume. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: k['opp'] = round(k['volume'] * k['rank'] / 100, 1) if k['rank'] > 10 el… | Evidence: print(f"opp={k['opp']:>7} rank {k['rank']:>2} {k['keyword']}")

🛠️ Reader to Writer Bridge

1. Read: explain score opportunity from volume and current rank in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 199.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 201 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"opp={k['opp']:>7} rank {k['rank']:>2} {k['keyword']}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score opportunity from volume and current rank and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Keywords already ranking in the top ten get zero opportunity (the win is captured), while those further down score in proportion to volume and how far they sit from page one.

```
keywords = [
    {'keyword': 'seo tools', 'volume': 8000, 'rank': 18},
    {'keyword': 'free seo audit', 'volume': 5000, 'rank': 4},
    {'keyword': 'keyword research', 'volume': 6000, 'rank': 25},
]
```

```
for k in keywords:
    k['opp'] = round(k['volume'] * k['rank'] / 100, 1) if k['rank'] > 10 else 0
ranked = sorted(keywords, key=lambda k: -k['opp'])
for k in ranked:
    print(f"opp={k['opp']:>7}  rank {k['rank']:>2}  {k['keyword']}")
```

```
output
opp= 1500.0  rank 25  keyword research
opp= 1440.0  rank 18  seo tools
opp=      0  rank  4  free seo audit
```

How it works:

1. A list of dicts holds keyword, volume, and current rank.
2. Each gets an opp key: volume times rank over 100 when rank exceeds 10, else 0.
3. sorted orders the list by negative opp so the largest opportunity leads.
4. Each line prints the opportunity, the rank, and the keyword.

Try it:

1. Treat ranks 11 to 20 as the striking-distance sweet spot and weight them higher.
2. Add a difficulty field and divide the opportunity by it.
3. Print a clear 'page-one already' note for the zero-scored keywords.
4. Change the page-one cutoff from 10 to 3 and re-rank.

⚠ Common Mistakes

- Rewarding rank 1 with a high score chases keywords you have already won.
- Using `>= 10` instead of `> 10` would zero out a keyword sitting exactly at rank 10.
- Sorting ascending buries the biggest opportunity at the bottom.

Skills gained opportunity scoring | conditional formula | descending sort

→ Where You'll Use This: Striking-distance reports lean on exactly this logic to spotlight near-miss keywords where a small ranking push converts into outsized traffic gains.

Mental Model

Like a sprinter in fourth place with the longest stride: not yet on the podium, but the closest to a medal if they push, so coach them first.

Project 201 Estimate Traffic from a CTR-by-Position Table

The Idea Behind It

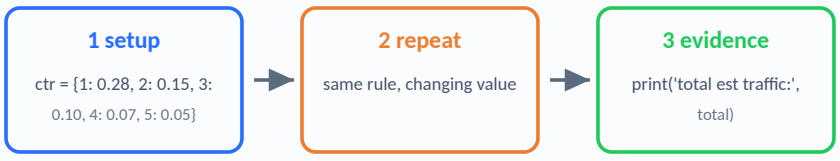
Ranking position drives click-through rate, so a position-to-CTR table converts rankings into a traffic forecast. The code looks up each keyword's position in the ctr dict, multiplies volume by that rate, rounds to whole clicks, and accumulates a running total. Position 1 pulls 28 percent of 12000 searches for 3360 clicks, and the loop prints each estimate before reporting the summed total.

What You'll Build & Learn

Estimate monthly clicks per keyword and overall by combining volume with a CTR-by-position table.

- CTR varies sharply by SERP position
- Dict lookup of position to rate
- Accumulating a running total in a loop

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 200: score opportunity from volume and current rank. Project 202 changes the surface problem while preserving the underlying method. *progress check*

Reading target: estimate traffic from a ctr-by-position table is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('total est traffic:', total)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for kw, vol, pos in rows:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('total est traffic:', total)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for kw, vol, pos in rows:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Estimate Traffic from a CTR-by-Position Table: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: ctr, rows, seo, guide, keyword. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.

Layer	What to read
Evidence	Entry: ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05} | Core: for kw, vol, pos in rows: | Evidence: print('total est traffic:', total)

🛠️ Reader to Writer Bridge

1. Read: explain estimate traffic from a ctr-by-position table in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 200.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 202 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total est traffic:', total)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of estimate traffic from a ctr-by-position table and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Looking up each ranking's CTR and multiplying by volume yields per-keyword estimated clicks, which sum to a total traffic projection.

```
ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}
rows = [('seo guide', 12000, 1), ('keyword tool', 8000, 3), ('rank tracker',
5000, 5)]
total = 0
for kw, vol, pos in rows:
    traffic = round(vol * ctr[pos])
    total += traffic
    print(f'pos {pos}  ctr {ctr[pos]:.0%}  est {traffic:>5}  {kw}')
print('total est traffic:', total)
```

```
output
pos 1  ctr 28%  est  3360  seo guide
pos 3  ctr 10%  est   800  keyword tool
```

```
pos 5  ctr 5%  est   250  rank tracker
total est traffic: 4410
```

How it works:

1. The ctr dict maps positions one through five to click-through rates.
2. rows holds tuples of keyword, volume, and position, and total starts at zero.
3. The loop multiplies volume by the looked-up CTR, rounds it, and adds it to total.
4. Each keyword prints with its position, CTR, and estimate, then the grand total prints.

Try it:

1. Add a default CTR for positions beyond five using dict.get.
2. Apply a brand-vs-generic CTR adjustment per keyword.
3. Report the percentage each keyword contributes to total traffic.
4. Add position 6-10 to the CTR table with smaller values.

⚠ Common Mistakes

- Looking up a position not in the table (e.g. 6) raises KeyError without a `.get` fallback.
- Multiplying volume by a CTR stored as a percent (28) not a fraction (0.28) inflates traffic 100x.
- Forgetting `round` leaves long floats in the estimated click counts.

Skills gained traffic forecasting | CTR table lookup | running total

→ Where You'll Use This: CTR curves turn rank data into projected sessions, the language executives understand, so traffic forecasts justify SEO investment in business terms.

Mental Model

Like estimating a shop's sales from foot traffic and a conversion rate: visitors times the chance each buys gives a revenue forecast before the month even starts.

Project 202 Extract Question Keywords

The Idea Behind It

Keywords that open with who, what, why, or how are explicit questions, prime targets for FAQ content and featured snippets. A list comprehension keeps every keyword whose first split word sits in a question-word tuple. Checking only the first token cleanly isolates true questions from phrases that merely contain a question word elsewhere, and the code prints the count then the sorted matches.

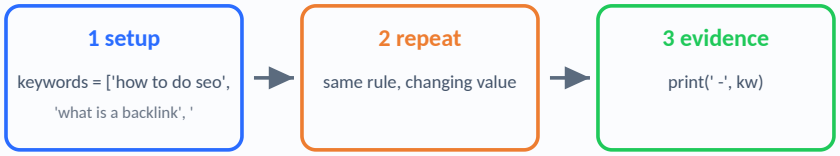
What You'll Build & Learn

Extract question keywords by testing whether the first word is an interrogative.

- Questions start with interrogative words
- Filtering by the first token only
- List comprehension with a membership test

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 201: estimate traffic from a ctr-by-position table. Project 203 changes the surface problem while preserving the underlying method.



progress check

Reading target: extract question keywords is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = ['how to do seo', 'what is a backlink', 'seo tips', 'why does ranking drop', 'who invented pagerank']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(' -', kw)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['how to do seo', 'what is a backlink', 'seo tips', 'why does ranking drop', 'who invented pagerank']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.

Move	Code to inspect	Why it matters
2. Apply the rule	`questions = [kw for kw in keywords if kw.split()[0] in qwords]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' -', kw)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `questions = [kw for kw in keywords if kw.split()[0] in qwords]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Extract Question Keywords: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, how, to, seo, what. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = ['how to do seo', 'what is a backlink', 'seo tips', 'why doe... | Core: questions = [kw for kw in keywords if kw.split()[0] in qwords] | Evidence: print(' -', kw)

Reader to Writer Bridge

1. Read: explain extract question keywords in one sentence before touching the code; the goal gives the syntax context.

2. Trace: follow the actual values from setup to output, then carry forward the move from Project 201.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 203 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' –', kw)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `keywords = ['how to do seo', 'what is a backlink', 'seo tips', 'why does ranking drop', 'who invented pagerank']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of extract question keywords and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Testing the first token against a tuple of question words flags interrogative keywords; sorting the matches keeps the printed list stable.

```
keywords = ['how to do seo', 'what is a backlink', 'seo tips', 'why does
ranking drop', 'who invented pagerank']
qwords = ('who', 'what', 'why', 'how', 'when', 'where', 'which')
questions = [kw for kw in keywords if kw.split()[0] in qwords]
print('questions:', len(questions))
for kw in sorted(questions):
    print(' –', kw)
```

```
output
questions: 4
 – how to do seo
 – what is a backlink
 – who invented pagerank
 – why does ranking drop
```

How it works:

1. A list holds five keywords, some questions and some not.
2. qwords is a tuple of interrogatives like who, what, and how.
3. A comprehension keeps each keyword whose kw.split()[0] is in qwords.
4. The code prints how many questions were found, then each sorted question.

Try it:

1. Include keywords ending in a question mark even without a question word.
2. Group the questions by their interrogative word.
3. Add 'can' and 'does' to the interrogative set.
4. Add 'can' and 'does' as question starters and re-run.

⚠ Common Mistakes

- Checking `qword in kw` (substring) flags 'showcase' because it contains 'how'.
- Calling `kw.split()[0]` on an empty string would raise an IndexError.
- Case sensitivity misses a keyword written 'How to do seo' unless you lowercase first.

Skills gained question extraction | first-token check | list comprehension

→ Where You'll Use This: Question keywords feed FAQ schema, People Also Ask targeting, and featured-snippet plays, so isolating them drives a whole content format strategy.

⚡ Mental Model

Like skimming a survey for forms that open with a question mark: the first cue tells you it expects an answer, so you route it to the FAQ desk.

Project 203 Count Modifier Words Across Keywords

💡 The Idea Behind It

Modifiers like best, cheap, free, or 2026 shape both intent and content angle. A Counter tallies how often each modifier appears across the whole keyword list by scanning every word and incrementing when it matches the modifier set. Sorting by descending count then alphabetically shows 'best' leading with two hits, revealing which qualifiers dominate the demand you are working with.

What You'll Build & Learn

Tally modifier words across a keyword list to see which qualifiers dominate.

- Counter for frequency tallies
- Membership filtering inside a loop
- Sorting by count then alphabetically

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 202: extract question keywords. Project 204 changes the surface problem while preserving the underlying method.

progress check

Reading target: count modifier words across keywords is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{mod}: {n}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if w in modifiers:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{mod}: {n}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of count modifier words across keywords and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Iterating every word and counting hits against a modifier set with a `Counter` reveals the qualifiers your audience appends most often.

```
from collections import Counter
keywords = ['best seo tool', 'cheap seo tool', 'seo tool near me', 'best
keyword tool', 'free seo tool 2026']
modifiers = ('best', 'cheap', 'free', 'top', 'near', 'me', '2026')
found = Counter()
for kw in keywords:
    for w in kw.split():
        if w in modifiers:
            found[w] += 1
for mod, n in sorted(found.items(), key=lambda x: (-x[1], x[0])):
    print(f'{mod}: {n}')
```

```
output
best: 2
2026: 1
cheap: 1
free: 1
me: 1
near: 1
```

How it works:

1. modifiers is a tuple of qualifier words, and found is an empty Counter.
2. Nested loops walk each keyword's words and increment found[w] whenever w is a known modifier.
3. found.items() is sorted by negative count then by modifier name.
4. Each modifier prints with its total occurrences.

Try it:

1. Add commercial modifiers like 'review' and 'compare' to the set.
2. Report each modifier's share as a percentage of all matches.
3. Count two-word modifiers such as 'near me' as a single unit.
4. Add 'review' and 'vs' to the modifier set.

⚠ Common Mistakes

- Treating 'near me' as one token misses both 'near' and 'me' that split apart.
- Sorting only by count leaves equal counts in nondeterministic order without the name tiebreaker.
- Putting '2026' in the set as an int (2026) never matches the string token '2026'.

Skills gained modifier analysis | Counter | frequency sort

→ Where You'll Use This: Modifier frequency exposes whether your keyword set skews toward price-shoppers, deal-seekers, or year-specific queries, shaping headlines and meta copy.

⚡ Mental Model

Like counting adjectives in a stack of restaurant reviews: if 'cheap' keeps surfacing, you learn your audience cares more about price than ambience.

Project 204 Split Branded from Non-Branded Keywords

💡 The Idea Behind It

Branded keywords contain your brand name and convert differently from generic discovery terms, so reports separate the two. Two list comprehensions split the keywords: one keeps phrases where the brand is a whole word in the split, the other keeps those where it is not. The whole-word check via split avoids matching the brand inside an unrelated longer word, and counts print with each group.

What You'll Build & Learn

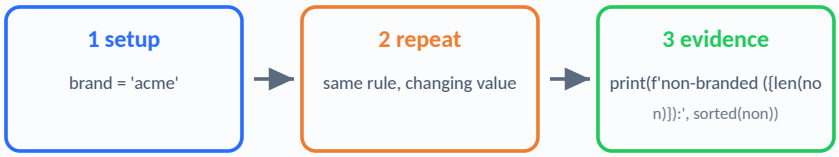
Split a keyword list into branded and non-branded buckets using a whole-word brand check.

- Branded versus generic keyword behaviour
- Whole-word matching via split membership
- Two complementary comprehensions

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 203: count modifier words across keywords. Project 205 changes the surface problem while preserving the underlying method.

progress check



Reading target: split branded from non-branded keywords is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `brand = 'acme'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'non-branded ({len(non)}):', sorted(non))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`brand = 'acme'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`branded = [k for k in keywords if brand in k.split()]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'non-branded ({len(non)}):', sorted(non))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `branded = [k for k in keywords if brand in k.split()]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Split Branded from Non-Branded Keywords: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: brand, acme, keywords, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: brand = 'acme' | Core: branded = [k for k in keywords if brand in k.split()] | Evidence: print(f'non-branded ({len(non)}):', sorted(non))

🛠️ Reader to Writer Bridge

1. Read: explain split branded from non-branded keywords in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 203.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 205 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'non-branded ({len(non)}):', sorted(non))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `brand = 'acme'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of split branded from non-branded keywords and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Testing `brand in k.split()` matches the brand as a whole word, partitioning keywords into branded and non-branded buckets for separate analysis.

```
brand = 'acme'
keywords = ['acme running shoes', 'best running shoes', 'acme login', 'cheap
trainers', 'acme reviews']
branded = [k for k in keywords if brand in k.split()]
non = [k for k in keywords if brand not in k.split()]
print(f'branded ({len(branded)}):', sorted(branded))
print(f'non-branded ({len(non)}):', sorted(non))
```

```
output
branded (3): ['acme login', 'acme reviews', 'acme running shoes']
non-branded (2): ['best running shoes', 'cheap trainers']
```

How it works:

1. brand is set to 'acme' and keywords holds five mixed phrases.
2. branded keeps each keyword where brand is in kw.split(), a whole-word test.
3. non keeps the complement where brand is absent from the words.
4. Both groups print with their counts and sorted keywords.

Try it:

1. Support a list of brand aliases instead of a single string.
2. Make the brand match case-insensitive.
3. Report the share of total volume that is branded versus generic.
4. Lowercase keywords first so 'ACME store' counts as branded.

⚠ Common Mistakes

- Using `brand in k` (substring) would match a brand fragment inside an unrelated word.
- Case sensitivity misses 'Acme Login' unless both sides are lowercased.
- A multi-word brand like 'acme corp' will not match a single-token membership test.

Skills gained `brand segmentation` `whole-word matching` `list comprehension`

→ **Where You'll Use This:** Separating branded from non-branded keywords is standard in performance reporting because brand traffic and generic discovery deserve different goals and budgets.

⚡ Mental Model

Like separating mail addressed to you by name from flyers addressed 'to the resident': the named ones already know who you are, so they behave differently.

Project 205 Map Keywords to Funnel Stages

💡 The Idea Behind It

Awareness, consideration, and decision keywords each need a different page, so a stage function maps trigger words to a funnel position. It builds a set of the keyword's words and tests for intersection with stage-specific word sets, returning awareness, consideration, or decision in priority order. Using set intersection means any matching trigger fires the stage, and unmatched keywords fall through to unknown.

What You'll Build & Learn

Map each keyword to a marketing-funnel stage using stage-specific trigger words.

- Funnel stages from trigger vocabulary
- Set intersection to test membership
- Ordered checks as stage priority

🧭 Skill Roadmap

`Skill step:` moves you from recognition toward independent tracing. It builds on Project 204: split branded from non-branded keywords. Project 206 changes the surface problem while preserving the underlying method. *progress check*

`Reading target:` map keywords to funnel stages is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- `Setup:` `keywords = ['what is seo', 'best seo tools', 'seo software pricing', 'buy seo plan']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- `Writing move:` this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.

- Evidence: `print(f'{stage(kw):14} {kw}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['what is seo', 'best seo tools', 'seo software pricing', 'buy seo plan']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if w & {'what', 'how', 'guide', 'is'}: return 'awareness'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{stage(kw):14} {kw}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if w & {'what', 'how', 'guide', 'is'}: return 'awareness'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Map Keywords to Funnel Stages: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, what, is, seo, best. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: keywords = ['what is seo', 'best seo tools', 'seo software pricing', 'b... | Core: if w & {'what', 'how', 'guide', 'is'}: return 'awareness' | Evidence: print(f'{stage(kw):14} {kw}')

🛠️ Reader to Writer Bridge

1. Read: explain map keywords to funnel stages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 204.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 206 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{stage(kw):14} {kw}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = ['what is seo', 'best seo tools', 'seo software pricing', 'buy seo plan']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of map keywords to funnel stages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Intersecting each keyword's word set with stage-specific trigger sets routes it to the funnel stage whose triggers it matches first.

```
keywords = ['what is seo', 'best seo tools', 'seo software pricing', 'buy seo
plan']
def stage(kw):
    w = set(kw.split())
    if w & {'what', 'how', 'guide', 'is'}: return 'awareness'
    if w & {'best', 'top', 'review', 'vs'}: return 'consideration'
    if w & {'buy', 'price', 'pricing', 'plan', 'demo'}: return 'decision'
    return 'unknown'
for kw in keywords:
    print(f'{stage(kw):14} {kw}')
```

```
output
awareness      what is seo
consideration  best seo tools
decision       seo software pricing
decision       buy seo plan
```

How it works:

1. A list holds four keywords spanning the funnel.
2. stage turns each keyword into a set of words.
3. It returns awareness, consideration, or decision when that word set intersects the matching trigger set, checked in order.
4. The loop prints each padded stage beside its keyword.

Try it:

1. Add a retention stage with words like 'cancel' and 'support'.
2. Return the matched trigger word alongside the stage for transparency.
3. Count how many keywords land in each funnel stage.
4. Add a 'retention' stage for 'support' and 'renew' keywords.

⚠ Common Mistakes

- Set intersection on a string instead of `kw.split()` compares characters, not words.
- Order of checks matters: an awareness trigger fires before a later decision one.
- A keyword matching no stage silently returns 'unknown' with no warning.

Skills gained funnel mapping | set intersection | intent staging

→ Where You'll Use This: Funnel mapping tells content teams whether a keyword wants a top-of-funnel guide, a mid-funnel comparison, or a bottom-of-funnel pricing page.

Mental Model

Like a shop greeter reading body language: a browser gets a brochure, a comparer gets a demo, and a wallet-out customer gets the checkout, each at the right moment.

Project 206 Dedupe Near-Identical Keywords by Canonical Form

The Idea Behind It

Keyword exports are full of cosmetic duplicates: different case, extra spaces, reordered words. A canon function lowercases each keyword, splits it, sorts the words, and rejoins them into a canonical form. A seen set tracks which canonical forms have appeared, so only the first variant of each survives in unique. Five noisy inputs collapse to two genuine keywords, with the original spelling preserved.

What You'll Build & Learn

Deduplicate keywords that differ only in case, spacing, or word order via a canonical form.

- Canonicalising for fuzzy deduplication
- Sorting words to ignore order
- A seen set to keep first occurrences

Skill Roadmap

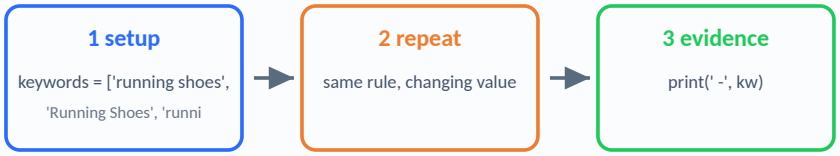
Skill step: moves you from recognition toward independent tracing. It builds on Project 205: map keywords to funnel stages. Project 207 changes the surface problem while preserving the underlying method.

progress check

Reading target: dedupe near-identical keywords by canonical form is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `keywords = ['running shoes', 'Running Shoes', 'running shoes', 'shoes running', 'trail shoes']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(' –', kw)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['running shoes', 'Running Shoes', 'running shoes', 'shoes running', 'trail shoes']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if c not in seen:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(' –', kw)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if c not in seen:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Layer	What to read
Intent	Dedupe Near-Identical Keywords by Canonical Form: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, running, shoes, Running, Shoes. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: keywords = ['running shoes', 'Running Shoes', 'running shoes', 'shoes r... | Core: if c not in seen: | Evidence: print(' -', kw)

🛠️ Reader to Writer Bridge

1. Read: explain dedupe near-identical keywords by canonical form in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 205.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 207 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -', kw)`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = ['running shoes', 'Running Shoes', 'running shoes', 'shoes running', 'trail shoes']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of dedupe near-identical keywords by canonical form and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Lowercasing, splitting, sorting the words, and rejoining produces a canonical key that ignores case, spacing, and word order, so a `seen` set keeps only the first of each variant.

```
keywords = ['running shoes', 'Running Shoes', 'running  shoes', 'shoes
running', 'trail shoes']
def canon(kw):
    return ' '.join(sorted(kw.lower().split()))
seen, unique = set(), []
```

```
    for kw in keywords:
        c = canon(kw)
        if c not in seen:
            seen.add(c)
            unique.append(kw)
    print('input:', len(keywords), 'unique:', len(unique))
    for kw in unique:
        print(' -', kw)
```

```
output
input: 5 unique: 2
 - running shoes
 - trail shoes
```

How it works:

1. canon lowercases a keyword, splits it, sorts the words, and joins them with single spaces.
2. seen is an empty set and unique an empty list.
3. Each keyword's canonical form is checked against seen; new forms are recorded and the original keyword kept.
4. The code prints the input and unique counts, then each surviving keyword.

Try it:

1. Strip punctuation inside canon so 'shoes,' matches 'shoes'.
2. Keep the variant with the highest volume instead of the first seen.
3. Report which originals collapsed into each canonical form.
4. Drop the word-sort step and see 'shoes running' survive as distinct.

⚠ Common Mistakes

- Comparing raw strings misses 'Running Shoes' and 'shoes running' as duplicates.
- Sorting words treats 'dog food' and 'food dog' as the same, which may be wrong for ordered phrases.
- Splitting on `kw.split(' ')` keeps empty tokens from double spaces; bare `.split()` collapses them.

Skills gained keyword deduplication | canonical form | set tracking

→ Where You'll Use This: Canonical dedupe cleans messy multi-tool keyword exports before analysis, stopping the same query from being counted three times under different spellings.

Mental Model

Like alphabetising the letters of each word to spot anagrams: 'shoes running' and 'running shoes' resolve to the same fingerprint, so you keep just one.

Project 207 Rank Keywords by Estimated Commercial Value

The Idea Behind It

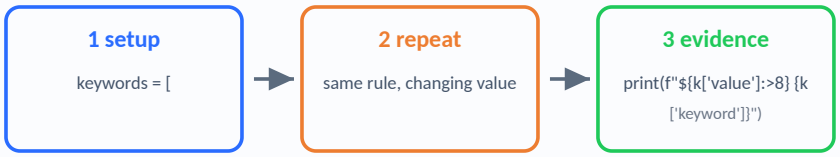
Volume alone ignores money, so estimated value multiplies volume by cost-per-click and conversion rate to surface keywords worth the most revenue rather than the most clicks. The loop writes a value key into each dict, and sorting by negative value ranks them. 'enterprise seo', low in volume but high in CPC and conversion, beats a 12000-volume term, proving that traffic and revenue are not the same.

What You'll Build & Learn

Rank keywords by estimated commercial value from volume, cost-per-click, and conversion rate.

- Commercial value beats raw volume
- A three-factor revenue proxy formula
- Sorting dicts by a computed field

Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 206: dedupe near-identical keywords by canonical form. Project 208 changes the surface problem while preserving the underlying method. *progress check*

Reading target: rank keywords by estimated commercial value is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"${k['value']:>8} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for k in keywords:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"${k['value']:>8} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for k in keywords:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Rank Keywords by Estimated Commercial Value: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, tool, volume. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: for k in keywords: | Evidence: print(f"${k['value']:>8} {k['keyword']}")

Reader to Writer Bridge

1. Read: explain rank keywords by estimated commercial value in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 206.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 208 should feel like a variation, not a brand-new mystery.

   from example to tool

Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"${k['value']:>8} {k['keyword']}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank keywords by estimated commercial value and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

From Concept to Code (Python)

Multiplying volume by CPC by conversion rate weights each keyword by likely revenue, so a low-volume but high-CPC, high-converting term can outrank a popular cheap one.

```
keywords = [
    {'keyword': 'seo tool', 'volume': 8000, 'cpc': 4.5, 'conv': 0.02},
    {'keyword': 'free seo', 'volume': 12000, 'cpc': 0.5, 'conv': 0.01},
    {'keyword': 'enterprise seo', 'volume': 1500, 'cpc': 12.0, 'conv': 0.05},
]
for k in keywords:
    k['value'] = round(k['volume'] * k['cpc'] * k['conv'], 1)
```

```
for k in sorted(keywords, key=lambda k: -k['value']):
    print(f"${k['value']:>8}  {k['keyword']}")
```

```
output
$   900.0  enterprise seo
$   720.0  seo tool
$    60.0  free seo
```

How it works:

1. A list of dicts holds keyword, volume, cpc, and conv (conversion rate).
2. The loop computes value as volume times cpc times conv, rounded, into each dict.
3. sorted orders the dicts by negative value, most valuable first.
4. Each line prints a dollar-prefixed value beside the keyword.

Try it:

1. Add a difficulty field and divide value by it for value-per-effort.
2. Print the dollar values formatted to two decimal places.
3. Multiply by an average order value instead of a flat conversion rate.
4. Add a 'margin' factor and multiply it into the value.

⚠ Common Mistakes

- Ranking by volume alone would put 'free seo' on top despite its tiny value.
- Storing conversion as a percent (2) not a fraction (0.02) inflates value 100x.
- Sorting ascending lists the least valuable keyword first.

Skills gained value scoring | revenue proxy | descending sort

→ Where You'll Use This: Value-based ranking aligns keyword strategy with revenue, helping you defend why a low-traffic high-intent term outranks a vanity keyword in the roadmap.

⚡ Mental Model

Like a fishing spot with few but huge fish beating a crowded pond of minnows: you weigh the catch's worth, not just how many bites you get.

Project 208 Map Keywords to Target URLs

💡 The Idea Behind It

Each keyword should have one page that owns it, so a keyword-to-URL map lets you check coverage and spot orphans. A mapping dict pairs keywords with their target URLs, and the code looks up each query with dict.get,

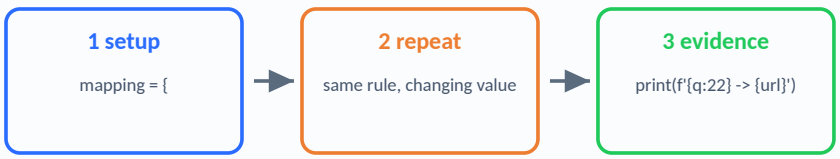
supplying a 'NO TARGET PAGE' fallback. Matched queries print their URL; the unmapped 'climbing shoes' prints the fallback, instantly revealing a content gap.

What You'll Build & Learn

Match queries to their owning URL and flag any keyword with no target page.

- One keyword maps to one owning page
- dict.get with a default fallback
- Detecting coverage gaps

🧭 Skill Roadmap



Skill step: moves you from recognition toward independent tracing. It builds on Project 207: rank keywords by estimated commercial value. Project 209 changes the surface problem while preserving the underlying method. *progress check*

Reading target: map keywords to target urls is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `mapping = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{q:22} -> {url}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`mapping = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for q in queries:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{q:22} -> {url}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for q in queries:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Map Keywords to Target URLs: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: mapping, best, running, shoes, blog. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: mapping = { | Core: for q in queries: | Evidence: print(f'{q:22} -> {url}')

🛠️ Reader to Writer Bridge

1. Read: explain map keywords to target urls in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 207.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 209 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{q:22} -> {url}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `mapping = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of map keywords to target urls and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

A dict lookup with `.get` and a default returns the owning URL or a clear flag, exposing keywords that still need a landing page.

```
mapping = {
    'best running shoes': '/blog/best-running-shoes',
    'running shoes': '/shop/running-shoes',
    'trail shoes': '/shop/trail-shoes',
}
queries = ['running shoes', 'best running shoes', 'climbing shoes']
for q in queries:
    url = mapping.get(q, 'NO TARGET PAGE')
    print(f'{q:22} -> {url}')
```

```
output
running shoes          -> /shop/running-shoes
best running shoes     -> /blog/best-running-shoes
climbing shoes         -> NO TARGET PAGE
```

How it works:

1. The mapping dict pairs three keywords with their target URLs.
2. queries lists the terms to check, including an unmapped one.
3. For each query, dict.get returns the URL or the 'NO TARGET PAGE' default.

4. Each query prints left-padded beside its resolved URL or the gap marker.

Try it:

1. Collect all unmapped queries into a separate gap list.
2. Allow one URL to own multiple keywords and validate the reverse.
3. Load the mapping from a CSV export of your site structure.
4. Collect all queries that returned NO TARGET PAGE into a gap list.

⚠ Common Mistakes

- Using `mapping[q]` instead of `.get` raises KeyError for an unmapped keyword.
- Case or whitespace mismatches between query and map keys cause silent misses.
- Treating the default string as a real URL downstream would break link generation.

Skills gained keyword-to-URL mapping | dict.get default | gap detection

→ Where You'll Use This: Keyword-to-URL maps are the backbone of content gap audits, showing which target terms still lack a dedicated landing page to win them.

⚡ Mental Model

Like a seating chart at a wedding: every guest should have one assigned table, and an unlisted name means someone has nowhere to sit yet.

Project 209 Flag Keywords for SERP-Feature Targeting

💡 The Idea Behind It

Some keywords trigger SERP features like featured snippets you can win with structured content. The code stores a list of SERP features per keyword, then flags any keyword whose feature list contains the chosen target. A simple membership test sets the flag to TARGET or a dash, so two keywords showing featured_snippet get flagged while a shopping-only keyword does not, focusing optimisation effort.

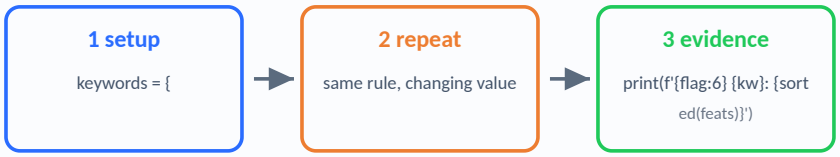
What You'll Build & Learn

Flag keywords whose SERP shows a chosen feature, like featured snippets, for targeting.

- SERP features as winnable opportunities
- Membership test against a feature list
- Conditional flag formatting

🧭 Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 208: map keywords to target urls. Project 210 changes the surface problem while preserving the underlying method.



progress check

Reading target: flag keywords for serp-feature targeting is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{flag:6} {kw}: {sorted(feats)}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`flag = 'TARGET' if target in feats else '-'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{flag:6} {kw}: {sorted(feats)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `flag = 'TARGET' if target in feats else '–'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Keywords for SERP-Feature Targeting: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, how, to, tie, shoes. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = { | Core: flag = 'TARGET' if target in feats else '-' | Evidence: print(f'{flag:6} {kw}: {sorted(feats)}')

🛠️ Reader to Writer Bridge

1. Read: explain flag keywords for serp-feature targeting in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 208.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 210 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{flag:6} {kw}: {sorted(feats)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag keywords for serp-feature targeting and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Testing whether the target feature is in each keyword's feature list flags the snippet-winnable opportunities, with sorted features for stable output.

```
keywords = {
    'how to tie shoes': ['featured_snippet'],
    'nike shoes': ['shopping', 'image_pack'],
    'shoe size chart': ['featured_snippet', 'people_also_ask'],
}
target = 'featured_snippet'
for kw in sorted(keywords):
    feats = keywords[kw]
    flag = 'TARGET' if target in feats else '-'
    print(f'{flag:6} {kw}: {sorted(feats)}')
```

```
output
TARGET how to tie shoes: ['featured_snippet']
-      nike shoes: ['image_pack', 'shopping']
TARGET shoe size chart: ['featured_snippet', 'people_also_ask']
```

How it works:

1. The keywords dict maps each keyword to a list of SERP features it triggers.
2. target is set to 'featured_snippet'.
3. For each sorted keyword, flag becomes 'TARGET' when target is in its feature list, else a dash.
4. Each line prints the flag, the keyword, and its sorted features.

Try it:

1. Accept a list of target features and flag a match on any of them.
2. Count how many keywords trigger each distinct SERP feature.
3. Sort flagged keywords ahead of unflagged ones in the output.
4. Switch the target to 'people_also_ask' and re-run.

⚠ Common Mistakes

- Checking `target == feats` compares a string to a list and never matches.
- Not sorting the feature lists makes the printed order vary by insertion order.
- Hard-coding one target misses keywords that show other winnable features.

Skills gained SERP feature targeting | list membership | flag formatting

→ Where You'll Use This: SERP-feature flags direct structured-content efforts toward snippets, image packs, or People Also Ask boxes where a format tweak can capture extra visibility.

Mental Model

Like scanning a stage for open mic slots: you only step up where there's a spot you can actually fill, ignoring the segments already locked down.

Project 210 Filter Keywords by a Difficulty-to-Volume Ratio

The Idea Behind It

A volume-to-difficulty ratio ranks bang-for-buck, but a hard difficulty ceiling stops you chasing impossible terms. The loop computes ratio as volume over difficulty, then sorts descending. A verdict flags GO when difficulty is at or below 40, else skip, which is why 'seo' has the top ratio yet still gets skipped at difficulty 90. Combining the ratio with the cap yields a realistic shortlist.

What You'll Build & Learn

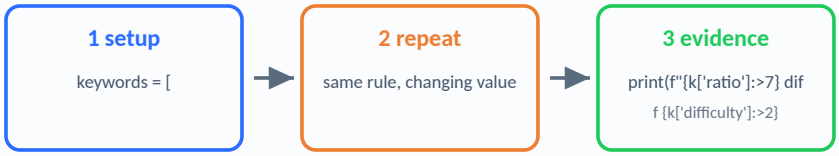
Rank keywords by a volume-to-difficulty ratio while capping out terms above a difficulty ceiling.

- Volume-to-difficulty as bang-for-buck
- Why a hard ceiling matters too
- Combining a ratio with a gate

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 209: flag keywords for serp-feature targeting. Project 211 changes the surface problem while preserving the underlying method.

progress check



Reading target: filter keywords by a difficulty-to-volume ratio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"{k['ratio']:>7} diff {k['difficulty']:>2} {verdict:4} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`verdict = 'GO' if k['difficulty'] <= 40 else 'skip'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{k['ratio']:>7} diff {k['difficulty']:>2} {verdict:4} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Filter Keywords by a Difficulty-to-Volume Ratio: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, basics, volume. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: keywords = [| Core: verdict = 'GO' if k['difficulty'] <= 40 else 'skip' | Evidence: print(f"{k['ratio']:>7} diff {k['difficulty']:>2} {verdict:4} {k['keywo...

🛠️ Reader to Writer Bridge

1. Read: explain filter keywords by a difficulty-to-volume ratio in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 209.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 211 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{k['ratio']:>7} diff {k['difficulty']:>2} {verdict:4} {k['keyword']}")`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of filter keywords by a difficulty-to-volume ratio and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The ratio ranks efficiency while the separate difficulty ceiling vetoes terms that are too hard, so a high-ratio but brutally hard keyword still reads 'skip'.

```
keywords = [
    {'keyword': 'seo basics', 'volume': 5000, 'difficulty': 20},
    {'keyword': 'seo', 'volume': 40000, 'difficulty': 90},
    {'keyword': 'local seo guide', 'volume': 3000, 'difficulty': 25},
]
for k in keywords:
    k['ratio'] = round(k['volume'] / k['difficulty'], 1)
for k in sorted(keywords, key=lambda k: -k['ratio']):
    verdict = 'GO' if k['difficulty'] <= 40 else 'skip'
    print(f"{k['ratio']:>7}  diff {k['difficulty']:>2}  {verdict:4}
{k['keyword']}")
```

```
output
  444.4  diff 90  skip  seo
  250.0  diff 20  GO    seo basics
  120.0  diff 25  GO    local seo guide
```

How it works:

1. A list of dicts holds keyword, volume, and difficulty.
2. The loop writes ratio as volume divided by difficulty, rounded.
3. sorted orders by negative ratio, best value first.
4. Each line's verdict is GO when difficulty is 40 or less, otherwise skip, printed beside the keyword.

Try it:

1. Make the difficulty ceiling a tunable variable.
2. Add a minimum volume floor so tiny terms drop out.
3. Show the GO keywords first regardless of ratio order.
4. Lower the difficulty ceiling to 25 and watch 'local seo guide' flip.

⚠ Common Mistakes

- Relying on ratio alone keeps 'seo' on top despite a difficulty of 90.

- Sorting by volume instead of ratio loses the efficiency view.
- Using `<` instead of `<=` on the ceiling would skip a keyword at exactly 40.

Skills gained ratio scoring | difficulty ceiling | verdict labelling

→ **Where You'll Use This:** Ratio-plus-cap filtering builds a defensible target list that balances efficiency against realism, the judgment call every keyword shortlist must make.

Mental Model

Like shopping for value but refusing anything over a price cap: a luxury car may be great per dollar, yet it still busts the budget, so you skip it.

Project 211 Find Keywords Containing a Seed Term

The Idea Behind It

Keyword expansion starts from a seed: pull every phrase that contains your core word. A list comprehension keeps each keyword where the seed appears as a whole word in the split, so 'running' matches three of five phrases without firing on a substring inside a longer word. The code reports the hit ratio then prints the sorted matches, a tiny but reliable expansion filter.

What You'll Build & Learn

Find every keyword that contains a seed term using a whole-word match.

- Seed-based keyword expansion
- Whole-word matching with split
- Reporting a hit ratio

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 210: filter keywords by a difficulty-to-volume ratio. Project 212 changes the surface problem while preserving the underlying method.

progress check

Reading target: find keywords containing a seed term is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = ['running shoes', 'best running shoes', 'running shoe deals', 'trail hiking', 'wool socks']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(' –', kw)` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['running shoes', 'best running shoes', 'running shoe deals', 'trail hiking', 'wool socks']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`related = [kw for kw in keywords if seed in kw.split()]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(' –', kw)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `related = [kw for kw in keywords if seed in kw.split()]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Keywords Containing a Seed Term: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, running, shoes, best, shoe. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = ['running shoes', 'best running shoes', 'running shoe deals'... | Core: related = [kw for kw in keywords if seed in kw.split()] | Evidence: print(' -', kw)

🛠️ Reader to Writer Bridge

1. Read: explain find keywords containing a seed term in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 210.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 212 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(' -', kw)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `keywords = ['running shoes', 'best running shoes', 'running shoe deals', 'trail hiking', 'wool socks']` and say why this line, value, import, or entry

point is needed before the rest of the Python can work.

3. Transfer: change one small part of find keywords containing a seed term and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Filtering by `seed in kw.split()` keeps only phrases that contain the seed as a standalone word, then sorting yields a stable expansion list.

```
keywords = ['running shoes', 'best running shoes', 'running shoe deals', 'trail
hiking', 'wool socks']
seed = 'running'
related = [kw for kw in keywords if seed in kw.split()]
print(f'seed {seed!r} appears in {len(related)} of {len(keywords)}')
for kw in sorted(related):
    print(' -', kw)
```

```
output
seed 'running' appears in 3 of 5
 - best running shoes
 - running shoe deals
 - running shoes
```

How it works:

1. A list holds five keywords and seed is set to 'running'.
2. A comprehension keeps each keyword where seed is in kw.split(), a whole-word test.
3. The code prints how many of the total contain the seed.
4. Each matching keyword prints sorted on its own line.

Try it:

1. Accept several seeds and keep keywords matching any of them.
2. Make the match case-insensitive.
3. Also report the keywords that do not contain the seed.
4. Switch the seed to 'shoes' and compare the matches.

⚠ Common Mistakes

- Using `seed in kw` (substring) would also match 'overrunning' or similar fragments.
- Case mismatch misses 'Running shoes' unless both sides are lowercased.
- Forgetting to sort makes the printed expansion order depend on input order.

Skills gained seed expansion whole-word match list comprehension

→ Where You'll Use This: Seed filtering powers keyword expansion workflows, isolating every phrase built around a core topic word so you can map a cluster around it.

Mental Model

Like pulling every file folder with a project codeword on the tab: you skim for the exact word, not a chance letter run, so you grab only the right ones.

Project 212 Rank Token Frequency Across a Keyword List

The Idea Behind It

The most common words across a keyword set reveal dominant themes and likely pillar topics. A Counter tallies every token by scanning each keyword's words and incrementing per word, then most_common(4) returns the top four. 'shoes' leads at four and 'running' follows at three, showing how a simple word-frequency tally over the whole list surfaces the themes worth building around.

What You'll Build & Learn

Rank the most frequent tokens across a keyword list to expose dominant themes.

- Token frequency reveals themes
- Counter for tallying
- most_common for top-N results

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 211: find keywords containing a seed term. Project 213 changes the surface problem while preserving the underlying method.

progress check

Reading target: rank token frequency across a keyword list is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `from collections import Counter` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.

- Evidence: `print(f'{w}: {n}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import Counter`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for kw in keywords:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{w}: {n}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for kw in keywords:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Rank Token Frequency Across a Keyword List: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: collections, Counter, keywords, best, running. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import Counter | Core: for kw in keywords: | Evidence: print(f'{w}: {n}')

🛠️ Reader to Writer Bridge

1. Read: explain rank token frequency across a keyword list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 211.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 213 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{w}: {n}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `from collections import Counter` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of rank token frequency across a keyword list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Splitting every keyword into words and tallying with a `Counter` gives a frequency map; `most_common` returns the top tokens, with ties broken by first-seen order.

```
from collections import Counter
keywords = ['best running shoes', 'cheap running shoes', 'running shoes
review', 'trail shoes guide']
counts = Counter()
for kw in keywords:
    for w in kw.split():
        counts[w] += 1
for w, n in counts.most_common(4):
    print(f'{w}: {n}')
```

```
output
shoes: 4
running: 3
best: 1
cheap: 1
```

How it works:

1. counts is an empty Counter and keywords holds four phrases.
2. Nested loops split each keyword and increment counts for every word.
3. counts.most_common(4) returns the four highest-frequency tokens.
4. Each token prints with its total count.

Try it:

1. Exclude stopwords so generic glue words don't dominate.
2. Show the top ten tokens instead of four.
3. Report each token's percentage of all words.
4. Filter out a stop-word list before counting.

⚠ Common Mistakes

- Counting whole keywords instead of their words misses the shared-term theme.
- Stop words like 'for' and 'the' can dominate if you do not filter them out.
- Relying on a precise tie order assumes CPython's insertion-order tiebreak in `most_common`.

Skills gained token frequency | Counter | most_common

→ Where You'll Use This: Word-frequency analysis over a keyword list spots the recurring terms that should anchor pillar pages and inform internal-linking structure.

Mental Model

Like a word cloud rendered as a leaderboard: the words that recur most across your phrases loom largest and point at the topics demand circles around.

Project 213 Pick a Pillar Keyword per Cluster

The Idea Behind It

Each topic cluster needs one pillar page targeting its strongest keyword. A dict comprehension picks a pillar per cluster using max with a key of word count then the keyword itself, so the longest, most descriptive phrase wins, with alphabetical order breaking ties. The output prints each topic, its keyword count, and its chosen pillar, applying one clear heuristic for anchoring a hub page.

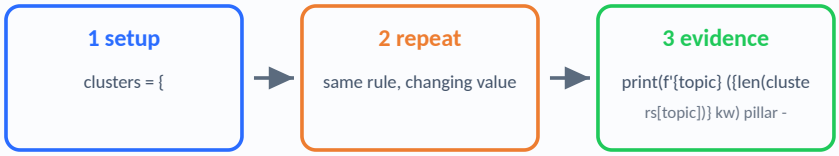
What You'll Build & Learn

Select one pillar keyword per cluster by favouring the longest, most descriptive phrase.

- Pillar pages anchor a cluster
- max() with a tuple key
- Word count as a descriptiveness proxy

Skill Roadmap

Skill step: moves you from recognition toward independent tracing. It builds on Project 212: rank token frequency across a keyword list. Project 214 changes the surface problem while preserving the underlying method. *progress check*



Reading target: pick a pillar keyword per cluster is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `clusters = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{topic} ({len(clusters[topic])} kw) pillar -> {pillars[topic]}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`clusters = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`pillars = {topic: max(kws, key=lambda k: (len(k.split()), k)) for topic, kws in clusters.items()}`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{topic} ({len(clusters[topic])} kw) pillar -> {pillars[topic]}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE

```
pillars = {topic: max(kws, key=lambda k: (len(k.split()), k)) for topic, kws in clusters.items()}
```

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Pick a Pillar Keyword per Cluster: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: clusters, shoes, running, trail, best. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: clusters = { | Core: pillars = {topic: max(kws, key=lambda k: (len(k.split()), k)) for topic... | Evidence: print(f'{topic} ({len(clusters[topic])} kw) pillar -> {pillars[topic]}')

🛠️ Reader to Writer Bridge

1. Read: explain pick a pillar keyword per cluster in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 212.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 214 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{topic} ({len(clusters[topic])} kw) pillar -> {pillars[topic]}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `clusters = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of pick a pillar keyword per cluster and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

`max` with a key of (word count, keyword) picks the longest keyword per cluster, using the keyword string as a deterministic tiebreaker when lengths match.

```
clusters = {
    'shoes': ['running shoes', 'trail shoes', 'best shoes'],
    'socks': ['running socks'],
    'apparel': ['running shorts', 'gym shirt'],
}
pillars = {topic: max(kws, key=lambda k: (len(k.split()), k)) for topic, kws in
clusters.items()}
for topic in sorted(clusters):
    print(f'{topic} ({len(clusters[topic])} kw) pillar -> {pillars[topic]}')
```

```
output
apparel (2 kw) pillar -> running shorts
shoes (3 kw) pillar -> trail shoes
socks (1 kw) pillar -> running socks
```

How it works:

1. The clusters dict maps three topics to lists of keywords.
2. A dict comprehension picks each topic's pillar via max keyed on word count then the keyword.
3. This favours the longest phrase, with the keyword string breaking ties.
4. The loop prints each topic, its keyword count, and the chosen pillar.

Try it:

1. Pick the pillar by highest search volume instead of word count.
2. Require a cluster to have at least two keywords before assigning a pillar.
3. Return the runner-up keyword as a suggested spoke page.
4. Pick the shortest keyword as the pillar instead and compare.

⚠ Common Mistakes

- Picking `max` by raw string length favours long single words over descriptive phrases.
- Omitting the keyword tiebreaker makes equal-length pillars nondeterministic.
- Choosing the longest keyword as a pillar is a heuristic, not always the right SEO call.

Skills gained pillar selection | max with key | dict comprehension

→ Where You'll Use This: Pillar selection is core to hub-and-spoke content architecture, naming the page that ties a cluster's supporting articles together for topical authority.

⚡ Mental Model

Like choosing a team captain: you pick the player whose role spans the most ground, then settle ties by jersey number so the choice is never arbitrary.

Project 214 Score Keywords with Normalized Volume and Difficulty

The Idea Behind It

Volume and difficulty live on different scales, so subtracting them raw is meaningless. A norm function min-max scales a list of values to the zero-to-one range, and the code normalises both volume and difficulty separately. Each keyword's score is normalised volume minus normalised difficulty, zipped back together. 'seo audit' wins on a fair high-volume-minus-difficulty basis once both metrics share a scale.

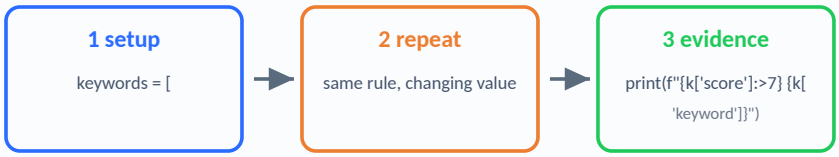
What You'll Build & Learn

Score keywords on a fair volume-minus-difficulty basis after min-max normalising both metrics.

- Min-max normalisation to a common scale
- Why mixing raw scales is invalid
- zip to recombine parallel lists

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 213: pick a pillar keyword per cluster. Project 215 changes the surface problem while preserving the underlying method.



progress check

Reading target: score keywords with normalized volume and difficulty is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"{k['score']:>7} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`return [(v - lo) / (hi - lo) for v in vals]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f"{k['score']:>7} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return [(v - lo) / (hi - lo) for v in vals]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Score Keywords with Normalized Volume and Difficulty: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, audit, volume. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: return [(v - lo) / (hi - lo) for v in vals] | Evidence: print(f"{k['score']:>7} {k['keyword']}")

🛠️ Reader to Writer Bridge

1. Read: explain score keywords with normalized volume and difficulty in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 213.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 215 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{k['score']:>7} {k['keyword']}")`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of score keywords with normalized volume and difficulty and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Min-max scaling maps each metric to 0-1 so the subtraction `normalised_volume - normalised_difficulty` compares like with like, rewarding high volume and low difficulty equally.

```
keywords = [
    {'keyword': 'seo audit', 'volume': 6000, 'difficulty': 35, 'cpc': 6.0},
    {'keyword': 'free tool', 'volume': 9000, 'difficulty': 70, 'cpc': 1.0},
    {'keyword': 'rank tracker', 'volume': 4000, 'difficulty': 40, 'cpc': 5.0},
]
def norm(vals):
```

```
    lo, hi = min(vals), max(vals)
    return [(v - lo) / (hi - lo) for v in vals]
vols = norm([k['volume'] for k in keywords])
diffs = norm([k['difficulty'] for k in keywords])
for k, nv, nd in zip(keywords, vols, diffs):
    k['score'] = round(nv - nd, 3)
for k in sorted(keywords, key=lambda k: -k['score']):
    print(f"{k['score']:>7}  {k['keyword']}")
```

```
output
    0.4  seo audit
    0.0  free tool
 -0.143  rank tracker
```

How it works:

1. norm min-max scales a list of values into the zero-to-one range.
2. vols and diffs apply norm to the volume and difficulty columns separately.
3. zip pairs each keyword with its normalised volume and difficulty, and score is the difference.
4. sorted by negative score prints the keywords best-first.

Try it:

1. Weight volume more heavily than difficulty in the score.
2. Add a normalised CPC term to the composite score.
3. Guard against a divide-by-zero when all values are equal.
4. Weight volume twice as heavily: `2 * nv - nd`.

⚠ Common Mistakes

- Subtracting raw volume and difficulty lets the larger-scaled metric dominate.
- A constant column (all values equal) makes `hi - lo` zero and divides by zero.
- Relying on `zip` assumes the normalised lists stay in the original keyword order.

Skills gained min-max normalisation | fair scoring | zip

→ Where You'll Use This: Normalised scoring lets you fairly blend metrics on wildly different scales, the foundation of any composite keyword or page-priority index.

Mental Model

Like converting heights and weights to percentiles before comparing athletes: only on a shared zero-to-one ruler does subtracting one from the other mean anything.

Project 215 Summarize Intent Distribution Across a List

The Idea Behind It

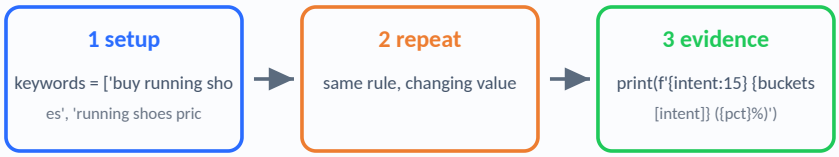
A quick portfolio check is the share of keywords in each intent class. The code keeps three counters and, for each keyword, tests its word set against transactional, commercial, then informational trigger sets in order, defaulting to transactional when nothing matches. Dividing each count by the total gives a percentage, so a list skewing 67 percent transactional flags whether the content mix fits the brand's goal.

What You'll Build & Learn

Summarise what share of a keyword list falls into each intent class.

- Intent distribution as a portfolio view
- Counters keyed by intent class
- Computing each class's percentage

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 214: score keywords with normalized volume and difficulty. Project 216 changes the surface problem while preserving the underlying method. *progress check*

Reading target: summarize intent distribution across a list is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = ['buy running shoes', 'running shoes price', 'cheap running shoes', 'what are running shoes', 'best running shoes', 'running shoes near me']` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{intent:15} {buckets[intent]} ({pct}%)')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = ['buy running shoes', 'running shoes price', 'cheap running shoes', 'what are running shoes', 'best running shoes', 'running shoes near me']`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if w & {'buy', 'price', 'cheap', 'order'}:`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{intent:15} {buckets[intent]} ({pct}%)')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if w & {'buy', 'price', 'cheap', 'order'}:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Summarize Intent Distribution Across a List: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, buy, running, shoes, price. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: keywords = ['buy running shoes', 'running shoes price', 'cheap running... | Core: if w & {'buy', 'price', 'cheap', 'order'}: | Evidence: print(f'{intent:15} {buckets[intent]} ({pct}%)')

🛠️ Reader to Writer Bridge

1. Read: explain summarize intent distribution across a list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 214.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 216 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{intent:15} {buckets[intent]} ({pct}%)')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `keywords = ['buy running shoes', 'running shoes price', 'cheap running shoes', 'what are running shoes', 'best running shoes', 'running shoes near me']` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of summarize intent distribution across a list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Tallying each keyword's intent into a fixed-key dict and converting counts to percentages gives the portfolio mix at a glance.

```
keywords = ['buy running shoes', 'running shoes price', 'cheap running shoes',
'what are running shoes', 'best running shoes', 'running shoes near me']
buckets = {'informational': 0, 'commercial': 0, 'transactional': 0}
```

```
    for kw in keywords:
        w = set(kw.split())
        if w & {'buy', 'price', 'cheap', 'order'}:
            buckets['transactional'] += 1
        elif w & {'best', 'top', 'review', 'vs'}:
            buckets['commercial'] += 1
        elif w & {'what', 'how', 'why', 'guide'}:
            buckets['informational'] += 1
        else:
            buckets['transactional'] += 1
    total = len(keywords)
    for intent in sorted(buckets):
        pct = round(100 * buckets[intent] / total)
        print(f'{intent:15} {buckets[intent]} ({pct}%)')
```

```
output
commercial      1 (17%)
informational   1 (17%)
transactional   4 (67%)
```

How it works:

1. buckets starts three intent counts at zero.
2. For each keyword, its word set is tested against transactional, then commercial, then informational trigger sets, with transactional as the fallback.
3. The matching bucket increments, and total is the keyword count.
4. Each intent prints with its count and rounded percentage.

Try it:

1. Add a navigational bucket and a brand-word trigger for it.
2. Print the distribution sorted by share, largest first.
3. Return the counts as a dict for charting elsewhere.
4. Add a 'navigational' bucket and a brand-name trigger.

⚠ Common Mistakes

- Routing unmatched keywords to transactional inflates that bucket; choose the default deliberately.
- Checking commercial before transactional flips the order and 'cheap' could be miscounted.
- Dividing integer counts before multiplying by 100 truncates the percentage to zero.

Skills gained intent distribution | set intersection | percentage reporting

→ Where You'll Use This: Intent-mix summaries reveal whether a keyword portfolio matches business goals, catching a commerce site that has accidentally over-indexed on informational terms.

Mental Model

Like checking the pie-chart split of a stock portfolio: if 70 percent sits in one sector when you wanted balance, the imbalance jumps out at a glance.

Project 216 Find Quick-Win Keywords by Volume and Difficulty

The Idea Behind It

Quick wins are keywords with real volume but low difficulty, the ones you can rank for soon. A list comprehension keeps keywords passing two conditions at once: difficulty under 30 and volume at least 1000. Sorting the survivors by negative volume prints the biggest quick win first, and a final count confirms how many made the cut from the larger list.

What You'll Build & Learn

Pull quick-win keywords that clear both a volume floor and a difficulty ceiling.

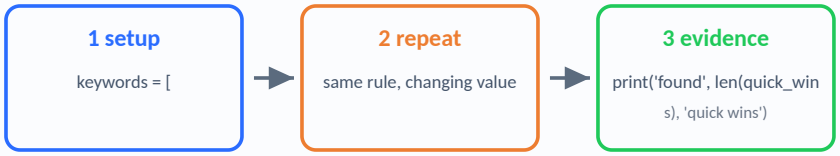
- Quick wins combine demand and ease
- Two-condition filter with and
- Sorting survivors by volume

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 215: summarize intent distribution across a list. Project 217 changes the surface problem while preserving the underlying method.

progress check

Reading target: find quick-win keywords by volume and difficulty is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('found', len(quick_wins), 'quick wins')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`quick_wins = [k for k in keywords if k['difficulty'] < 30 and k['volume'] >= 1000]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('found', len(quick_wins), 'quick wins')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `quick_wins = [k for k in keywords if k['difficulty'] < 30 and k['volume'] >= 1000]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Find Quick-Win Keywords by Volume and Difficulty: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, guide, volume. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: quick_wins = [k for k in keywords if k['difficulty'] < 30 and k['volume... | Evidence: print('found', len(quick_wins), 'quick wins')

🛠️ Reader to Writer Bridge

1. Read: explain find quick-win keywords by volume and difficulty in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 215.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 217 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('found', len(quick_wins), 'quick wins')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find quick-win keywords by volume and difficulty and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

A single comprehension applying both a difficulty ceiling and a volume floor isolates the easy, worthwhile keywords; sorting by volume orders the best first.

```
keywords = [
    {'keyword': 'seo guide', 'volume': 5000, 'difficulty': 22},
    {'keyword': 'link building', 'volume': 4000, 'difficulty': 55},
    {'keyword': 'meta tags', 'volume': 3000, 'difficulty': 18},
    {'keyword': 'serp features', 'volume': 800, 'difficulty': 40},
```

```
]
quick_wins = [k for k in keywords if k['difficulty'] < 30 and k['volume'] >=
1000]
for k in sorted(quick_wins, key=lambda k: -k['volume']):
    print(f"QUICK WIN: {k['keyword']} (vol {k['volume']}, diff
{k['difficulty']})")
print('found', len(quick_wins), 'quick wins')
```

```
output
QUICK WIN: seo guide (vol 5000, diff 22)
QUICK WIN: meta tags (vol 3000, diff 18)
found 2 quick wins
```

How it works:

1. A list of dicts holds keyword, volume, and difficulty.
2. quick_wins keeps keywords where difficulty is under 30 and volume is at least 1000.
3. Survivors sort by negative volume so the biggest prints first.
4. Each prints a QUICK WIN line, then the total count of quick wins prints.

Try it:

1. Make both thresholds adjustable function parameters.
2. Add a third condition requiring transactional or commercial intent.
3. Print the count of keywords that failed the filter too.
4. Loosen the difficulty ceiling to 40 and recount.

⚠ Common Mistakes

- Using `or` instead of `and` admits high-volume but brutally hard keywords.
- A volume floor of 0 lets near-zero-traffic terms count as wins.
- Forgetting the sort leaves the wins in arbitrary input order.

Skills gained quick-win filtering | compound condition | volume sort

→ Where You'll Use This: Quick-win lists give content teams an immediate sprint backlog: low-difficulty, decent-volume keywords that deliver early ranking momentum and stakeholder confidence.

⚡ Mental Model

Like picking low-hanging fruit that is also ripe: you want the apples both within reach and worth eating, not the green ones at the top of the tree.

Project 217 Detect Near-Duplicate Keywords with String Similarity

The Idea Behind It

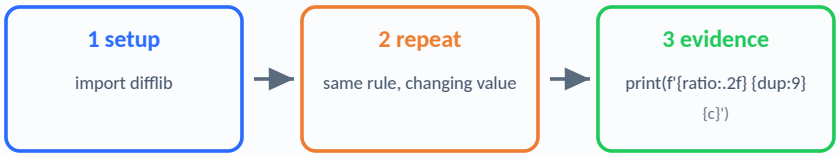
Typos and singular-plural variants bloat keyword lists in ways exact-match dedupe misses. The code uses difflib.SequenceMatcher to compute a character-level similarity ratio between a seed and each candidate, flagging NEAR-DUP at a 0.85 threshold. 'running shoe' and the misspelled 'runing shoes' both score 0.96 and get flagged, while genuinely different phrases stay distinct, catching fuzzy duplicates a set could never see.

What You'll Build & Learn

Flag near-duplicate keywords against a seed using a string-similarity ratio.

- String similarity catches fuzzy dupes
- difflib.SequenceMatcher ratio
- A similarity threshold for flagging

Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 216: find quick-win keywords by volume and difficulty. Project 218 changes the surface problem while preserving the underlying method. *progress check*

Reading target: detect near-duplicate keywords with string similarity is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `import difflib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{ratio:.2f} {dup:9} {c}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import difflib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`dup = 'NEAR-DUP' if ratio >= 0.85 else 'distinct'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{ratio:.2f} {dup:9} {c}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `dup = 'NEAR-DUP' if ratio >= 0.85 else 'distinct'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Detect Near-Duplicate Keywords with String Similarity: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: difflib, seed, running, shoes, candidates. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import difflib | Core: dup = 'NEAR-DUP' if ratio >= 0.85 else 'distinct' | Evidence: print(f'{ratio:.2f} {dup:9} {c}')

🛠️ Reader to Writer Bridge

1. Read: explain detect near-duplicate keywords with string similarity in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 216.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 218 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{ratio:.2f} {dup:9} {c}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import difflib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect near-duplicate keywords with string similarity and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

`difflib.SequenceMatcher.ratio` returns a 0-1 character-overlap score; a high threshold catches typos and singular/plural variants that exact comparison treats as different keywords.

```
import difflib
seed = 'running shoes'
candidates = ['running shoe', 'runing shoes', 'walking shoes', 'running shoes',
'trail shoes']
for c in candidates:
    ratio = difflib.SequenceMatcher(None, seed, c).ratio()
```

```
    dup = 'NEAR-DUP' if ratio >= 0.85 else 'distinct'
    print(f'{ratio:.2f}  {dup:9} {c}')
```

```
output
0.96  NEAR-DUP  running shoe
0.96  NEAR-DUP  runing shoes
0.69  distinct  walking shoes
1.00  NEAR-DUP  running shoes
0.67  distinct  trail shoes
```

How it works:

1. seed is 'running shoes' and candidates lists five variants and unrelated terms.
2. For each candidate, SequenceMatcher(None, seed, c).ratio() gives a similarity between zero and one.
3. dup becomes NEAR-DUP at a ratio of 0.85 or higher, else distinct.
4. Each line prints the ratio, the verdict, and the candidate.

Try it:

1. Compare every pair in a list, not just against one seed.
2. Lower the threshold and observe which distinct terms get caught.
3. Group flagged near-duplicates with the seed they matched.
4. Raise the threshold to 0.95 and watch 'running shoe' become distinct.

⚠ Common Mistakes

- Setting the threshold too low (e.g. 0.5) merges genuinely different keywords like 'walking shoes'.
- SequenceMatcher is character-based, so it can score reordered phrases lower than expected.
- Comparing without lowercasing lets case differences drag the ratio down.

Skills gained fuzzy deduplication | difflib similarity | thresholding

→ Where You'll Use This: Fuzzy similarity catches the typo and plural variants that exact dedupe leaves behind, tightening keyword lists before clustering or reporting.

Mental Model

Like a spell-checker that underlines words almost but not quite right: it scores how close the letters line up and warns you when two phrases are suspiciously alike.

Project 218 Compare Two Keywords by SERP Overlap

The Idea Behind It

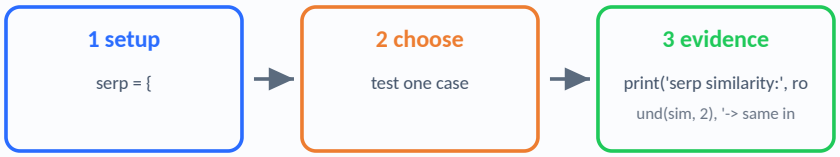
Two keywords with the same ranking pages probably share search intent and should target one page. The code stores top domains per keyword, takes the intersection and union of two keywords' domain sets, and divides their sizes for a SERP-overlap similarity. At 0.5 overlap the verdict reads 'same intent', so a domain-overlap measure decides whether to merge or separate two terms.

What You'll Build & Learn

Compare two keywords by SERP domain overlap to judge whether they share intent.

- Shared ranking pages signal shared intent
- Set overlap of SERP domains
- An inline verdict via conditional expression

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 217: detect near-duplicate keywords with string similarity. Project 219 changes the surface problem while preserving the underlying method. *progress check*

Reading target: compare two keywords by serp overlap is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `serp = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-> different')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`serp = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-> different')`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. slow line
3. Check the evidence	`print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-> different')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE
```
print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-> different')
```

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Compare Two Keywords by SERP Overlap: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: serp, seo, tools, ahrefs, com. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: serp = { | Core: print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4... | Evidence: print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4...

🛠️ Reader to Writer Bridge

1. Read: explain compare two keywords by serp overlap in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 217.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 219 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-> different')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `serp = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of compare two keywords by serp overlap and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Jaccard overlap of the two keywords' ranking domains estimates shared intent, so a high overlap argues for one page covering both keywords rather than two competing ones.

```
serp = {
    'seo tools': ['ahrefs.com', 'semrush.com', 'moz.com'],
    'best seo tools': ['ahrefs.com', 'semrush.com', 'forbes.com'],
    'keyword research': ['backlinko.com', 'ahrefs.com', 'moz.com'],
}
a, b = 'seo tools', 'best seo tools'
overlap = set(serp[a]) & set(serp[b])
sim = len(overlap) / len(set(serp[a]) | set(serp[b]))
print(f'{a!r} vs {b!r}')
print('shared domains:', sorted(overlap))
print('serp similarity:', round(sim, 2), '-> same intent' if sim >= 0.4 else '-
> different')
```

```
output
'seo tools' vs 'best seo tools'
shared domains: ['ahrefs.com', 'semrush.com']
serp similarity: 0.5 -> same intent
```

How it works:

1. The serp dict maps each keyword to its top-ranking domains.
2. a and b name two keywords to compare, and overlap is the intersection of their domain sets.
3. sim divides the overlap size by the union size of both domain sets.
4. The code prints the shared domains and the rounded similarity with an inline same-or-different intent verdict.

Try it:

1. Lower the same-intent threshold and recheck the verdict.
2. Compare all keyword pairs and report the most similar.
3. Weight overlap by ranking position so top spots count more.
4. Compare 'seo tools' with 'keyword research' and watch the similarity drop.

⚠ Common Mistakes

- Dividing by `len(a) + len(b)` instead of the union size overstates the denominator.
- Comparing the ranked lists as ordered (position-sensitive) when only domain presence matters here.
- Picking the 0.4 threshold arbitrarily; real tools tune it against labelled SERP data.

Skills gained SERP overlap | set similarity | intent comparison

→ Where You'll Use This: SERP-overlap analysis decides whether near-synonym keywords can share one page or need separate ones, a core call in content consolidation work.

Mental Model

Like noticing two job ads draw the same shortlist of applicants: if Google serves the same pages, the queries are after the same thing, so merge the effort.

Project 219 Classify Keywords by Word Count into Head, Body, Tail

The Idea Behind It

Keyword length predicts behaviour: one-word head terms are high-volume and hard, while long tails are specific and easy. The loop counts words and assigns a type of head, body, or long-tail via cascading checks at one and three words. An order dict then sorts the keywords by type rank, so the printout structures the whole list from broad head terms down to specific long tails.

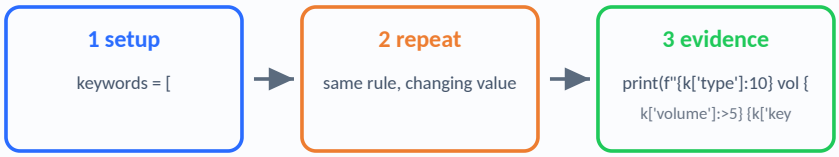
What You'll Build & Learn

Split keywords into head, body, and long-tail by word count and sort by that type.

- Length predicts keyword behaviour
- Three-way banding by word count
- Sorting by a custom type order

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 218: compare two keywords by serp overlap. Project 220 changes the surface problem while preserving the underlying method.



progress check

Reading target: classify keywords by word count into head, body, tail is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"{k['type']:10} vol {k['volume']:>5} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if n <= 1: k['type'] = 'head'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{k['type']:10} vol {k['volume']:>5} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if n <= 1: k['type'] = 'head'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Classify Keywords by Word Count into Head, Body, Tail: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, seo, volume, tips. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: if n <= 1: k['type'] = 'head' | Evidence: print(f"{k['type']:10} vol {k['volume']:>5} {k['keyword']}")

🛠️ Reader to Writer Bridge

1. Read: explain classify keywords by word count into head, body, tail in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 218.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 220 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{k['type']:10} vol {k['volume']:>5} {k['keyword']}")`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of classify keywords by word count into head, body, tail and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Word count drives a three-band label, and a small order map lets you sort by that label from head down to long-tail, mirroring the demand curve.

```
keywords = [
    {'keyword': 'seo', 'volume': 50000},
    {'keyword': 'seo tips', 'volume': 8000},
    {'keyword': 'seo tips for beginners', 'volume': 1200},
    {'keyword': 'free seo tips for small business', 'volume': 200},
]
for k in keywords:
    n = len(k['keyword'].split())
    if n <= 1: k['type'] = 'head'
    elif n <= 3: k['type'] = 'body'
    else: k['type'] = 'long-tail'
order = {'head': 0, 'body': 1, 'long-tail': 2}
for k in sorted(keywords, key=lambda k: order[k['type']]):
    print(f"{k['type']:10} vol {k['volume']:>5}  {k['keyword']}")
```

```
output
head       vol 50000  seo
body       vol  8000  seo tips
long-tail  vol  1200  seo tips for beginners
long-tail  vol   200  free seo tips for small business
```

How it works:

1. A list of dicts holds keyword and volume.
2. Each keyword's word count sets type to head at one word, body up to three, else long-tail.
3. An order dict maps each type to a sort rank.
4. sorted by that rank prints type, volume, and keyword from head down to long-tail.

Try it:

1. Adjust the band boundaries and observe how terms reclassify.
2. Sum volume per type to see where demand concentrates.
3. Add a fourth band for keywords beyond six words.
4. Shift the body/tail boundary to 4 words and re-run.

⚠ Common Mistakes

- Boundary off-by-one: a two-word keyword is 'body' here because head is `<= 1`.
- Sorting by the label string alphabetically would scramble the head-body-tail order.
- Counting characters instead of words mislabels one long word as long-tail.

Skills gained keyword segmentation | word-count banding | custom sort order

→ Where You'll Use This: Head, body, and tail segmentation shapes content strategy, balancing competitive head bets against the easier long-tail wins that build early traffic.

⚡ Mental Model

Like sorting fish by size before market: the big head terms are the prize catch but hard to land, while the small fry are plentiful and quick to sell.

Project 220 Assign Priority Tiers to a Ranked Keyword List

💡 The Idea Behind It

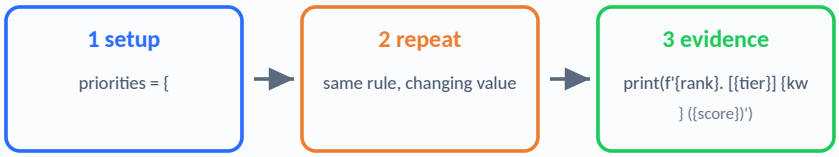
A flat ranked list is hard to action, so this slices a ranking into priority tiers. The priorities dict pairs keywords with scores; sorting by negative score then keyword produces a stable order. enumerate gives each a rank number, and an inline conditional assigns P1 to the top two, P2 to the next two, and P3 beyond, telling a team what to tackle this sprint versus later.

What You'll Build & Learn

Assign P1, P2, and P3 tiers to a ranked keyword list based on rank position.

- Tiers make a ranking actionable
- enumerate for rank numbers
- Position-based tier assignment

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 219: classify keywords by word count into head, body, tail. Project 221 changes the surface problem while preserving the underlying method. *progress check*

Reading target: assign priority tiers to a ranked keyword list is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `priorities = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{rank}. [{tier}] {kw} ({score})')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`priorities = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`tier = 'P1' if rank <= 2 else 'P2' if rank <= 4 else 'P3'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{rank}. [{tier}] {kw} ({score})')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `tier = 'P1' if rank <= 2 else 'P2' if rank <= 4 else 'P3'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Assign Priority Tiers to a Ranked Keyword List: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: priorities, seo, audit, keyword, tool. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: priorities = { | Core: tier = 'P1' if rank <= 2 else 'P2' if rank <= 4 else 'P3' | Evidence: print(f'{rank}. [{tier}] {kw} ({score})')

🛠️ Reader to Writer Bridge

1. Read: explain assign priority tiers to a ranked keyword list in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 219.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 221 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{rank}. [{tier}] {kw} ({score})')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `priorities = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of assign priority tiers to a ranked keyword list and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Sorting by descending score (with the keyword as a tiebreaker) and slicing rank positions into tiers turns a continuous score into a clear work queue.

```
priorities = {
    'seo audit': 88.5,
    'keyword tool': 72.0,
    'link building': 65.3,
    'meta tags': 91.2,
    'serp tracking': 54.0,
}
ranked = sorted(priorities.items(), key=lambda x: (-x[1], x[0]))
for rank, (kw, score) in enumerate(ranked, 1):
    tier = 'P1' if rank <= 2 else 'P2' if rank <= 4 else 'P3'
    print(f'{rank}. [{tier}] {kw} ({score})')
```

```
output
1. [P1] meta tags (91.2)
2. [P1] seo audit (88.5)
3. [P2] keyword tool (72.0)
4. [P2] link building (65.3)
5. [P3] serp tracking (54.0)
```

How it works:

1. The priorities dict pairs five keywords with priority scores.
2. ranked sorts the items by negative score then keyword for a stable order.
3. enumerate starting at 1 numbers each keyword's rank.
4. An inline conditional sets P1 for ranks one to two, P2 for three to four, else P3, printed per line.

Try it:

1. Tier by score thresholds instead of by rank position.
2. Make the tier cutoffs configurable parameters.
3. Add a P0 tier for any score above ninety.
4. Change the tier cutoffs to top-1 / next-2 / rest.

⚠ Common Mistakes

- Tiering by score thresholds instead of rank position gives uneven tier sizes.

- Dropping the keyword tiebreaker makes equal scores rank unpredictably.
- Starting `enumerate` at 0 throws off the rank numbers and the tier cutoffs.

Skills gained `tier assignment` `enumerate` `ranked sort`

→ **Where You'll Use This:** Priority tiers translate a long keyword ranking into sprint planning, telling teams plainly what to ship now, next, and someday.

Mental Model

Like a triage nurse tagging patients red, yellow, and green: the ordering already exists, but the colour band tells the team who gets attention first.

Project 221 Weight Volume by Intent to Get Effective Demand

The Idea Behind It

Raw volume overrates low-intent traffic, so multiplying each keyword's volume by an intent weight gives effective demand. A weights dict scores each intent class, a separate vols dict holds the volumes, and the loop multiplies the looked-up weight by the volume per keyword. A navigational term with 6000 volume drops below a 4000-volume informational query once intent is weighed in.

What You'll Build & Learn

Compute effective demand by weighting each keyword's volume by its intent class.

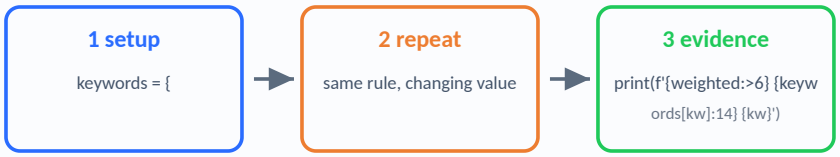
- Effective demand discounts low intent
- Weighting volume by intent class
- Joining two dicts by key

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 220: assign priority tiers to a ranked keyword list. Project 222 changes the surface problem while preserving the underlying method.

progress check

Reading target: weight volume by intent to get effective demand is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `keywords = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{weighted:>6} {keywords[kw]:14} {kw}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for kw in sorted(keywords):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{weighted:>6} {keywords[kw]:14} {kw}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for kw in sorted(keywords):`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Weight Volume by Intent to Get Effective Demand: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, how, to, start, blog. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = { | Core: for kw in sorted(keywords): | Evidence: print(f'{weighted:>6} {keywords[kw]:14} {kw}')

🛠️ Reader to Writer Bridge

1. Read: explain weight volume by intent to get effective demand in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 220.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 222 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{weighted:>6} {keywords[kw]:14} {kw}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `keywords = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of weight volume by intent to get effective demand and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Looking up each keyword's intent weight and multiplying by its volume produces effective demand, where a smaller transactional term can outweigh a larger informational one.

```
keywords = {
    'how to start a blog': 'informational',
    'best blogging platform': 'commercial',
    'wordpress pricing': 'transactional',
    'wix login': 'navigational',
}
weights = {'informational': 0.5, 'commercial': 1.5, 'transactional': 2.0,
'navigational': 0.3}
vols = {'how to start a blog': 9000, 'best blogging platform': 4000, 'wordpress
pricing': 2000, 'wix login': 6000}
for kw in sorted(keywords):
    weighted = round(vols[kw] * weights[keywords[kw]])
    print(f'{weighted:>6}  {keywords[kw]:14} {kw}')
```

```
output
  6000  commercial     best blogging platform
  4500  informational  how to start a blog
  1800  navigational   wix login
  4000  transactional  wordpress pricing
```

How it works:

1. The keywords dict maps each keyword to its intent label.
2. weights scores each intent class and vols holds each keyword's volume.
3. For each sorted keyword, weighted is its volume times its intent's weight, rounded.
4. Each line prints the weighted demand, the intent, and the keyword.

Try it:

1. Tune the weights to match your conversion data.
2. Sort the output by weighted demand rather than by keyword.
3. Add an unknown-intent class with a neutral weight of one.
4. Sort the output by weighted demand descending.

⚠ Common Mistakes

- An intent value missing from the weights dict raises KeyError.
- Weighting all intents equally collapses effective demand back to raw volume.
- Iterating without sorting the keys gives nondeterministic line order.

Skills gained `effective demand` `intent weighting` `dict join`

→ **Where You'll Use This:** Intent-weighted volume reranks a keyword list by likely business impact, demoting high-traffic but low-value navigational and informational terms.

⚡ Mental Model

Like adjusting nominal salaries for cost of living: the headline number flatters until you weight it by what it's really worth in context.

Project 222 Find Reachable Keywords by Difficulty and Current Rank

💡 The Idea Behind It

A keyword is realistically reachable if it is not too hard and you are either unranked or already close. A reachable function returns true when difficulty is at most 45 and rank is either 0 (unranked) or within 20. A comprehension keeps the reachable keywords, sorts them by negative volume, and prints them, while the skipped terms are listed separately, building an honest target list.

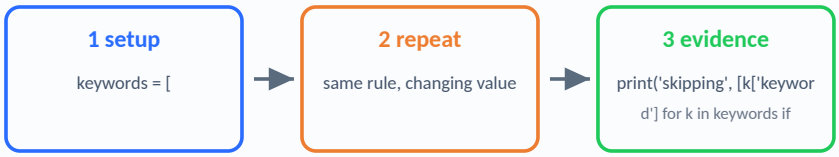
What You'll Build & Learn

Build an honest target list of keywords that pass both a difficulty cap and a rank window.

- Reachability combines difficulty and rank
- Treating unranked as a special case
- Separating kept from skipped keywords

🧭 Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 221: weight volume by intent to get effective demand. Project 223 changes the surface problem while preserving the underlying method. *progress check*



Reading target: find reachable keywords by difficulty and current rank is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('skipping', [k['keyword'] for k in keywords if not reachable(k)])` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`wins = [k for k in keywords if reachable(k)]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('skipping', [k['keyword'] for k in keywords if not reachable(k)])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `wins = [k for k in keywords if reachable(k)]`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Find Reachable Keywords by Difficulty and Current Rank: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, cheap, flights, volume. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: keywords = [| Core: wins = [k for k in keywords if reachable(k)] | Evidence: print('skipping', [k['keyword'] for k in keywords if not reachable(k)])

🛠️ Reader to Writer Bridge

1. Read: explain find reachable keywords by difficulty and current rank in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 221.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 223 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('skipping', [k['keyword'] for k in keywords if not reachable(k)])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of find reachable keywords by difficulty and current rank and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

The `reachable` predicate folds a difficulty ceiling and a rank window into one test, where rank 0 (unranked) is treated as a fresh opportunity rather than an existing position.

```
keywords = [
    {'keyword': 'cheap flights', 'volume': 20000, 'difficulty': 85, 'rank': 0},
    {'keyword': 'cheap flights to rome', 'volume': 3000, 'difficulty': 40,
'rank': 12},
    {'keyword': 'last minute flights rome', 'volume': 900, 'difficulty': 25,
'rank': 6},
]
def reachable(k):
    return k['difficulty'] <= 45 and (k['rank'] == 0 or k['rank'] <= 20)
wins = [k for k in keywords if reachable(k)]
for k in sorted(wins, key=lambda k: -k['volume']):
    print(f"reachable: {k['keyword']} (diff {k['difficulty']}, rank
{k['rank']})")
print('skipping', [k['keyword'] for k in keywords if not reachable(k)])
```

```
output
reachable: cheap flights to rome (diff 40, rank 12)
reachable: last minute flights rome (diff 25, rank 6)
skipping ['cheap flights']
```

How it works:

1. A list of dicts holds keyword, volume, difficulty, and rank.
2. reachable returns true when difficulty is 45 or less and rank is 0 or within 20.
3. wins keeps the reachable keywords, sorted by negative volume.
4. Each reachable keyword prints, then the skipped keywords print as a list.

Try it:

1. Treat an unranked keyword as lower priority than a close one.
2. Make the difficulty cap and rank window tunable.
3. Sort reachable keywords by current rank instead of volume.
4. Tighten the difficulty ceiling to 30 and recount the reachable set.

⚠ Common Mistakes

- Treating rank 0 as the best position (not 'unranked') inverts the rank logic.
- Using `or` between the difficulty and rank tests admits keywords that fail one condition.
- A keyword at rank exactly 20 is included because the test is `<= 20`.

Skills gained reachability filter compound condition kept-versus-skipped split

→ **Where You'll Use This:** Reachability filtering keeps a roadmap honest by dropping unwinnable head terms and surfacing keywords where effort can plausibly move the ranking.

⚡ Mental Model

Like a climber picking routes within their grade and near their current foothold: too hard or too far off, and it goes on the someday list, not today's.

Project 223 Cluster Keywords by Any Shared Token

💡 The Idea Behind It

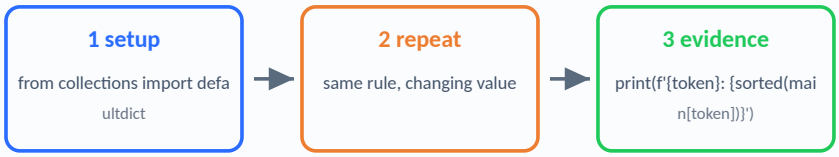
A keyword can belong to several clusters at once, so this indexes every keyword under each of its meaningful tokens. A defaultdict of sets adds each keyword to the set for every word it contains, skipping stopwords like best, for, and the. Filtering to tokens with at least two keywords keeps the real clusters, so 'best running shoes' shows up under both running and shoes, revealing overlapping groups.

What You'll Build & Learn

Cluster keywords under every meaningful token they contain, allowing multi-cluster membership.

- Keywords can join multiple clusters
- defaultdict(set) for token indexing
- Stopword skipping and a size filter

🧭 Skill Roadmap



Skill step: pushes the same idea into a less automatic situation. It builds on Project 222: find reachable keywords by difficulty and current rank. Project 224 changes the surface problem while preserving the underlying method. *progress check*

Reading target: cluster keywords by any shared token is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `from collections import defaultdict` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f'{token}: {sorted(main[token])}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`from collections import defaultdict`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if token not in ('best', 'for', 'the'):`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{token}: {sorted(main[token])}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if token not in ('best', 'for', 'the'):`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Cluster Keywords by Any Shared Token: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: collections, defaultdict, keywords, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: from collections import defaultdict | Core: if token not in ('best', 'for', 'the'): | Evidence: print(f'{token}: {sorted(main[token])}')

🛠️ Reader to Writer Bridge

1. Read: explain cluster keywords by any shared token in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 222.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 224 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{token}: {sorted(main[token])}')`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `from collections import defaultdict` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of cluster keywords by any shared token and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Adding each keyword to a set under every non-stop-word token produces overlapping clusters; filtering to tokens with two or more members keeps only the meaningful groups.

```
from collections import defaultdict
keywords = ['running shoes', 'best running shoes', 'trail running shoes', 'kids shoes', 'kids socks', 'best socks']
clusters = defaultdict(set)
for kw in keywords:
    for token in kw.split():
        if token not in ('best', 'for', 'the'):
            clusters[token].add(kw)
main = {t: kws for t, kws in clusters.items() if len(kws) >= 2}
for token in sorted(main):
    print(f'{token}: {sorted(main[token])}')
```

```
output
kids: ['kids shoes', 'kids socks']
running: ['best running shoes', 'running shoes', 'trail running shoes']
shoes: ['best running shoes', 'kids shoes', 'running shoes', 'trail running shoes']
socks: ['best socks', 'kids socks']
```

How it works:

1. A defaultdict(set) named clusters indexes keywords by token.
2. For each keyword, every token except stopwords like best, for, and the is added under that token.
3. main keeps only tokens whose keyword set has two or more members.
4. Each surviving token prints with its sorted keywords.

Try it:

1. Expand the stopword set with more glue words.
2. Raise the minimum cluster size to three keywords.
3. Report how many clusters each keyword belongs to.
4. Drop the stop-word filter and watch 'best' become a cluster.

⚠ Common Mistakes

- Using a list instead of a set lets a repeated token add the same keyword twice.
- Not filtering stop words puts 'best' and 'for' at the top as noise clusters.
- Keeping single-keyword tokens clutters the output with trivial clusters.

Skills gained multi-token clustering | defaultdict of sets | stopword filtering

→ Where You'll Use This: Multi-token clustering builds overlapping topic maps that mirror how real content interlinks, beyond the rigid one-bucket-per-keyword view of simpler methods.

Mental Model

Like tagging a photo with several labels at once: a beach sunset lives under both 'beach' and 'sunset', so it surfaces in more than one album.

Project 224 Forecast Traffic Uplift from Rank Improvements

The Idea Behind It

The point of ranking higher is more clicks, so this quantifies the uplift each optimisation delivers. Using a position-to-CTR table, the code estimates current traffic from the current rank and projected traffic from the target rank, with dict.get supplying a tiny fallback CTR for unlisted positions. The difference is the gain per keyword, summed into a total uplift that justifies the work.

What You'll Build & Learn

Forecast the traffic uplift from moving keywords from their current to a target rank.

- Uplift is target traffic minus current
- CTR-table lookup with a fallback
- Summing per-keyword gains

Skill Roadmap

Skill step: pushes the same idea into a less automatic situation. It builds on Project 223: cluster keywords by any shared token. Project 225 changes the surface problem while preserving the underlying method.

progress check

Reading target: forecast traffic uplift from rank improvements is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.

- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print('total uplift:', sum(k['gain'] for k in keywords))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`for k in keywords:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('total uplift:', sum(k['gain'] for k in keywords))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `for k in keywords:`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Forecast Traffic Uplift from Rank Improvements: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: ctr, keywords, keyword, seo, guide. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05} | Core: for k in keywords: | Evidence: print('total uplift:', sum(k['gain'] for k in keywords))

🛠️ Reader to Writer Bridge

1. Read: explain forecast traffic uplift from rank improvements in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 223.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 225 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('total uplift:', sum(k['gain'] for k in keywords))`. Then compare punctuation, spacing, and order.

   prediction before proof

2. Explain: point to `ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of forecast traffic uplift from rank improvements and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Estimating clicks at both positions via the CTR table (with a tiny default for off-table ranks) and subtracting gives the per-keyword uplift, summed into a total business case.

```
ctr = {1: 0.28, 2: 0.15, 3: 0.10, 4: 0.07, 5: 0.05}
keywords = [
    {'keyword': 'seo guide', 'volume': 12000, 'current': 8, 'target': 3},
    {'keyword': 'keyword tool', 'volume': 6000, 'current': 5, 'target': 2},
]
for k in keywords:
    now = round(k['volume'] * ctr.get(k['current'], 0.01))
    later = round(k['volume'] * ctr[k['target']])
    k['gain'] = later - now
    print(f"{k['keyword']}: {now} -> {later} traffic (+{k['gain']})")
print('total uplift:', sum(k['gain'] for k in keywords))
```

```
output
seo guide: 120 -> 1200 traffic (+1080)
keyword tool: 300 -> 900 traffic (+600)
total uplift: 1680
```

How it works:

1. The ctr dict maps positions to click-through rates, and keywords hold volume, current, and target ranks.
2. now uses ctr.get on the current rank with a small fallback; later uses the target rank's CTR.
3. k['gain'] is later minus now, printed per keyword.
4. The total uplift sums every keyword's gain.

Try it:

1. Apply a confidence discount to the projected gains.
2. Forecast revenue uplift by adding conversion and value fields.
3. Sort keywords by their gain to prioritise the work.
4. Extend the CTR table to position 8 with a real value.

⚠ Common Mistakes

- Looking up `ctr[k['current']]` without `.get` raises KeyError for an off-table rank like 8.

- Using the same position for now and later yields a zero, hiding the uplift.
- Forgetting `round` leaves fractional clicks in the forecast.

Skills gained `uplift forecasting` `CTR lookup` `gain summation`

→ **Where You'll Use This:** Uplift forecasts build the business case for SEO work, translating planned ranking gains into a concrete, defensible estimate of extra monthly clicks.

Mental Model

Like estimating the extra customers from moving your shop from a side street to the high street: same store, better position, and the footfall math proves the move.

Project 225 Build a Full Keyword Prioritization Report

The Idea Behind It

This capstone ties the chapter together. An intent function classifies each keyword from its trigger words, a weights dict scores those intents, and the loop computes score as volume times intent weight divided by difficulty. Sorting by negative score then keyword prints a single ranked decision table with a header, so classification, weighting, and difficulty fuse into the one prioritised view a keyword strategy delivers.

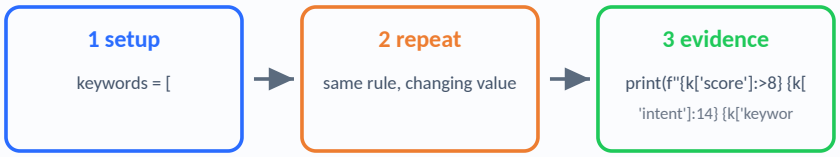
What You'll Build & Learn

Produce a full prioritisation report combining intent classification, intent weighting, and difficulty.

- Composing intent, weight, and difficulty
- A reusable intent classifier
- Printing a headed decision table

Skill Roadmap

Skill step: closes the chapter by asking you to apply the pattern with less hand-holding. It builds on Project 224: forecast traffic uplift from rank improvements. By the end of this chapter, you should be able to explain the pattern without copying the exact example. *progress check*



Reading target: build a full keyword prioritization report is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `keywords = [` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
- Evidence: `print(f"{k['score']:>8} {k['intent']:14} {k['keyword']}")` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`keywords = [`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
2. Apply the rule	`if w & {'buy', 'price', 'order'}: return 'transactional'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f"{k['score']:>8} {k['intent']:14} {k['keyword']}")`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Keyword Research and Intent as Data becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if w & {'buy', 'price', 'order'}: return 'transactional'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Build a Full Keyword Prioritization Report: connect the surface task to the chapter skill, score, prioritise and cluster keywords; classify serp intent; model difficulty against volume.
Names	Watch these names first: keywords, keyword, best, running, shoes. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: keywords = [| Core: if w & {'buy', 'price', 'order'}: return 'transactional' | Evidence: print(f" {k['score']:>8} {k['intent']:14} {k['keyword']}")

🛠️ Reader to Writer Bridge

1. Read: explain build a full keyword prioritization report in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 224.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, use this as the chapter checkpoint before moving to the next topic.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f"{k['score']:>8} {k['intent']:14} {k['keyword']}")`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `keywords = [` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build a full keyword prioritization report and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Each keyword is classified, weighted, and scored in one pass, then a single sort by descending score (with a keyword tiebreaker) produces the ranked decision table that drives the content plan.

```
keywords = [
    {'keyword': 'best running shoes', 'volume': 8000, 'difficulty': 45},
    {'keyword': 'buy running shoes online', 'volume': 3000, 'difficulty': 30},
    {'keyword': 'what are running shoes', 'volume': 2000, 'difficulty': 15},
    {'keyword': 'nike store', 'volume': 12000, 'difficulty': 70},
]
weights = {'informational': 0.5, 'commercial': 1.5, 'transactional': 2.0,
'navigational': 0.3}
def intent(kw):
    w = set(kw.split())
    if w & {'buy', 'price', 'order'}: return 'transactional'
    if w & {'best', 'top', 'review'}: return 'commercial'
    if w & {'what', 'how', 'why'}: return 'informational'
    return 'navigational'
for k in keywords:
    k['intent'] = intent(k['keyword'])
    k['score'] = round(k['volume'] * weights[k['intent']] / k['difficulty'], 1)
print(f"{'SCORE':>8}  {'INTENT':14} KEYWORD")
for k in sorted(keywords, key=lambda k: (-k['score'], k['keyword'])):
    print(f"{k['score']:>8}  {k['intent']:14} {k['keyword']}")
```

```
output
   SCORE  INTENT         KEYWORD
   266.7  commercial     best running shoes
   200.0  transactional  buy running shoes online
    66.7  informational  what are running shoes
    51.4  navigational   nike store
```

How it works:

1. A list of dicts holds keyword, volume, and difficulty, with a weights dict per intent.
2. intent classifies each keyword from its word set into one of four classes.
3. The loop writes intent and a score of volume times that intent's weight over difficulty into each dict.
4. A header prints, then keywords sorted by negative score and keyword print as the ranked table.

Try it:

1. Add a CPC factor so commercial value shapes the score.
2. Append a priority tier column to the table.
3. Export the ranked rows to a CSV file.
4. Add a CPC field and fold it into the score for a value-weighted ranking.

⚠ Common Mistakes

- A 12000-volume navigational term ('nike store') scores low because of its 0.3 weight and high difficulty, which surprises volume-only thinkers.
- Forgetting the keyword tiebreaker would make any two equal scores order nondeterministically.
- An intent that has no entry in the weights dict raises KeyError mid-report.

Skills gained prioritisation report | intent weighting | decision table

→ Where You'll Use This: This composite report is the deliverable a keyword research engagement ends on, a ranked table fusing intent and difficulty that a team can act on directly.

Mental Model

Like a final scorecard at the end of a competition: every earlier judging round folds into one ranked sheet that names the winner without further argument.

✅ Chapter Progress Checkpoint

What this chapter added: after 35 mini-projects, Keyword Research and Intent as Data should feel like a reusable Python move: score, prioritise and cluster keywords; classify serp intent; model difficulty against volume. *chapter checkpoint*

1 Read
Open any project from Projects 191-225 and mark setup, rule, and evidence without looking back at the explanation.

2 Write
Create one sibling program that keeps the same logic but changes the purpose, data, or output wording.
transfer proves learning

3 Explain
Say what this chapter builds on and where it leads: Next, Chapter 7 (Canonicalization, Duplicate and Thin Content) will reuse this chapter's reading habit with a new surface skill.

Ready-to-move-on test: if you can predict a project, explain the rule, and safely change one detail, the concept is becoming a writing skill rather than a copied example.

Quiz

6 questions · 4 categories · graded

2 Recall | 2 Meaning | 1 Structure | 1 Transfer

6.1.Q1 Recall MEDIUM
Turn back to Project 204 (Split Branded from Non-Branded Keywords). Without running it, what exactly does it print?

6.1.Q2 Meaning MEDIUM
Turn back to Project 198 (Measure Keyword-Set Overlap with Jaccard). Without running it, what exactly does it print?

6.1.Q3 Structure EASY Someone searches "buy nike air max". What is the search intent, and what page should rank?

- A Informational — a blog guide
- B Navigational — the homepage
- C Transactional — a product/checkout page
- D Commercial — a comparison post

6.1.Q4 Transfer HARD Keyword A: volume 4000, difficulty 30, intent_weight 3. Keyword B: volume 9000, difficulty 60, intent_weight 2. Using score = volume × weight ÷ difficulty, which ranks higher?

- A A (400) over B (300)
- B B (300) over A (400)
- C They tie
- D B, because it has more volume

6.1.Q5 Recall EASY Why are long-tail keywords (4+ words) often worth targeting despite low volume?

- A They are illegal to skip
- B They have lower difficulty and sharper intent, so they are easier to rank for and convert better
- C They always have higher volume
- D Search engines ignore short keywords

6.1.Q6 Meaning MEDIUM You find that /running-shoes and /shoes/running both target "best running shoes". What problem is this and how do you fix it?

Answer key for this chapter follows. Score yourself: 80%+ to advance, otherwise re-read the grammar block and re-take the quiz.

Answer Key – Chapter 6 – Keyword Research and Intent as Data

6.1.Q1. `branded (3): ['acme login', 'acme reviews', 'acme running shoes']` then `non-branded (2): ['best running shoes', 'cheap trainers']`

6.1.Q2. `shared: ['best shoes', 'running shoes']` then `jaccard: 0.4`

6.1.Q3. C "buy" is a transactional trigger; the searcher is ready to act, so a product page (not a guide) should rank.

6.1.Q4. A A scores 4000×3÷30 = 400 and B scores 9000×2÷60 = 300, so A ranks higher despite lower volume.

6.1.Q5. B long-tail terms face less competition and the searcher is more specific, so they rank more easily and convert at a higher rate.

6.1.Q6. Keyword cannibalization — two of your own pages compete and split rankings. Fix by choosing one canonical page and merging or 301-redirecting the other into it.

Chapter 7 · Canonicalization, Duplicate and Thin Content

Check canonical consistency, detect duplicates with shingling/Jaccard, and flag thin pages.

Chapter Skill Map

What this chapter adds: In Canonicalization, Duplicate and Thin Content, the focus is check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages. You practise it across 38 short, runnable Python projects — each one a single deliberate move from recognition to fluency, never a race through examples. *chapter arc*

What it builds on: Chapter 7 assumes the reading habits from Chapter 6: Keyword Research and Intent as Data. You should carry forward the habit of predicting output before trusting the page.

Where it leads: Chapter 8, Site Speed and Core Web Vitals, reuses this chapter's discipline with a new kind of problem.

1 **Projects 226-237**	2 **Projects 238-249**	3 **Projects 250-263**
Recognise the pattern and read the code slowly. *name it first*	Trace similar programs with less prompting and explain what changed.	Modify the idea, predict the result, then verify with output. *own the move*

The Idea Behind It

One page, many URLs is the default state of the web — your job is to collapse the copies and keep the credit on one URL. *dedupe, then consolidate*

The same page hides behind a dozen addresses. `https://Example.com/Page/`, `https://example.com/page`, the `www.` version, the `?utm_source=ad` version, the trailing-slash version — every one of them serves the *same* content, yet a naive crawler sees a dozen distinct URLs. That is duplication, and it costs you twice: it burns crawl budget fetching the same bytes over and over, and it splits ranking signals — links and relevance that should pile onto one URL scatter across the copies, so none of them ranks as well as the consolidated page would.

The cure has two halves. First, URL normalization: a deterministic function that rewrites every variant into one canonical string, so duplicates become *literally equal* and a dictionary can group them. Second, the canonical tag (`<link rel="canonical">`): a hint in each page's HTML naming which URL is the representative, so the engine folds the duplicate's signals onto the chosen one. A healthy ordinary page points its canonical at *itself* — a self-referencing canonical is the baseline of a clean site.

Normalization is just string surgery, applied in a fixed order. Lowercase the host (hostnames are case-insensitive), drop the fragment, sort the query parameters, and trim the trailing slash. Do it the same way every time and the variants snap together:

```
url = 'https://Example.COM/Blog/Post/?b=2&a=1#section'

def normalize(u):
```

```
    scheme, rest = u.split('://', 1)
    rest = rest.split('#', 1)[0]            # drop the fragment
    if '?' in rest:
        hostpath, query = rest.split('?', 1)
        query = '?' + '&'.join(sorted(query.split('&')))
    else:
        hostpath, query = rest, ''
    host, slash, path = hostpath.partition('/')
    path = '/' + path
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]                    # trim non-root trailing slash
    return scheme + '://' + host.lower() + path + query

print(normalize(url))
```

```
output
https://example.com/Blog/Post?a=1&b=2
```

Notice the host is lowercased but the *path* is not — `/Blog/Post` stays cased because paths are case-sensitive on most servers. Get the order and the rules right and exact duplicates collapse to one key.

normalize the host, not the path

Exact copies are the easy case. The harder problem is the near-duplicate — pages that differ by a word or two ("for every home" vs "for every house"), which a hash will not catch because one changed character flips the whole digest. For those you need a *similarity* measure: break each page into overlapping word windows called shingles, then compute the Jaccard similarity — shared shingles over total shingles, on a 0-to-1 scale. Above a threshold, the pages are near-duplicates of each other. And running underneath both is thin content: pages with so few unique words they satisfy no searcher, which an engine treats as low-value and may decline to index.

CANONICAL TAG

A `<link rel="canonical" href="...">` in a page's HTML that names which URL is the indexing representative. The engine folds duplicate signals onto that target. An ordinary page should self-reference (canonical == its own URL).

URL NORMALIZATION

A deterministic function that rewrites every variant of a URL (case, slash, query order, fragment, tracking params, www, default port) into one canonical string, so duplicates become literally equal.

DUPLICATE CONTENT

Two or more URLs serving byte-identical (after normalising case/whitespace) visible text. Detected with a content hash: identical text → identical digest.

NEAR-DUPLICATE

Pages whose text differs only slightly. A hash misses these, so similarity is measured with shingles + Jaccard, MinHash or SimHash above a chosen threshold.

SHINGLE

A sliding window of k consecutive tokens (words or characters) from a page. The set of a page's shingles captures local word order, the unit every near-duplicate detector compares.

THIN CONTENT

A page with too little unique value — very few words, or mostly boilerplate nav/footer text — that rarely satisfies a searcher and looks low-value to an engine. A soft 404 is the extreme: a 200 status with no real content.

A self-referencing canonical is the baseline

Every ordinary page should carry a canonical tag that points at *its own* URL. That tells the engine "this is the representative — index me." The simplest audit is one comparison: does the canonical equal the page's URL? When it points elsewhere, the page is deliberately folding itself into another, which is right for a duplicate but a bug on a page that should stand alone.

```
pages = {
    'https://example.com/a': 'https://example.com/a',
    'https://example.com/b': 'https://example.com/canonical-b',
    'https://example.com/c': 'https://example.com/c',
}
for url, canon in pages.items():
    flag = 'SELF' if url == canon else 'OTHER'
    print(f'{flag} {url} -> {canon}')
```

```
output
SELF https://example.com/a -> https://example.com/a
OTHER https://example.com/b -> https://example.com/canonical-b
SELF https://example.com/c -> https://example.com/c
```

The canonical is only a *hint*, and it must not contradict the page's other signals. A page that redirects elsewhere yet still self-canonicalises sends two opposite messages ("go away" and "index me"); a canonical pointing at a `noindex` page, a `404`, a redirect, or a different domain is wasted or harmful. The rule of thumb: the canonical target should be a same-site URL that returns `200` and is itself indexable.

Normalize the URL, then group

Before you can declare two URLs duplicates you must agree on what "same" means. Each normalization rule kills one class of accidental variant. The biggest single source on a real site is tracking parameters — every ad campaign appends `utm_source`, `utm_medium` and friends, spawning a fresh URL for one page. Strip them before anything else:

```
url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&page=2'
base, _, query = url.partition('?')
kept = [kv for kv in query.split('&') if not kv.startswith('utm_')]
clean = base + ('?' + '&'.join(kept) if kept else '')
print('clean:', clean)
print('dropped:', len(query.split('&')) - len(kept))
```

```
output
clean: https://example.com/sale?id=42&page=2
dropped: 2
```

The other classic folds are the same idea: `www.` vs the bare host, `http` vs `https`, the explicit default port `:443`, a mixed-case host, and query parameters in a different order (`?a=1&b=2` is the same page as `?b=2&a=1`). A full canonicaliser applies every rule at once, and *then* duplicates collapse into one dictionary key:

```
urls = [
    'https://www.Example.com/Page/',
    'https://example.com/page',
    'https://example.com/page?utm_source=x',
    'https://example.com/other',
]
def canon(u):
    scheme, rest = u.split('://', 1)
    rest = rest.split('#', 1)[0]
    hostpath, _, query = rest.partition('?')
    host, slash, path = hostpath.partition('/')
    host = host.lower()
    if host.startswith('www.'):
        host = host[4:]
    path = '/' + path
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]
    kept = [kv for kv in query.split('&') if kv and not kv.startswith('utm_')]
    q = '?' + '&'.join(sorted(kept)) if kept else ''
    return scheme + '://' + host + path.lower() + q
```

```
clusters = {}
for u in urls:
    clusters.setdefault(canon(u), []).append(u)
for c in sorted(clusters):
    print(f'{c} <- {sorted(clusters[c])}')
```

```
output
https://example.com/other <- ['https://example.com/other']
https://example.com/page <- ['https://example.com/page', 'https://example.com/page?
utm_source=x', 'https://www.Example.com/Page/']
```

Exact duplicates: hash the content

Once URLs are normalized, compare the *content*. Two pages with byte-identical visible text are exact duplicates. Comparing every page to every other is wasteful; instead, `fingerprint` each page — normalise whitespace and case, then take a `SHA-1` digest — and group by digest. Identical text yields an identical hash, so duplicate detection becomes a single dictionary lookup. (Use `hashlib.sha1`, never Python's builtin `hash`, which is salted per process and so is not stable across runs.)

```
import hashlib

def fingerprint(text):
    return hashlib.sha1(' '.join(text.lower().split()).encode()).hexdigest()

pages = {
    'https://example.com/a': 'Buy   Red Shoes Today',
    'https://example.com/b': 'buy red shoes today',
    'https://example.com/c': 'Buy Blue Shoes Today',
}
groups = {}
for url, text in pages.items():
    groups.setdefault(fingerprint(text), []).append(url)
for h, urls in groups.items():
    tag = 'DUP' if len(urls) > 1 else 'unique'
    print(f'{tag} {h[:8]} {sorted(urls)}')
```

```
output
DUP 42f8e1ec ['https://example.com/a', 'https://example.com/b']
unique 8f815bf4 ['https://example.com/c']
```

The normalisation step is what makes the fingerprint *stable across cosmetic edits but reactive to real ones*. "Buy Red Shoes Today" and "buy red shoes today" hash the same (good — they are the same page); adding a "!" would change the digest (also good — that is a real edit). *normalise, then hash*

Near-duplicates: shingles and Jaccard

A hash is all-or-nothing: change one word and the digest is completely different, so hashing can never catch a page that was barely tweaked. For that you measure *overlap*. Break each page into k-shingles — every window of k consecutive words — then compare the two sets. The Jaccard similarity is the size of the intersection over the size of the union: how much the two pages share, from 0 (nothing) to 1 (identical).

```
def shingles(text, k=2):
    w = text.lower().split()
    return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}

a = shingles('red running shoes for sale')
b = shingles('red running shoes on sale')
inter = a & b
union = a | b
print('shared shingles:', len(inter))
print('total shingles:', len(union))
print('jaccard:', round(len(inter) / len(union), 3))
```

```
output
shared shingles: 2
total shingles: 6
jaccard: 0.333
```

Pick a threshold (say 0.5) and any pair clearing it is a near-duplicate. Comparing every pair across a set surfaces clusters of barely-changed pages — the "we made fifty city landing pages by find-and-replacing the town name" pattern that engines penalise. For web scale you would replace the all-pairs scan with cheaper estimators (MinHash, SimHash) that approximate Jaccard from a tiny fingerprint, but the metric being approximated is always this one.

Thin content: count what is actually there

Duplication is one failure mode; thinness is the other. A page with a handful of words rarely answers a query and looks low-value to an engine. The crudest gate is a word count, and a sharper one is the boilerplate-to-content ratio — the share of words that are templated nav/footer junk ("home", "login", "privacy") rather than real content. When boilerplate dominates, the unique content is too thin to rank, even if the raw count looks fine.

```
import re
pages = {
    'https://example.com/full': 'Our complete guide explains every step of
installing solar panels safely at home this season.',
    'https://example.com/thin': 'Solar panels. Buy now.',
    'https://example.com/ok': 'Solar panels convert sunlight into electricity using
photovoltaic cells mounted on your roof.',
}
threshold = 10
for url in sorted(pages):
```

```
    wc = len(re.findall(r"[a-zA-Z']+", pages[url]))
    tag = 'THIN' if wc < threshold else 'ok'
    print(f'{tag} {wc} words {url}')
```

```
output
ok 15 words https://example.com/full
ok 13 words https://example.com/ok
THIN 4 words https://example.com/thin
```

The capstone of any audit ties all three together in one pass over the page set: confirm the canonical is self-referencing, hash the body to catch exact duplicates, and count words to flag thinness — three independent checks, one loop. *self-canonical? duplicate? thin?*

Example 1

A page at `https://example.com/b` carries a self-referencing canonical (`canonical == url`) but the server returns a 301 redirect to `https://example.com/c`. Is that page healthy?

SOLUTION

1. The canonical says "index me, I am the representative" — a normal, indexable page.
2. But the 301 redirect says the opposite: "this URL has moved, go to /c instead." The two signals `contradict`.
3. An engine cannot both index /b and follow it away to /c. The redirect should win, so /b should *not* self-canonicalise — it should drop the tag, or /c should be the canonical.

No — it is a conflict: a redirecting URL must not also self-canonicalise.

redirect and self-canonical are mutually exclusive

Example 2

Two product pages read "cheap blue widgets for every home" and "cheap blue widgets for every house". Using 2-word shingles, are they near-duplicates at a 0.5 threshold?

SOLUTION

1. Shingles of A: {(cheap,blue),(blue,widgets),(widgets,for),(for,every),(every,home)} — 5 shingles.
2. Shingles of B: the same five except the last is (every,house) instead of (every,home). The four leading shingles are `shared`.
3. Intersection = 4, union = 6, so Jaccard = 4/6 = `0.667`, which clears the 0.5 threshold.

Yes — Jaccard 0.667 ≥ 0.5, so they are flagged as near-duplicates (only the last word changed).

one word swapped, signals split.

Example 3

You collect four URLs that all serve one product page: `.../product?ref=ad&color=red`, `.../product`, `.../product/`, `.../product?color=red`. Which should you pick as the canonical, by a "shortest URL, ties broken alphabetically" policy?

SOLUTION

1. Normalise: the trailing-slash and the tracking-param variants all reduce toward the bare path, but for the *choice* you score the candidates by `(len(url), url)`.
2. The shortest is `https://example.com/product` (no query, no slash) — every other variant is strictly longer.
3. Choose it as the representative and fold the other three onto it via canonical tags.

Pick `https://example.com/product` — the shortest, cleanest URL — and canonicalise the rest to it.

one page, one chosen URL

⚡ Mental-Math Shortcut

Normalize, then consolidate. Duplicate work is wasted twice — once in crawl budget, once in split ranking signals. First make copies *literally equal* with a deterministic URL normaliser (lowercase host, drop fragment, strip `utm_`, sort params, trim slash); then *consolidate* the credit onto one representative with a canonical tag that the page's redirect, status, and indexability all agree with. Hash catches exact copies; shingles + Jaccard catch the near ones; a word count catches the thin ones.

⚠ Common Mistakes

- Using Python's builtin `hash()` for content fingerprints — it is salted per process, so the same text hashes differently across runs and your duplicate groups silently break. Use `hashlib.sha1` (or sha256).
- Lowercasing the whole URL during normalization. The host is case-insensitive, but the path usually is not, so `/Page` and `/page` can be genuinely different resources — only lowercase the host.
- Expecting a canonical tag to deduplicate by force. It is a hint, not a redirect: if the page also returns a redirect, is `noindex`, 404s, or points cross-domain, the engine may ignore or distrust it.
- Trying to catch near-duplicates with a content hash. One changed word flips the whole digest, so hashing reports "all unique" while fifty find-and-replace landing pages slip through — that is what Jaccard/shingles are for.

This chapter contains 38 hands-on mini-projects (Projects 226–263). Type each one out, run it, and experiment.

Project 226 Check a Canonical Is Self-Referencing

💡 The Idea Behind It

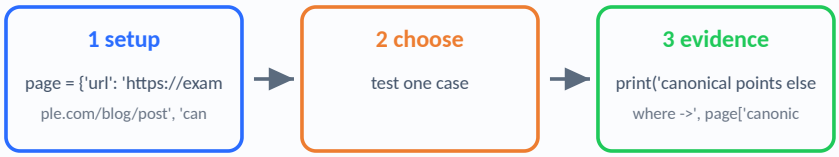
A healthy page declares itself the master copy by pointing its canonical tag back at its own URL. This project models one page as a dictionary holding a url and a canonical key, then compares the two strings. When they match, the page is self-referencing; when they differ, the canonical defers indexing credit to somewhere else. It is the smallest possible canonical health check and the baseline every audit starts from.

What You'll Build & Learn

Confirm a single page canonicalises to itself by comparing its url and canonical fields.

- What a self-referencing canonical means
- Comparing two URL strings for equality
- The baseline of a healthy page

Skill Roadmap



Skill step: opens the chapter by setting the first concrete pattern. It starts a new chapter sequence, so the first job is to name the pattern before typing it. Project 227 changes the surface problem while preserving the underlying method. *progress check*

Reading target: check a canonical is self-referencing is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `page = {'url': 'https://example.com/blog/post', 'canonical': 'https://example.com/blog/post'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The condition splits the world into cases. Read the test aloud, then follow only the branch that matches the current data.
- Writing move: this project practises how to express a choice clearly enough that only one branch wins. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('canonical points elsewhere ->', page['canonical'])` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`page = {'url': 'https://example.com/blog/post', 'canonical': 'https://example.com/blog/post'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if page['url'] == page['canonical']:`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. slow line
3. Check the evidence	`print('canonical points elsewhere ->', page['canonical'])`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if page['url'] == page['canonical']:`

Construction pattern

The construction splits into cases. Translate the condition into plain English, then follow only the matching branch.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Make a branch table with condition true/false and the exact statement that runs in each case.

Rewrite drill

Choose one value that takes the other branch and explain why the test changes.

Code Reading Stack

Layer	What to read
Intent	Check a Canonical Is Self-Referencing: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: page, url, https, example, com. Names are the reader's map of roles and responsibilities.
Flow	conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: page = {'url': 'https://example.com/blog/post', 'canonical': 'https://e... | Core: if page['url'] == page['canonical']: | Evidence: print('canonical points elsewhere ->', page['canonical'])

🛠️ Reader to Writer Bridge

1. Read: explain check a canonical is self-referencing in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then start by making this chapter's core idea concrete. *read with a pencil*
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 227 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('canonical points elsewhere ->', page['canonical'])`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `page = {'url': 'https://example.com/blog/post', 'canonical': 'https://example.com/blog/post'}` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of check a canonical is self-referencing and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A self-referencing canonical means `url == canonical`; comparing the two strings is the entire check that a page is claiming itself as the indexable version.

```
page = {'url': 'https://example.com/blog/post', 'canonical':
'https://example.com/blog/post'}
if page['url'] == page['canonical']:
    print('self-referencing canonical: OK')
```

```
    else:
        print('canonical points elsewhere ->', page['canonical'])
```

```
output
self-referencing canonical: OK
```

How it works:

1. A dictionary stores the page url alongside its declared canonical URL
2. The if checks whether url equals canonical with a string comparison
3. When equal it prints an OK message confirming self-reference
4. The else branch reports where the canonical actually points instead

Try it:

1. Change the canonical to a different URL and watch the else branch fire
2. Wrap the check in a function that returns True or False
3. Add a third key for the http status and only pass pages returning 200
4. Point the canonical at `https://example.com/other` and watch the branch flip.

⚠ Common Mistakes

- Comparing only the path and ignoring the scheme or host hides a cross-origin canonical.
- Treating a missing canonical as self-referencing: an absent tag is a different state, not OK.
- Forgetting that a trailing slash or case difference makes two equal-looking URLs compare unequal.

Skills gained dict access | string equality | canonical basics

→ Where You'll Use This: Every site audit begins by confirming pages self-canonicalise; a crawler flags any page whose canonical tag silently hands authority to another URL.

Mental Model

A canonical tag is a page raising its hand to say 'I am the original.' A self-referencing one is the page pointing at itself.

Project 227 Detect a Canonical Pointing to Another URL

The Idea Behind It

Scaling the single-page check up to a whole set means walking a dictionary of url-to-canonical mappings and labelling each entry. The loop reads every pair, tags it SELF when the URL equals its canonical and OTHER when it points elsewhere, then prints an arrow line. Some OTHER entries are deliberate, folding a tracking-parameter variant into the clean URL, while others may be mistakes worth investigating.

What You'll Build & Learn

Iterate a set of pages and label each as self-referencing or deferring to another URL.

- Looping a url-to-canonical dictionary with items
- Tagging each page SELF or OTHER
- Reading intentional versus accidental canonicals

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 226: check a canonical is self-referencing. Project 228 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect a canonical pointing to another url is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'{flag} {url} -> {canon}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output.

visual trace

Worked Trace

Move	Code to inspect	Why it matters

3. Transfer: change one small part of detect a canonical pointing to another url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Mapping each URL to its declared canonical and labelling `SELF` versus `OTHER` separates pages that index themselves from those that point at a representative URL.

```
pages = {
    'https://example.com/a': 'https://example.com/a',
    'https://example.com/b': 'https://example.com/canonical-b',
    'https://example.com/c': 'https://example.com/c',
    'https://example.com/d?ref=ad': 'https://example.com/d',
}
for url, canon in pages.items():
    flag = 'SELF' if url == canon else 'OTHER'
    print(f'{flag} {url} -> {canon}')
```

```
output
SELF https://example.com/a -> https://example.com/a
OTHER https://example.com/b -> https://example.com/canonical-b
SELF https://example.com/c -> https://example.com/c
OTHER https://example.com/d?ref=ad -> https://example.com/d
```

How it works:

1. A dictionary maps four page URLs to their canonical targets
2. The for loop unpacks each url and canon pair via items

3. A ternary sets flag to SELF when url equals canon, else OTHER
4. An f-string prints the flag, source URL and arrow to the canonical

Try it:

1. Count how many pages are SELF versus OTHER and print a summary
2. Filter the output to show only the OTHER rows
3. Add a page whose query string is the only difference from its canonical
4. Sort the pages by key so the report order is alphabetical.

⚠ Common Mistakes

- Assuming `OTHER` is always wrong: a duplicate pointing to its representative is correct behaviour.
- Relying on dict order for output and forgetting it is insertion order, not sorted.
- Not stripping tracking params first, so `/d?ref=ad` looks like a distinct page from `/d`.

Skills gained dict iteration | ternary expression | f-string formatting

→ Where You'll Use This: Bulk canonical reports look exactly like this: one row per crawled URL showing whether it claims itself or points away, so an SEO can scan thousands of pages fast.

⚡ Mental Model

Like roll call in a classroom: each page either answers 'present, that's me' or points across the room to whoever should answer instead.

Project 228 Follow a Canonical Chain to Its End

💡 The Idea Behind It

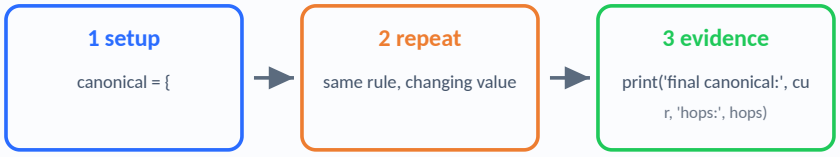
When page A canonicalises to B and B to C, the signals form a chain that a crawler must resolve to the true endpoint. This project walks the chain with a while loop guarded at ten hops, appending each URL visited and stopping when a page canonicalises to itself. It prints the full path and the final canonical plus the hop count, because search engines may give up on chains that run too long.

What You'll Build & Learn

Resolve a canonical chain to its terminal URL and report how many hops it took.

- Following a chain of canonical pointers
- Guarding a loop against infinite cycles
- Why long chains are risky

Skill Roadmap



Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 227: detect a canonical pointing to another url. Project 229 changes the surface problem while preserving the underlying method. *progress check*

Reading target: follow a canonical chain to its end is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

2. Explain: point to `canonical = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of follow a canonical chain to its end and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Walking the canonical map until a URL canonicalises to itself resolves the true target; a hop guard stops a malformed loop from spinning forever.

```
canonical = {
    'https://example.com/p1': 'https://example.com/p2',
    'https://example.com/p2': 'https://example.com/p3',
    'https://example.com/p3': 'https://example.com/p3',
}
start, cur, chain, hops = 'https://example.com/p1', 'https://example.com/p1',
[], 0
while hops < 10:
    chain.append(cur)
    nxt = canonical.get(cur, cur)
    if nxt == cur:
        break
    cur, hops = nxt, hops + 1
print(' -> '.join(chain))
print('final canonical:', cur, 'hops:', hops)
```

```
output
https://example.com/p1 -> https://example.com/p2 -> https://example.com/p3
final canonical: https://example.com/p3 hops: 2
```

How it works:

1. A dictionary encodes a chain where p1 points to p2 and p2 to p3
2. The while loop runs while hops stays under ten as a safety cap
3. Each pass appends cur to chain then looks up the next target
4. When the next equals cur the loop breaks, marking the chain's end
5. It prints the joined path and the final URL with its hop count

Try it:

1. Insert a cycle where p3 points back to p1 and confirm the ten-hop cap stops it
2. Lower the hop cap to two and see a long chain truncate
3. Return the resolved canonical from a function for any starting URL

4. Add a fourth link `p3 -> p4` and watch the chain lengthen.

⚠ Common Mistakes

- No hop guard means a cycle (A->B->A) loops until the process is killed.
- Appending after stepping drops the start URL from the printed chain.
- Counting URLs in the chain instead of transitions overstates the hop count by one.

Skills gained `while loop` `dict.get default` `loop guard`

→ Where You'll Use This: Real audits flag canonical chains because engines often follow only a hop or two; tracing each one to its endpoint shows which pages will actually be indexed.

⚡ Mental Model

A canonical chain is a relay race of batons; the engine wants the finish line, but if the track is too long it stops watching partway.

Project 229 Flag Conflicting Canonical vs Redirect

💡 The Idea Behind It

A page that issues a redirect yet also self-canonicalises is shouting two contradictory orders: the redirect says 'leave this URL' while the canonical says 'index this URL'. The project stores each page as a nested dict with canonical and redirect fields, then flags the conflict when a redirect exists and the canonical still points at the page itself. Clean pages with no redirect, or redirects without self-canonicalisation, pass.

What You'll Build & Learn

Detect pages that redirect elsewhere while still naming themselves canonical.

- Spotting contradictory canonical and redirect signals
- Reading nested dictionary fields
- Why two signals must agree

🧭 Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 228: follow a canonical chain to its end. Project 230 changes the surface problem while preserving the underlying method.

progress check

Reading target: flag conflicting canonical vs redirect is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

🔎 Logic Lens

- Setup: `pages = {` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'OK {url}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`pages = {`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if m['redirect'] and m['canonical'] == url:`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'OK {url}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if m['redirect'] and m['canonical'] == url:`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Conflicting Canonical vs Redirect: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: pages, https, example, com, canonical. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: pages = { | Core: if m['redirect'] and m['canonical'] == url: | Evidence: print(f'OK {url}')

🛠️ Reader to Writer Bridge

1. Read: explain flag conflicting canonical vs redirect in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 228.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 230 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'OK {url}')`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `pages = {` and say why this line, value, import, or entry point is needed before the rest of the Python can work.

3. Transfer: change one small part of flag conflicting canonical vs redirect and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

The conflict is the conjunction of two facts: a redirect target exists AND the canonical still names the page itself; either alone is fine.

```
pages = {
    'https://example.com/a': {'canonical': 'https://example.com/a', 'redirect':
None},
    'https://example.com/b': {'canonical': 'https://example.com/b', 'redirect':
'https://example.com/c'},
    'https://example.com/d': {'canonical': 'https://example.com/d', 'redirect':
None},
}
for url, m in pages.items():
    if m['redirect'] and m['canonical'] == url:
        print(f'CONFLICT {url}: self-canonical but redirects to
{m["redirect"]}')
    else:
        print(f'OK {url}')
```

```
output
OK https://example.com/a
CONFLICT https://example.com/b: self-canonical but redirects to
https://example.com/c
OK https://example.com/d
```

How it works:

1. Each page maps to a nested dict holding its canonical and an optional redirect
2. The loop checks if a redirect is set and the canonical equals the URL
3. When both hold it prints a CONFLICT line naming the redirect target
4. Otherwise the page is reported OK

Try it:

1. Add a page that redirects and canonicalises to the redirect target instead, and treat it as OK
2. Print the redirect destination's own canonical to follow the trail
3. Count conflicts and exit non-zero when any are found
4. Change page b's canonical to its redirect target and watch the conflict clear.

⚠ Common Mistakes

- Checking only the redirect and ignoring whether the canonical agrees with it.

- Treating an empty-string redirect as truthy if you do not normalise to `None`.
- Reporting a conflict when the canonical already points at the redirect target (that is consistent).

Skills gained `nested dict` `boolean and` `conflict detection`

→ **Where You'll Use This:** Crawlers cross-check the redirect chain against the canonical tag because a page cannot honestly say 'index me' and 'go away' at once; this catches a common migration bug.

Mental Model

Like a shop with a 'we've moved' sign on the door but a fresh 'open for business' banner in the window: customers and crawlers alike get confused.

Project 230 Normalize a URL to One Canonical Form

The Idea Behind It

The same page can hide behind dozens of URL spellings that differ only by case, a trailing slash, query-parameter order or a fragment. This normaliser splits the URL apart, drops the fragment after a hash, sorts the query parameters, lowercases the host while leaving the path intact, and strips a trailing slash from non-root paths. The result is one canonical string so two cosmetic variants become literally equal.

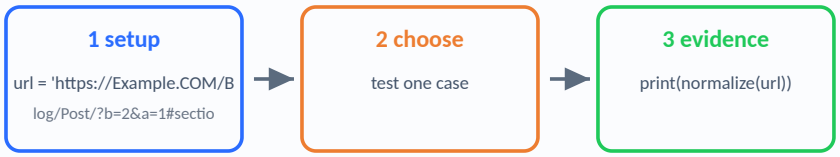
What You'll Build & Learn

Collapse case, slash, query-order and fragment variants of a URL into one canonical form.

- Decomposing a URL into scheme, host, path and query
- Sorting query parameters for stability
- Lowercasing only the host

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 229: flag conflicting canonical vs redirect. Project 231 changes the surface problem while preserving the underlying method. *progress check*



Reading target: normalize a url to one canonical form is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

Logic Lens

- Setup: `url = 'https://Example.COM/Blog/Post/?b=2&a=1#section'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The function boundary is the lesson: inputs enter, a rule runs, and a return value can be reused somewhere else.

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(normalize(url))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, choose applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`url = 'https://Example.COM/Blog/Post/?b=2&a=1#section'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`if '?' in rest:`	This line chooses a case. Read the test in plain English, then follow only the branch that matches. *slow line*
3. Check the evidence	`print(normalize(url))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `if '?' in rest:`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Comparison/logic: Decides truth, branches, filters, or loop continuation.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Normalize a URL to One Canonical Form: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: url, https, Example, Blog, Post. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: url = 'https://Example.COM/Blog/Post/?b=2&a=1#section' | Core: if '?' in rest: | Evidence: print(normalize(url))

🛠️ Reader to Writer Bridge

1. Read: explain normalize a url to one canonical form in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 229.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 231 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(normalize(url))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `url = 'https://Example.COM/Blog/Post/?b=2&a=1#section'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of normalize a url to one canonical form and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

Dropping the fragment, sorting query params, lowercasing only the host, and trimming a non-root trailing slash produces a canonical form that is stable across cosmetic variants.

```
url = 'https://Example.COM/Blog/Post/?b=2&a=1#section'

def normalize(u):
    scheme, rest = u.split('://', 1)
    rest = rest.split('#', 1)[0]
    if '?' in rest:
        hostpath, query = rest.split('?', 1)
        params = sorted(query.split('&'))
        query = '?' + '&'.join(params)
    else:
        hostpath, query = rest, ''
    host, slash, path = hostpath.partition('/')
    path = '/' + path
    if len(path) > 1 and path.endswith('/'):
        path = path[:-1]
    return scheme + '://' + host.lower() + path + query

print(normalize(url))
```

```
output
https://example.com/Blog/Post?a=1&b=2
```

How it works:

1. The function splits scheme from the rest then drops everything after the hash fragment
2. If a question mark exists it splits and sorts the ampersand-separated params
3. partition separates host from path, and the path is reassembled with a leading slash
4. A trailing slash is trimmed from any path longer than the root
5. It returns scheme, lowercased host, path and the sorted query joined back together

Try it:

1. Also lowercase the path and compare results on a mixed-case path
2. Strip a leading www from the host as part of normalisation
3. Decode percent-encoded characters before sorting the query
4. Add a `utm_source` param and decide whether to drop it before sorting.

⚠ Common Mistakes

- Lowercasing the whole URL corrupts case-sensitive paths; only the host is safe to lowercase.
- Stripping the trailing slash from the root path `'/'` would wrongly empty it.
- Sorting query params as one string instead of splitting on `&` reorders characters, not parameters.

Skills gained `str.split` `str.partition` `param sorting`

→ **Where You'll Use This:** URL normalisation underpins every deduplication pipeline; before you can group duplicates you must reduce each address to one canonical spelling the way search engines do internally.

Mental Model

Like filing names alphabetically by 'Smith, John' regardless of how someone scrawled it: messy inputs, one tidy index entry.

Project 231 Strip Tracking Params from a URL

The Idea Behind It

Marketing campaign tags such as utm_source mint a brand-new URL for every ad placement even though all of them serve one page. This project partitions the URL at its question mark, keeps only the parameters that do not start with utm_, and rebuilds a clean address, appending the query only when something survives. It also reports how many tracking parameters were dropped, which is the duplicate count you just prevented.

What You'll Build & Learn

Remove utm_ tracking parameters from a URL and count how many were stripped.

- Splitting a URL on its query string
- Filtering parameters by prefix
- Rebuilding a clean URL conditionally

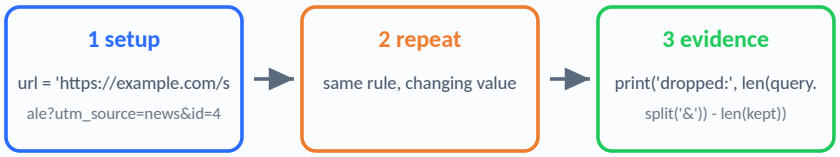
Skill Roadmap

`Skill step:` adds one small variation while the chapter pattern is still new. It builds on Project 230: normalize a url to one canonical form. Project 232 changes the surface problem while preserving the underlying method.

progress check

`Reading target:` strip tracking params from a url is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result



Logic Lens

- `Setup:` `url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&page=2'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- `Core logic:` The comprehension compresses a loop into a readable noun phrase: `make this` for `each item` if `it qualifies`. Expand it mentally when it feels dense.
- `Writing move:` this project practises how to compress a readable loop into a collection-building expression. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard,

and flag thin pages.

- Evidence: `print('dropped:', len(query.split('&')) - len(kept))` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&page=2'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`kept = [kv for kv in query.split('&') if not kv.startswith('utm_')]`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('dropped:', len(query.split('&')) - len(kept))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `kept = [kv for kv in query.split('&') if not kv.startswith('utm_')]`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Strip Tracking Params from a URL: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: url, https, example, com, sale. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&... | Core: kept = [kv for kv in query.split('&') if not kv.startswith('utm_')] | Evidence: print('dropped:', len(query.split('&')) - len(kept))

🛠️ Reader to Writer Bridge

1. Read: explain strip tracking params from a url in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 230.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 232 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('dropped:', len(query.split('&')) - len(kept))`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&page=2'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of strip tracking params from a url and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

Splitting the query on `&` and keeping only params that do not start with `utm_` removes campaign tags while preserving functional parameters like `id` and `page`.

```
url = 'https://example.com/sale?utm_source=news&id=42&utm_medium=email&page=2'
base, _, query = url.partition('?')
kept = [kv for kv in query.split('&') if not kv.startswith('utm_')]
clean = base + ('?' + '&'.join(kept) if kept else '')
print('clean:', clean)
print('dropped:', len(query.split('&')) - len(kept))
```

```
output
clean: https://example.com/sale?id=42&page=2
dropped: 2
```

How it works:

1. partition splits the URL into base, separator and the query string
2. A list comprehension keeps every key-value pair not starting with utm_
3. The clean URL re-adds a question mark and the kept params only if any remain
4. It prints the cleaned URL and the count of dropped parameters

Try it:

1. Extend the filter to also drop fbclid and gclid parameters
2. Keep a configurable allowlist of parameters that truly change the page
3. Preserve the original parameter order instead of the input order
4. Add `gclid` and `fbclid` to the strip list alongside `utm_`.

⚠ Common Mistakes

- Using `'utm_' in kv` instead of `startswith` would also drop a param like `x=utm_demo`.
- Forgetting the `'?' if kept else ''` guard leaves a dangling `?` when every param is stripped.
- Stripping all params loses pagination or product variants that genuinely change the page.

Skills gained str.partition | list comprehension | prefix filter

→ Where You'll Use This: Analytics and ad URLs flood a crawler with utm variants of one page; stripping them before indexing keeps the index lean and concentrates ranking signals on the real address.

Mental Model

Tracking tags are stickers slapped on the same product box for each store; peel them off and you see it was one box all along.

Project 232 Detect Exact Duplicates via SHA-1 of Text

The Idea Behind It

Two pages whose visible text is byte-identical after whitespace and case are flattened count as exact duplicates. This project normalises each body by lowercasing and collapsing runs of spaces, hashes the result with SHA-1, and groups URLs under their digest in a dictionary. Pages sharing a digest land in the same bucket and are tagged DUP, turning an expensive pairwise comparison into a single hash lookup.

What You'll Build & Learn

Group pages with identical normalised text by hashing their content with SHA-1.

- Normalising text before hashing
- Using a content hash as a dictionary key
- Grouping URLs by digest

Skill Roadmap

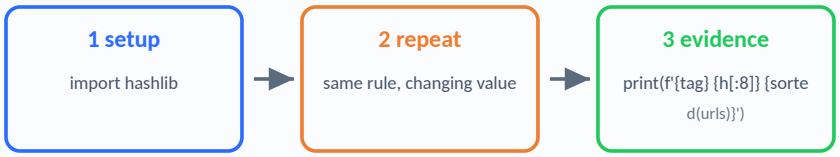
Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 231: strip tracking params from a url. Project 233 changes the surface problem while preserving the underlying method.

progress check

Reading target: detect exact duplicates via sha-1 of text is the surface task; the transferable Python move is to mark setup, rule, and output before running.

setup -> rule -> result

Logic Lens



- Setup: `import hashlib` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape.

repeat, test, update

- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'{tag} {h[:8]} {sorted(urls)}')` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import hashlib`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`tag = 'DUP' if len(urls) > 1 else 'unique'`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print(f'{tag} {h[:8]} {sorted(urls)}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `tag = 'DUP' if len(urls) > 1 else 'unique'`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Write the contract in words: given these inputs, this block returns or prints this kind of result.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Detect Exact Duplicates via SHA-1 of Text: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: hashlib, norm, join, lower, split. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; functions/methods create reusable boundaries; loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: import hashlib | Core: tag = 'DUP' if len(urls) > 1 else 'unique' | Evidence: print(f'{tag} {h[:8]} {sorted(urls)}')

🛠️ Reader to Writer Bridge

1. Read: explain detect exact duplicates via sha-1 of text in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 231.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 233 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{tag} {h[:8]} {sorted(urls)}')`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `import hashlib` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of detect exact duplicates via sha-1 of text and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Normalising whitespace and case before `hashlib.sha1(...).hexdigest()` means cosmetically different copies hash to the same digest, so grouping by digest clusters exact duplicates.

```
import hashlib

def norm(t):
    return ' '.join(t.lower().split())
```

```
pages = {
    'https://example.com/a': 'Buy   Red Shoes Today',
    'https://example.com/b': 'buy red shoes today',
    'https://example.com/c': 'Buy Blue Shoes Today',
}
fp = {}
for url, text in pages.items():
    h = hashlib.sha1(norm(text).encode()).hexdigest()
    fp.setdefault(h, []).append(url)
for h, urls in fp.items():
    tag = 'DUP' if len(urls) > 1 else 'unique'
    print(f'{tag} {h[:8]} {sorted(urls)}')
```

```
output
DUP 42f8e1ec ['https://example.com/a', 'https://example.com/b']
unique 8f815bf4 ['https://example.com/c']
```

How it works:

1. The norm helper lowercases the text and joins split tokens to flatten whitespace
2. Each page's normalised body is encoded and hashed with hashlib.sha1
3. setdefault appends the URL to a list keyed by its hex digest
4. The final loop tags any digest shared by more than one URL as DUP

Try it:

1. Switch the digest to SHA-256 and confirm the grouping is unchanged
2. Print only the duplicate clusters and skip the unique ones
3. Strip HTML tags from each body before normalising
4. Add a fourth page identical to page c and watch its group become a DUP.

⚠ Common Mistakes

- Hashing the raw text without normalising whitespace makes `'red shoes'` and `'red shoes'` look distinct.
- Calling `.encode()` is required: `hashlib.sha1` rejects a `str` directly.
- Comparing only the first 8 hex chars for the final verdict risks a collision; the full digest groups them here.

Skills gained hashlib.sha1 | text normalization | setdefault grouping

→ Where You'll Use This: Exact-duplicate detection on a large site reduces to one hash per page; identical digests instantly reveal which URLs serve the same copy and should be canonicalised together.

Mental Model

Hashing text is like a fingerprint scanner at a door: identical fingerprints mean the same person, no matter how they dressed up the spacing.

Project 233 Build K-Shingles from Page Text

The Idea Behind It

A shingle is a sliding window of k consecutive words, and this project builds the 3-word shingles of a short sentence. It splits the text into words and uses a comprehension with a range that stops k-1 words from the end, capturing each tuple of three adjacent terms. Shingles preserve local word order, which is exactly the signal a near-duplicate detector needs because reordered or slightly edited text shares most of its shingles.

What You'll Build & Learn

Generate the overlapping k-word shingles of a sentence and count them.

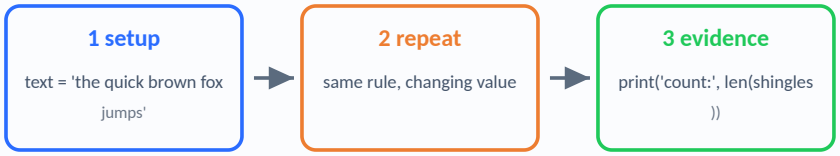
- What a k-shingle is
- Building sliding windows with a range
- Why local word order matters

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 232: detect exact duplicates via sha-1 of text. Project 234 changes the surface problem while preserving the underlying method.

progress check

Reading target: build k-shingles from page text is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `text = 'the quick brown fox jumps'` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop is the engine: it repeats the same rule over changing values. Name the value that changes each pass, then the repeated action becomes easy to predict.
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('count:', len(shingles))` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`text = 'the quick brown fox jumps'`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`shingles = [tuple(words[i:i + k]) for i in range(len(words) - k + 1)]`	This line controls repeated work. Name what changes each pass and what stays fixed. slow line
3. Check the evidence	`print('count:', len(shingles))`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. proof line

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `shingles = [tuple(words[i:i + k]) for i in range(len(words) - k + 1)]`

Construction pattern

The construction repeats one rule over changing values. Identify the changing variable and the fixed rule before running it.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Build K-Shingles from Page Text: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: text, the, quick, brown, fox. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: text = 'the quick brown fox jumps' | Core: shingles = [tuple(words[i:i + k]) for i in range(len(words) - k + 1)] | Evidence: print('count:', len(shingles))

🛠️ Reader to Writer Bridge

1. Read: explain build k-shingles from page text in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 232.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 234 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('count:', len(shingles))`. Then compare punctuation, spacing, and order. *prediction before proof*
2. Explain: point to `text = 'the quick brown fox jumps'` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of build k-shingles from page text and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A document of n words yields `n - k + 1` overlapping k-word windows; the windows preserve phrasing that a bag-of-words count would discard.

```
text = 'the quick brown fox jumps'
words = text.split()
k = 3
shingles = [tuple(words[i:i + k]) for i in range(len(words) - k + 1)]
for s in shingles:
```

```
    print(' '.join(s))
print('count:', len(shingles))
```

```
output
the quick brown
quick brown fox
brown fox jumps
count: 3
```

How it works:

1. The text is split into a list of individual words
2. k is fixed at three for the window width
3. A comprehension slices words from i to i+k for each valid start index
4. The range stops at len(words) minus k plus one so no window runs off the end
5. Each shingle tuple is printed and the total count reported

Try it:

1. Change k to two and observe how the shingle count grows
2. Build character shingles instead of word shingles
3. Lowercase and strip punctuation before shingling for cleaner matches
4. Change k to 2 and watch the shingle count rise by one.

⚠ Common Mistakes

- Looping to `len(words)` instead of `len(words) - k + 1` produces short, truncated tail shingles.
- Using a list of shingles where order does not matter; a set is better for similarity but allows duplicates here.
- Choosing k larger than the document length yields zero shingles with no error.

Skills gained list slicing | tuple creation | sliding window

→ Where You'll Use This: Shingling is the front end of MinHash, Jaccard and SimHash pipelines; every near-duplicate page detector starts by chopping content into these overlapping word windows.

Mental Model

Reading text through a small window that slides one word at a time, like dragging a magnifying glass across a sentence three words wide.

Project 234 Jaccard Similarity of Two Pages

The Idea Behind It

Jaccard similarity scores how much two pages overlap as the size of their shingle intersection divided by the size of their union, landing between zero and one. The project builds 2-word shingle sets for two near-identical phrases, computes the shared and total shingles with set operators, and rounds the ratio. Because it works on sets, repeated phrases do not inflate the score, making it the classic near-duplicate yardstick.

What You'll Build & Learn

Measure the Jaccard overlap of two short pages from their shingle sets.

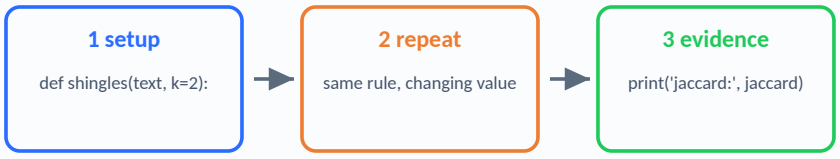
- The Jaccard formula intersection over union
- Building shingle sets
- Reading a 0-to-1 similarity score

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 233: build k-shingles from page text. Project 235 changes the surface problem while preserving the underlying method.

progress check

Reading target: jaccard similarity of two pages is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `def shingles(text, k=2):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The comprehension compresses a loop into a readable noun phrase: make this for each item if it qualifies. Expand it mentally when it feels dense.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print('jaccard:', jaccard)` exposes the result; match it against the output before changing the program.

output proves the trace

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output.

visual trace

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`def shingles(text, k=2):`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print('jaccard:', jaccard)`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}`

Construction pattern

The construction is a callable unit: name inputs, perform a rule, return or print evidence. The boundary is what makes the idea reusable.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Expand the comprehension into an ordinary loop, then compress it back once you can explain each slot.

Rewrite drill

Call the same function with a different input and predict the returned or printed value.

Code Reading Stack

Layer	What to read
Intent	Jaccard Similarity of Two Pages: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: shingles, text, lower, split, tuple. Names are the reader's map of roles and responsibilities.
Flow	functions/methods create reusable boundaries; loops repeat a rule.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: def shingles(text, k=2): | Core: return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)} | Evidence: print('jaccard:', jaccard)

🛠️ Reader to Writer Bridge

1. Read: explain jaccard similarity of two pages in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 233.

read with a pencil

3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 235 should feel like a variation, not a brand-new mystery.

from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print('jaccard:', jaccard)`. Then compare punctuation, spacing, and order.

prediction before proof

2. Explain: point to `def shingles(text, k=2):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of jaccard similarity of two pages and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

same idea, new surface

🔍 From Concept to Code (Python)

Set intersection counts shared shingles and union counts distinct ones; their ratio is Jaccard similarity, which is 1.0 for identical shingle sets and 0.0 for disjoint ones.

```
def shingles(text, k=2):
    w = text.lower().split()
    return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}

a = shingles('red running shoes for sale')
b = shingles('red running shoes on sale')
inter = a & b
union = a | b
jaccard = round(len(inter) / len(union), 3)
print('shared shingles:', len(inter))
print('total shingles:', len(union))
print('jaccard:', jaccard)
```

```
output
shared shingles: 2
total shingles: 6
jaccard: 0.333
```

How it works:

1. The shingles function lowercases, splits and forms a set of 2-word tuples
2. Two phrases differing in one word are converted to sets a and b
3. The intersection operator finds shared shingles, union finds all distinct ones
4. The Jaccard score divides intersection size by union size, rounded to three places

Try it:

1. Raise k to three and watch the similarity drop for short texts
2. Wrap the calculation in a function taking two strings
3. Guard against an empty union to avoid dividing by zero
4. Make the two strings identical and confirm Jaccard is 1.0.

⚠ Common Mistakes

- Dividing by `len(a) + len(b)` instead of the union double-counts shared shingles.
- Using a list instead of a set makes `&` and `|` unavailable and breaks the maths.
- Forgetting to lowercase lets `Red` and `red` form different shingles.

Skills gained set intersection | set union | jaccard ratio

→ Where You'll Use This: Jaccard is the reference metric behind 'these two pages are 80% the same'; SEO tools quote it when flagging templated or scraped content that barely differs across URLs.

⚡ Mental Model

Two overlapping circles in a Venn diagram: Jaccard is the shared lens divided by the whole figure, a clean fraction of agreement.

Project 235 Near-Duplicate Detection Above a Threshold

💡 The Idea Behind It

Auditing a set for near-duplicates means scoring every pair and reporting the ones that clear a threshold. This project builds 2-word shingle sets per page, then runs a nested loop over the sorted items so each pair is compared once, computing inline Jaccard. Any pair at or above 0.5 prints a NEAR-DUP line. Two pages differing by a single word score high while an unrelated page stays apart.

What You'll Build & Learn

Flag every page pair whose Jaccard similarity meets a near-duplicate threshold.

- Comparing all unique pairs once
- Applying a similarity threshold

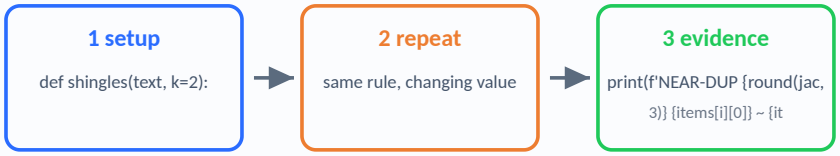
- Surfacing near-duplicate clusters

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 234: jaccard similarity of two pages. Project 236 changes the surface problem while preserving the underlying method.

progress check

Reading target: near-duplicate detection above a threshold is the surface task; the transferable Python move is to mark setup, rule, and output before running.



setup -> rule -> result

Logic Lens

- Setup: `def shingles(text, k=2):` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: A nested loop means outer choice plus inner repeated work. Read one full inner pass before jumping ahead; that reveals the grid, table, or pairwise pattern.
- Writing move: this project practises how to turn a working idea into a reusable unit. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'NEAR-DUP {round(jac, 3)} {items[i][0]} ~ {items[j][0]}')` exposes the result; match it against the output before changing the program.

output proves the trace

Reader to Writer Bridge

1. Read: explain near-duplicate detection above a threshold in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 234.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 236 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'NEAR-DUP {round(jac, 3)} {items[i][0]} ~ {items[j][0]}')`. Then compare punctuation, spacing, and order.

   prediction before proof
2. Explain: point to `def shingles(text, k=2):` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of near-duplicate detection above a threshold and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format.

   same idea, new surface

🔍 From Concept to Code (Python)

An upper-triangular double loop (`j` starts at `i + 1`) compares each unordered pair exactly once, flagging those whose similarity meets the threshold.

```
def shingles(text, k=2):
    w = text.lower().split()
    return {tuple(w[i:i + k]) for i in range(len(w) - k + 1)}

pages = {
    'https://example.com/p1': 'cheap blue widgets for every home',
    'https://example.com/p2': 'cheap blue widgets for every house',
    'https://example.com/p3': 'premium handcrafted oak furniture sets',
}
threshold = 0.5
items = sorted(pages.items())
for i in range(len(items)):
    for j in range(i + 1, len(items)):
        a, b = shingles(items[i][1]), shingles(items[j][1])
        jac = len(a & b) / len(a | b)
        if jac >= threshold:
            print(f'NEAR-DUP {round(jac, 3)} {items[i][0]} ~ {items[j][0]}')
```

```
output
NEAR-DUP 0.667 https://example.com/p1 ~ https://example.com/p2
```

How it works:

1. A shingles helper turns each page body into a set of word-pair tuples
2. Items are sorted so the nested loops produce deterministic, non-repeating pairs
3. The inner loop starts at i+1 to avoid comparing a page with itself or twice
4. Inline Jaccard divides intersection by union for each pair
5. Pairs scoring at or above the 0.5 threshold print a NEAR-DUP report

Try it:

1. Lower the threshold to 0.3 and see more pairs flagged
2. Store flagged pairs in a list instead of printing immediately
3. Skip the O(n squared) sweep by bucketing pages first for speed
4. Lower the threshold to 0.3 and watch p3 start matching.

⚠ Common Mistakes

- Starting the inner loop at `j = 0` compares a page to itself (Jaccard 1.0) and reports every pair twice.
- Setting the threshold too low floods the report with unrelated pairs.
- Sorting items is needed for deterministic output; iterating the raw dict relies on insertion order.

Skills gained nested loops | pairwise comparison | threshold filter

→ Where You'll Use This: Site-wide duplicate reports run this pairwise sweep to surface clusters of barely-edited pages, the kind that dilute crawl budget and split ranking signals across copies.

Mental Model

Like a teacher comparing every essay against every other for copied passages, raising a flag whenever two read too much alike.

Project 236 Flag Thin Content by Word Count

The Idea Behind It

A page with too few words rarely answers a searcher's question and reads as low value to an engine. This project counts the word-like tokens in each page body using a regex that matches runs of letters and apostrophes, then tags any page below a ten-word threshold as THIN. The regex deliberately ignores punctuation-only fragments so 'Buy now.' counts as two real words, not noise.

What You'll Build & Learn

Flag pages whose word count falls below a thin-content threshold.

- Counting word tokens with regex
- Applying a thin-content threshold
- Why short pages underperform

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 235: near-duplicate detection above a threshold. Project 237 changes the surface problem while preserving the underlying method. *progress check*

Reading target: flag thin content by word count is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*

🔎 Logic Lens

- Setup: `import re` gives the program its first fact, tool, or entry point. Use it as the anchor for the later logic.
- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'{tag} {wc} words {url}')` exposes the result; match it against the output before changing the program. *output proves the trace*

🖼️ Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

📝 Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`import re`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`tag = 'THIN' if wc < threshold else 'ok'`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'{tag} {wc} words {url}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `tag = 'THIN' if wc < threshold else 'ok'`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Colon: Opens Python blocks, separates keys from values, or assigns CSS properties to values. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Flag Thin Content by Word Count: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: re, pages, https, example, com. Names are the reader's map of roles and responsibilities.
Flow	imports load outside tools; loops repeat a rule; conditions choose a route.
Data shape	Scalar or small structured data: read names, literal values, and the operation that connects them.
Evidence	Entry: import re | Core: tag = 'THIN' if wc < threshold else 'ok' | Evidence: print(f'{tag} {wc} words {url}')

🛠️ Reader to Writer Bridge

1. Read: explain flag thin content by word count in one sentence before touching the code; the goal gives the syntax context.
2. Trace: follow the actual values from setup to output, then carry forward the move from Project 235.

   read with a pencil
3. Change: alter one value, condition, loop bound, object, or label and predict the exact output.
4. Create: write a sibling program with the same skeleton but a new purpose. If your new Python code still has setup, logic, and evidence, Project 237 should feel like a variation, not a brand-new mystery.

   from example to tool

✅ Project Self-Check

1. Predict: before running, write the exact output you expect from `print(f'{tag} {wc} words {url}')`. Then compare punctuation, spacing, and order. *prediction before proof*

2. Explain: point to `import re` and say why this line, value, import, or entry point is needed before the rest of the Python can work.
3. Transfer: change one small part of flag thin content by word count and name what must stay the same: the data shape, the rule, the branch, the loop pattern, or the output format. *same idea, new surface*

🔍 From Concept to Code (Python)

A regex for word-like tokens counts real words while ignoring punctuation, and comparing that count to a threshold flags pages too thin to rank.

```
import re
pages = {
    'https://example.com/full': 'Our complete guide explains every step of
installing solar panels safely at home this season.',
    'https://example.com/thin': 'Solar panels. Buy now.',
    'https://example.com/ok': 'Solar panels convert sunlight into electricity
using photovoltaic cells mounted on your roof.',
}
threshold = 10
for url in sorted(pages):
    wc = len(re.findall(r"[a-zA-Z']+", pages[url]))
    tag = 'THIN' if wc < threshold else 'ok'
    print(f'{tag} {wc} words {url}')
```

```
output
ok 15 words https://example.com/full
ok 13 words https://example.com/ok
THIN 4 words https://example.com/thin
```

How it works:

1. A dictionary maps three URLs to bodies of varying length
2. re.findall with a letters-and-apostrophe pattern extracts word tokens
3. len of that list gives the word count per page
4. Pages under the ten-word threshold are tagged THIN, the rest ok
5. Output prints the tag, count and URL for each sorted page

Try it:

1. Raise the threshold to fifty words for long-form requirements
2. Count sentences as well and require a minimum of both
3. Exclude boilerplate words before counting to measure unique content
4. Raise the threshold to 14 and watch the `ok` page flip to THIN.

⚠ Common Mistakes

- Splitting on whitespace counts `'panels.'` and `'now.'` with attached punctuation as words.
- Counting characters instead of words penalises pages with long words unfairly.
- A fixed threshold ignores page type: a contact page is legitimately short.

Skills gained re.findall | word counting | threshold tagging

→ Where You'll Use This: Thin-content reports rank pages by word count to find doorway, placeholder or auto-generated URLs that should be expanded, merged, or pruned from the index.

Mental Model

A word-count gate is the bouncer at a venue checking nobody slips in with an empty page where real content should be.

Project 237 Compute a Boilerplate-to-Content Ratio

The Idea Behind It

Templated navigation and footer terms like home, login and privacy repeat on every page, and when they crowd out the real content the page is effectively thin. This project keeps a set of boilerplate words, counts how many of a page's tokens fall in that set, and divides by the total to get a ratio. When boilerplate exceeds half the words, the unique content is too sparse to rank.

What You'll Build & Learn

Compute the share of a page's words that are boilerplate and judge it accordingly.

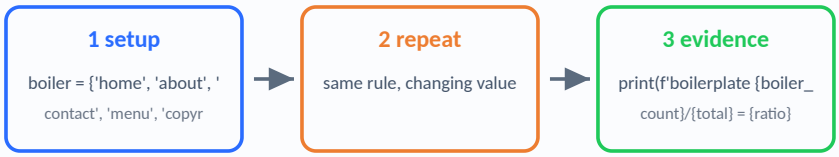
- Defining a boilerplate word set
- Computing a boilerplate ratio
- Distinguishing template from content

Skill Roadmap

Skill step: adds one small variation while the chapter pattern is still new. It builds on Project 236: flag thin content by word count. Project 238 changes the surface problem while preserving the underlying method.

progress check

Reading target: compute a boilerplate-to-content ratio is the surface task; the transferable Python move is to mark setup, rule, and output before running. *setup -> rule -> result*



Logic Lens

- Setup: `boiler = {'home', 'about', 'contact', 'menu', 'copyright', 'privacy', 'login'}` gives the program its first fact, tool, or entry point. Use it as the anchor for the

later logic.

- Core logic: The loop supplies repeated chances and the condition decides which chances count. That is the classic filter/count/accumulate shape. *repeat, test, update*
- Writing move: this project practises how to write one rule and let repetition do the volume work. It adds that move to the chapter skill: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
- Evidence: `print(f'boilerplate {boiler_count}/{total} = {ratio} -> {verdict}')` exposes the result; match it against the output before changing the program. *output proves the trace*

Visual Model

Read the project through this picture first: setup creates the facts, repeat applies the chapter idea, and evidence proves your trace against the output. *visual trace*

Worked Trace

Move	Code to inspect	Why it matters
1. Set up	`boiler = {'home', 'about', 'contact', 'menu', 'copyright', 'privacy', 'login'}`	This gives the project its starting fact, tool, object, or entry point. It connects the visible code to the chapter focus: check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
2. Apply the rule	`boiler_count = sum(1 for w in page_words if w in boiler)`	This line controls repeated work. Name what changes each pass and what stays fixed. *slow line*
3. Check the evidence	`print(f'boilerplate {boiler_count}/{total} = {ratio} -> {verdict}')`	The result becomes visible or reusable here. Confirm that your trace explains the exact output. *proof line*

Syntax Construction Lab

Construction focus: Canonicalization, Duplicate and Thin Content becomes practical when you can build the syntax shape yourself, not just recognise it on the page. Slow down at the core line and ask which token creates the behaviour.

CORE LINE `boiler_count = sum(1 for w in page_words if w in boiler)`

Construction pattern

The construction is repeat -> test -> update. Trace one pass first, then ask which passes are included or skipped.

Syntax tokens to inspect

Parentheses: Group function arguments, method parameters, conditions, or arithmetic subexpressions. Braces: Mark object literals, blocks, class bodies, CSS declarations, or interpolation boundaries depending on the language. Brackets: Signal indexing, lists/arrays, table-like access, or type shapes. Dot: Reads as ownership or access: object.method, module.function, package.name, or selector.class. Arrow/scope tokens: Often connect a parameter to a body, a type to a return value, or a namespace to a member.

Build-it-yourself move

Create a two-column trace: loop value on the left, changed result or side effect on the right.

Rewrite drill

Change the loop range or collection by one item and predict which output changes.

Code Reading Stack

Layer	What to read
Intent	Compute a Boilerplate-to-Content Ratio: connect the surface task to the chapter skill, check canonical consistency, detect duplicates with shingling/jaccard, and flag thin pages.
Names	Watch these names first: boiler, home, about, contact, menu. Names are the reader's map of roles and responsibilities.
Flow	loops repeat a rule; conditions choose a route.
Data shape	Collection data: list/array/map/set shape determines lookup, order, and uniqueness.
Evidence	Entry: boiler = {'home', 'about', 'contact', 'menu', 'copyright', 'privacy', '... | Core: boiler_count = sum(1 for w in page_words if w in boiler) | Evidence: print(f'boilerplate {boiler_count}/{total} = {ratio} -> {verdict}')

🛠️ Reader to Writer Bridge

1. Read: explain compute a boilerplate-to-content ratio in one sentence before touching the code; the goal gives the syntax context.
